axile placentation. Further study of this species complex, which is around *X. setigera*, may require reduction of several of these entities to the level of variety or subspecies.

81. Xyris setigera F. Oliver, Trans. Linn. Soc. London, Bot. 2: 285, pl. 50A, figs. 1–8. 1887. TYPE: Venezuela. Bolívar: Roraima (Venezuela), 4,000 ft., 4 Dec. 1884, *Everard F. im Thurn 62* (lectotype, K; isolectotypes, BM, US). Figure 81.

Xyris setigera var. *elongata* Steyerm., Fieldiana, Bot. 28(1): 112. 1951. TYPE: Venezuela. Bolívar: Ptari-tepui, dry sandy and rocky sandstone exposures on level ground adjacent to swamp on plateau portion of southeast-facing slopes, 1,600 m, 1 Nov. 1944, *J. A. Steyermark 59660* (holotype, F; isotypes, GH, NY).

Densely cespitose, stiffish perennial, mostly 1.5–6 dm high; stems contracted to slightly elongated. Leaves erect to spreading flabellately or ascending, 0.5–2.5 dm long; sheaths dark to pale, red-brown or purple-red, mostly more than ½ as long as blades, the edges long-ciliate, narrowing gradually from the dilated, scabro-rugose (rarely smooth) base into the blades, there eligulate or in high-elevation forms sometimes producing a ligule to 2 mm long, the blades narrowly linear to filiform (in high-elevation forms), usually flattened, 0.5–3 mm wide, at apex excentrically short-spinulose or narrowly conic-subulate, the margins thick, scabro-ciliate or tuberculate-scabrid with strumose, antrorsely or retrorsely bent, simple or branched trichomes or tubercles (rarely smooth in high-elevation forms), the surfaces deep green to maroon or olive, tuberculate-rugose or smooth, punctate. Scape sheaths shorter than leaves, the bases tubular, multicostate and keeled, often reddish or roseate or lucid brown, open distally, keeled, producing a short, strong blade similar to leaves. Scapes straight or flexuous, twisted, terete distally, ca. 0.5–1 mm thick, smooth, often lustrous, punctate, maroon to green. Spikes ovoid to ellipsoid, 0.5–1 cm long, aging obovoid or turbinate, pale to deep brown, of several loosely spirally imbricate, stiff bracts usually without distinct dorsal areas (occasional extremes with narrow, indistinct dorsal areas); sterile bracts few, oblong, spreading, ecarinate, smaller than and grading into fertile bracts, these oblong to narrowly obovate, ecarinate, 6–7 mm long, narrowly rounded apically, entire, aging lacerate, the backs slightly convex. Lateral sepals free, subequilateral, mostly oblanceolate, 5–6 mm long, acute, dark reddish brown, the keel at middle and above lacerate-serrulate to nearly entire. Petal blades broadly obovate, ca. 6 mm long, yellow, the rounded apex subentire. Staminodia bibrachiate, the slender branches densely long-penicillate. Anthers 1.7–2 mm long, narrowly oblong, deeply bifid and sagittate, on filaments 0.8–1 mm long. Capsule cylindric-ellipsoid, ca. 4.5 mm long, the placentation axile, the septa separating from the central (placental) axis as the valves part. Seeds numerous, ellipsoid-ovoid, ca. 0.5–0.6 mm long, 2-apiculate, dark amber, longitudinally finely but strongly ribbed and with several less distinct cross-lines.

Distribution. Medium- to high-elevation, sandy or rocky savanna, centering in the massifs of the Gran Sabana, Estado Bolívar, Venezuela, southward shortly over the border of Brazil, eastward into eastern Guyana and northern Territorio Roraima, Brazil.

Additional specimens examined. BRAZIL. RORAIMA: Mt. Roraima, *E. F. Thurn 62* (the type for the species at K shows that some of the set could have come from the Brazil side of Roraima); ? Philipp Swamp, 5,100–5,200 ft., 11 Nov. 1927, *Tate 336* (K—? locality listed for Brazil, British Guiana, and Venezuela, depending on collector at this site). GUYANA: Kaieteur Plateau, 2 May 1944, *Maguire & Fanshawe 23164* (K); southern Pakaraima Mts., Kopinang Savanna, Kopinang Falls, 2,700 ft., 29 Aug. 1961, *Maguire et al. 45988* (K, VEN). VENEZUELA. (Note—this is perhaps the most common and commonly collected species in Estado Bolívar; therefore few citations are given here. A complete list will be made available later.) BOLÍVAR: Cienagas del Cerro Uaipan, 1,750 m, Río Caroní, 26 Nov. 1946, *Cardona 200g* (US, VEN); 2 km S of La Ciudadella, 1,300 m, 3 Dec. 1973, *Davidse 4699* (MO, VDB); ca. 17 km NE Ikabarú, 1,100 m, 7 Oct. 1982, *Huber et al. 6727* (MYF, VDB, VEN)—this material has dorsal areas; sabanas, sector norte de la Gran Sabana, 1,030 m, 5 Mar. 1982, *Huber et al. 7337* (MYF, VDB, VEN); cumbre del Cerro Chirikayne ca. 15 km NW Sta. Elena de Uairen, 1,580 m, 25 June 1983, *Huber et al. 7601* (MYF, VDB); Cerro Venado ca. 20

Elena, S del Río Yuruaní, 1,200 m, 25 Aug. 1976, *Steyermark et al. 112341* (F, K, NY, US); Meseta del Jaua, Cerro Jaua cumbre, 28 Feb.–5 Mar. 1974, *Steyermark et al. 109427* (K, NY, US, VEN); Cerro Marutari, 1,200 m, 2 Jan. 1981, *Steyermark 123857* (NY, VDB); Meseta de Sarisarinama, 1,280 m, 14 Feb. 1981, *Steyermark 124319* (NY, VDB); Luépa (Ciudadela) savanna 200 m W of checkpoint, *Thomas 2702* (NY).

This species is, not surprisingly, the most variable xyrid in the Guayana Highlands, with populations being found throughout the Gran Sabana at elevations extending from 700 to 2,000 meters or more on tepuis. Those of the lower and middle elevations within this area mostly conform to the described morphology pretty well, with the foliage generally coarsely rugose; the leaf blade edges roughened with stiff, often branched hairs; the leaf tips excentrically short-spinulose; and the spike bracts many, dark, and erose with age. At the higher elevations in the tepuis, usually at ca. 2,000 meters upward, however, the plants are more slender in scape and leaf; the leaf tips are subulate-conic (rather than excentrically spinulose) with the surfaces and edges becoming smoother; and the blades are narrower and approaching terete. These are problem plants; many are in loans annotated *X. setigera* var. *elongata* Steyerm. Some need further study, as they border on or are the same as *X. byssacea*. A smut fungus infects flowers to produce a bright orange fruiting mass on the spikes, hence the erroneous records that some *Xyris* corollas are "orange."

82. Xyris riparia Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 20, fig. 5A–E. 1963. TYPE: Venezuela. Bolívar: frequent in clumps at stream edge, scrub forest near Summit Camp, 1,925 m, Chimantá Massif, central section, 2 Feb. 1955, *J. A. Steyermark & J. J. Wurdack 361* (holotype, NY; isotypes, MO, US, VEN). Figure 82.

Cespitose, slender, stiffish perennial ca. 4–5 dm high, the stems short to elongate, forming frondlike plates of leaves. Leaves spreading flabellately to erect, 1–2.5 dm long; sheaths coarsely to finely long-ciliate-margined (sometimes sparsely so), as long as blades, deeply dull reddish brown, dull brown or castaneous, scabro-rugose or smooth, tapering gradually from the dilated base to the blade, the backs narrowly rounded or keeled and scabrid, usually eligulate or with a short, erect ligule under 0.5 mm long; blades linear, flattened, slightly twisted, 2–3 mm wide, tapering gradually from ca. middle to apex, then abruptly narrowed to an excentric, narrowly conic-acute to short-subulate tip; margins thin or pale-incrassate, smooth to papillate, tuberculate or scabro-ciliate or ciliolate with pale hairs, the surfaces yellow-green to reddish, few-nerved, punctate. Scape sheaths shorter than principal leaves, the tubular base lustrous reddish or castaneous, multicostate above, ciliate-keeled, open, with a short, erect

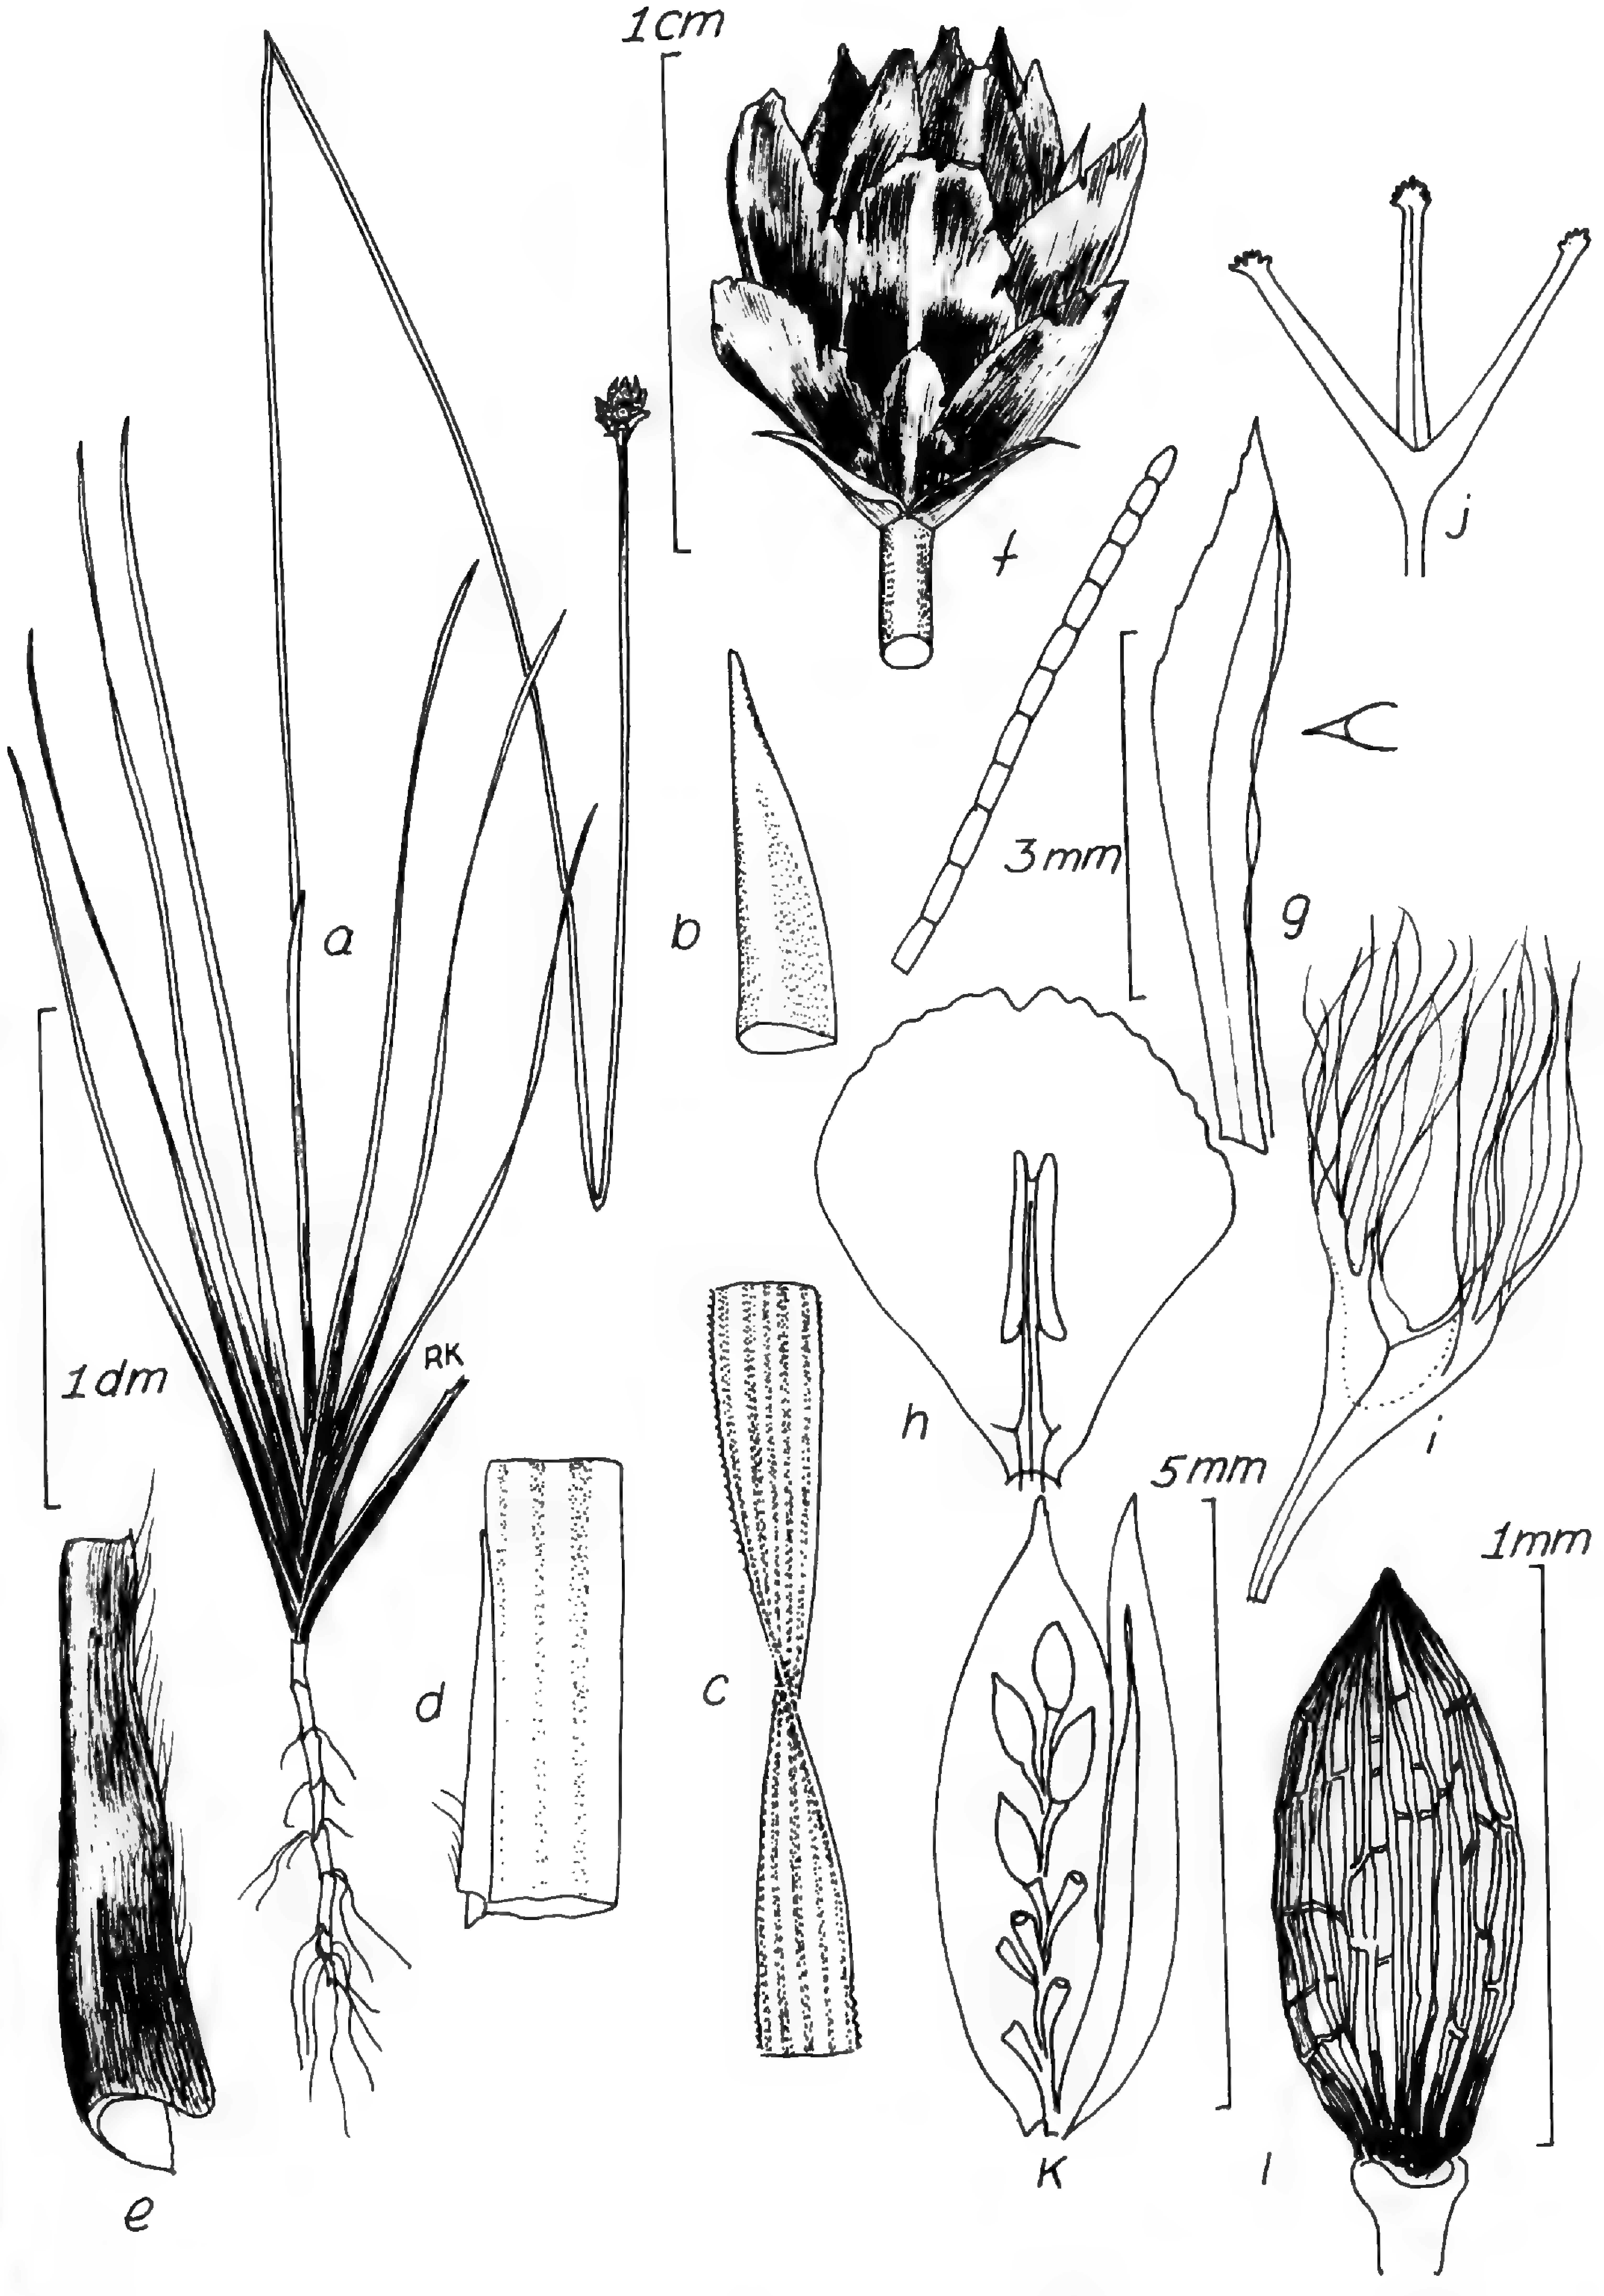

FIGURE 82. Xyris riparia *(from the type).—a. Habit sketch.—b. Leaf apex.—c. Leaf, midblade.—d. Leaf blade–sheath junction.—e. Leaf base.—f. Spike.—g. Lateral sepal.—h. Petal blade, stamen.—i. Staminode.—j. Stylar apex.—k. Capsule, one valve removed; side view of one valve to show septum and side view of placenta.—l. Seed.*

blade. Scapes straight or slightly flexuous, twisted distally, subterete or broadly oval in cross section, ca. 1 mm wide, ecostate, sometimes with few very low ridges, punctate. Spike broadly obovoid, drying turbinate, ca. 1 cm long, reddish brown, of several, firm, papillose bracts without dorsal areas and loosely imbricate in near vertical rows; sterile bracts with lowermost lance-ovate, much shorter than and narrower than the fertile bracts, carinate, grading into fertile bracts, these numerous, oblong to narrowly ovate, 6–8 mm long, narrowly rounded, entire, aging lacerate, the margins often narrowly squarrose. Lateral sepals linear-oblanceolate, 6.5–7 mm long, acuminate, dark red-brown, the firm, broad keel slightly lacerate distally. Petal blades broadly obovate, ca. 5 mm long, yellow, the broadly rounded apex crenulate. Staminodia clavate, indistinctly bibrachiate, the irregular margins long-penicillate. Anthers lance-oblong, ca. 2 mm long, shallowly bifid and sagittate, on filaments ca. 1 mm long. Capsule narrowly ellipsoid, ca. 5 mm long, the placentation appearing central but dehiscing valves with strong septa toward base. Seeds numerous on short, stout funiculi, narrowly ovoid, ca. 0.9–1 mm long, deep amber, apiculate, longitudinally strongly multiribbed and cross-lined.

Distribution. Local in high-elevation savanna, the Chimantá Massif and Cerro Guaiquinima, Estado Bolívar, Venezuela. The few known records, in addition to the type are as follows.

Additional specimens examined. VENEZUELA. BOLÍVAR: Cerro Guaiquinima, savanna vic. Cumbre Camp, 2,000 m, 25 Dec. 1951, *B. Maguire 32751* (NY); same locality, 1 km S of Cumbre Camp, 1,800 m, 29 Dec. 1951, *B. Maguire 32798* (NY); Macizo del Chimantá, sección centro-suroriental del Churi-tepui, ca. 2,250 m, 10–12 Feb. 1984, *Huber & Colella 8998* (VDB, VEN)—this an extreme bordering on *X. setigera.*

The material from Cerro Guaiquinima should perhaps be considered varietal, being more scabrid in sheath, more ciliate in leaf, and with a shorter range in leaf length, but at this stage of knowledge of the genus it is perhaps best to be conservative. In such a connection, it might be noted that there are many similarities between this taxon and the more common *X. setigera,* certainly as to the punctate leaves and scapes, the complex harsh hairs on edges of the leaf blade, and the excentrically spinulose-subulate leaf tips.

83. Xyris roraimae Malme in Pilger Notizbl. Bot. Gart. Berlin 6: 117. 1914. TYPE: Venezuela. Bolívar: "Auf den unteren Campos," 1,700 m, Jan. 1910, *Ule 8546* (lectotype, B; isolectotype and phototype, US). Figure 83.

Tall, solitary or small-tufted, brittle perennial to 1 m high or slightly higher, the stems contracted, the foliage totally papillose-rugulose, dull yellow-green. Leaves erect or ascending, twisted, 2–4 dm long; sheaths long-ciliate, ½ as long as blades or longer, abruptly dilated at very base, castaneous, thence abruptly narrowing, dull brown, gradually tapering into the blade, there eligulate or with a short, erect, ciliate ligule less than 0.5 mm long; blades strongly flattened, linear, 3–5 mm wide, above middle tapering to an erect, narrowly acute or acuminate, somewhat thickened, erect or incurved apex, the margins pale ciliate and tuberculate, the surfaces dull yellow-green, strongly nerved longitudinally. Scape sheaths shorter than leaves, twisted, carinate and strongly costate, opening toward apex, keeled, producing a very short, incurved blade. Scapes lineal, twisted and flexuous, flattened and ancipital distally, 2–3 mm wide, 2-costate, the costae reaching the edges and densely pale ciliate. Spikes broadly ovoid, ellipsoid, or cylindric, 1–3 cm long, blunt, pale red-brown or tan, of very many spirally imbricate, thin bracts without dorsal areas and, when young, with narrow but distinctive, reddish, scarious, lacerate borders; lowermost sterile bracts smallest, broadly ovate to suborbicular, slightly carinate, grading gradually into the fertile bracts, these broadly obovate to suborbicular, 5–6 mm long, ecarinate, aging lacerate (the red border friable and deciduous early). Lateral sepals free, very inequilateral, often exserted apically, oblanceolate, 4.5–5.5 mm long, acute, thin,

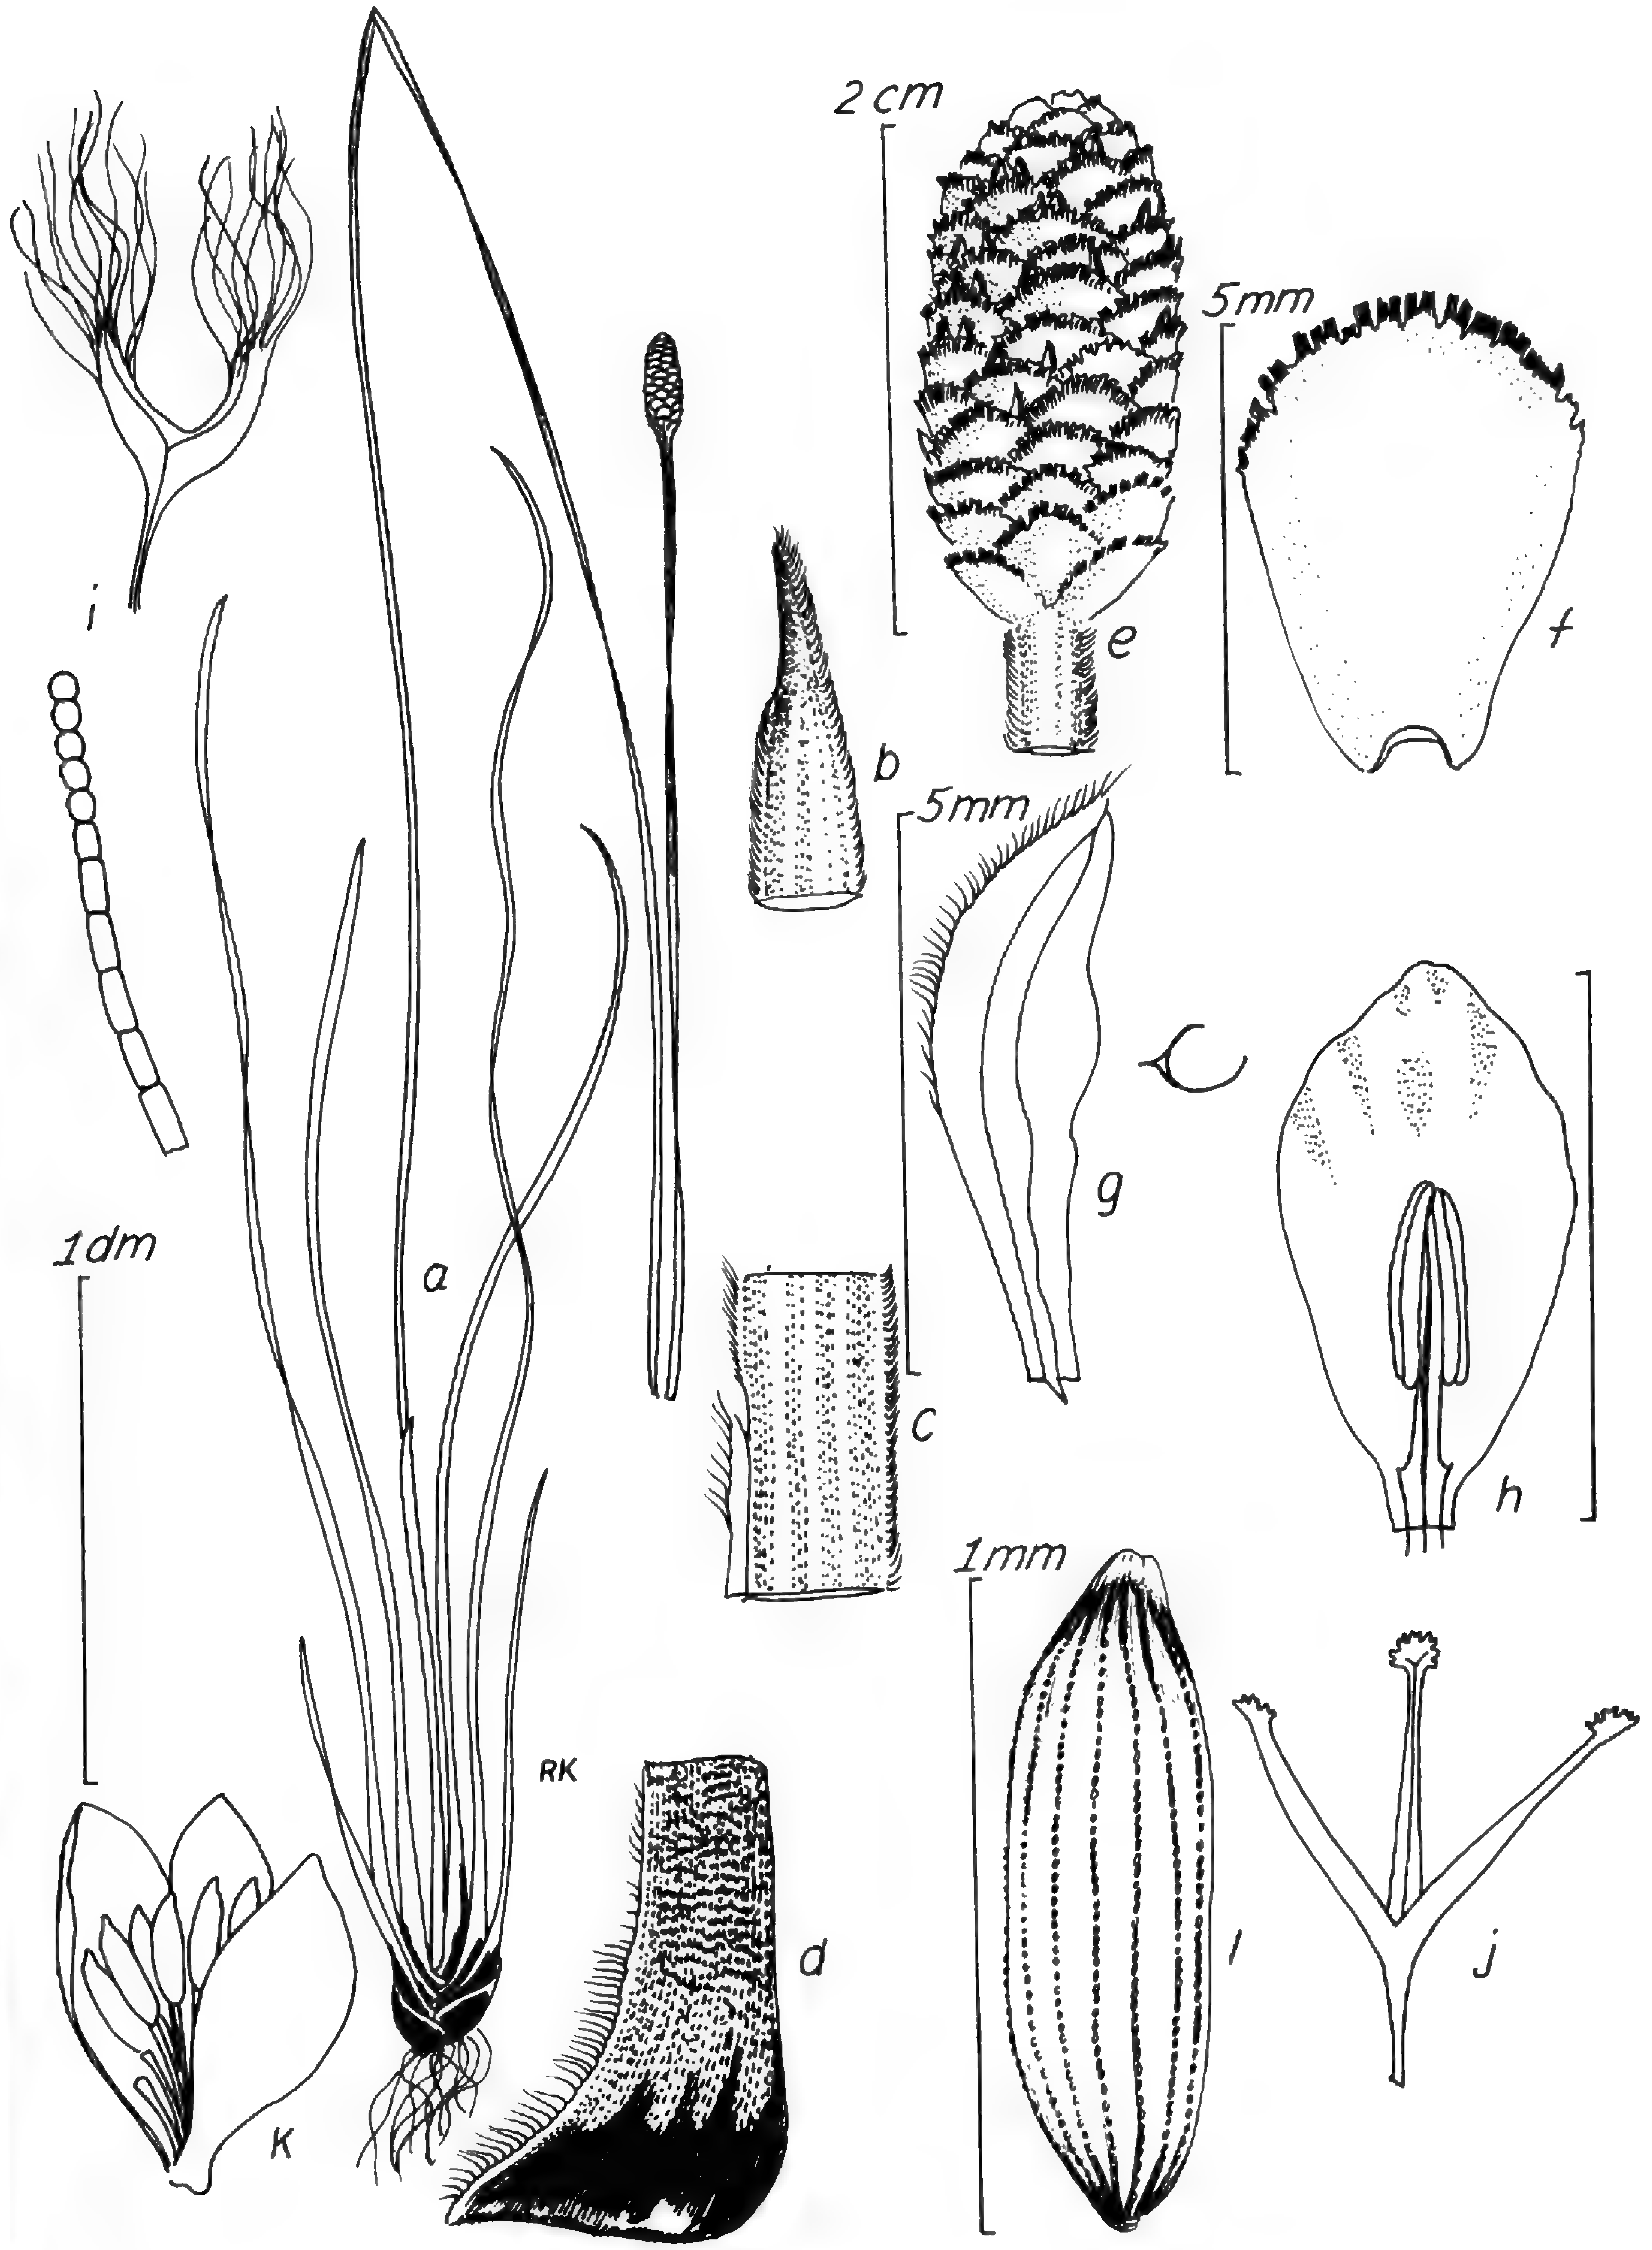

FIGURE 83. Xyris roraimae (Kral 70560).—*a. Habit sketch.—b. Leaf apex.—c. Leaf sheath–blade junction.—d. Leaf base.—e. Spike.—f. Fertile bract.—g. Lateral sepal.—h. Petal blade, stamen.—i. Staminode.—j. Stylar apex.—k. Open capsule.—l. Seed.*

with the broad keel lacerofimbriate or ciliate from ca. middle to apex. Petal blades obovate, ca. 5 mm long, yellow, the narrowly rounded apex subentire. Staminodia bibrachiate, the flat, narrow branches long-penicillate distally. Anthers lance-oblong, ca. 2 mm long, shallowly bifid apically, the base deeply sagittate, on filaments ca. 1 mm long. Capsule broadly obovoid, 2.5–3 mm long, the placentation basal, the valves without septa. Seeds ellipsoid-cylindric, ca. 1 mm long, amber, apiculate, finely but distinctly ribbed longitudinally.

Distribution. Savanna bogs, medium elevations (ca. 700–1,500 meters), Gran Sabana, Estado Bolívar, Venezuela; Guyana; occasional in the campos rupestres, the planalto of Brazil in Minas Gerais and Goiás. My Brazilian specimens tend to be proportionately larger in height (to 1.5 meters) and in spike diameter, but otherwise appear the same as the Venezuelan collections.

Additional specimens examined. BRAZIL. MINAS GERAIS: wet slopes over arenaceous rock, above Rio Itacambirucu, ca. 8 km WSW of Grão Mogul, 600–750 m, 10 July 1985, *Kral et al. 72705* (SP, VDB, and to be distributed) grass–sedge campo, Morro do Onca, 950–1,000 m N of Jouachim Felicio, 6 July 1985, *Kral et al. 72628* (SP, VDB, and to be distributed); below sandstone bluffs, Morro do Jucao, NNW Joachim Felicio, 1,100 m, ca. 14 km N of Jouaquim Felicio, 7 July 1985, *Kral et al. 72659* (SP, VDB, and to be distributed). GUYANA: Mt. Roraima, Philipp Swamp, 5,100–5,200 ft. (also at Glycon Swamp), 11 Nov. 1927, *Tate 348* (K). VENEZUELA. BOLÍVAR: bog ravine, 1 km E of Kavanayen, 26 July 1983, *Kral 70448* (VDB, VEN); 7 km E of Kavanayen, 1,100 m, bog, 26 July 1983, *Kral & Gonzalez 70466* (BM, F, K, L, MO, NY, SP, U, US, VDB, VEN, and others); S side of road, 1.5 km E of Kavanayen, Gran Sabana, *Kral & Gonzalez 70539* (F, MO, NY, SP, US, VDB, VEN); 46 km N of Sta. Elena on E side of Ven. 10, ca. 800 m, 28 July 1983, *Kral & Gonzalez 70560* (BM, F, L, MO, NY, SP, U, US, VDB, VEN, and others); colinas above Ven. 10, 8 km N of El Salto Yuruani, ca. 750 m, 29 July 1983, *Kral & Gonzalez 70582* (US, VDB, VEN); ca. 2 km S due E of Kavanayen, ca. 1,060 m, 15 Dec. 1984, *Kral 72089* (MYF, VDB, VEN, and to be distributed); Ilu-tepui, Gran Sabana, Río Aponangao at 1,200 m, 27–28 Mar. 1952, *Maguire 33646* (NY); Gran Sabana, cabeceras Río Aponguao, a lo largo Arauta-paru, km 148, 20 Dec. 1970, *Steyermark et al. 104116* (US, VEN); savanna with *Stegolepis* 16 km from Kavanayen, 1,340 m, 19 Dec. 1979, *Steyermark* with *Pruski 121052* (US, VEN).

This species, locally abundant in the rapateaceous bogs of the Gran Sabana, is at once one of the tallest of Venezuelan xyrids and the most roughened in foliage, the epidermal roughening giving the plants a glazed, dull, yellow-green color which is very distinctive in the field. Its spikes are a lovely tint of golden brown and on close inspection show a fine red color of bract border. Even larger versions of this attractive (for a *Xyris*) plant are to be found in the planalto of Brazil, where they belong to the most difficult complex around *X. ciliata* Thunb.

84. Xyris schneeana Lyman B. Smith & Steyerm., Acta. Bot. Venez. 1(7): 149–150. 1965. TYPE: Venezuela. Bolívar: Auyan-tepui, altiplanicie, 19 Apr. 1956, *Ludwig Schnee 1577* (holotype, MY; phototype, US). Figure 84.

Cespitose low perennial 1–3 dm high, the stems contracted. Leaves stiff, spreading flabellately, 5–10 cm long; sheaths as long as blades or longer, long-ciliate, papillose-rugulose, tan, much dilated at very base, thence narrowing gradually to blade, strongly keeled, eligulate, the blades flat, straight, 2–3 mm wide, lineal, abruptly narrowed at apex to an obtuse or broadly incurved-acute tip, this frequently apiculate, the margins white-ciliolate, the surfaces dull green, low-multiribbed, scaberulous-rugulose. Scape sheaths overtopping most leaves, the bases tubular, multicostate, carinate, above open, ciliate, the blade a mere apiculus. Scapes dull green, straight or flexuous, terete or oval distally, ca. 0.5 mm thick, with several low costae, the surface entirely rugulose-papillate or scaberulous. Spikes ovoid-ellipsoid, ca. 5 mm long, drying obovate, dark olive-castaneous, of several loosely subdecussate, thin bracts without evident dorsal areas, the sterile ones ca. 4, ecarinate, rounded, shorter than the few fertile bracts, these oblong, ca. 5 mm long, navicular but ecarinate, broadly rounded, entire or erose. Lateral sepals free, very inequilateral, oblong-elliptic to spathulate, ca. 5–5.5 mm long, acute or obtuse, dark and thin, the narrow, darker keel serrulate-ciliolate above middle, the apex often exserted. Petal blades elliptic, 5 mm long, yellow, the apex broadly acute,

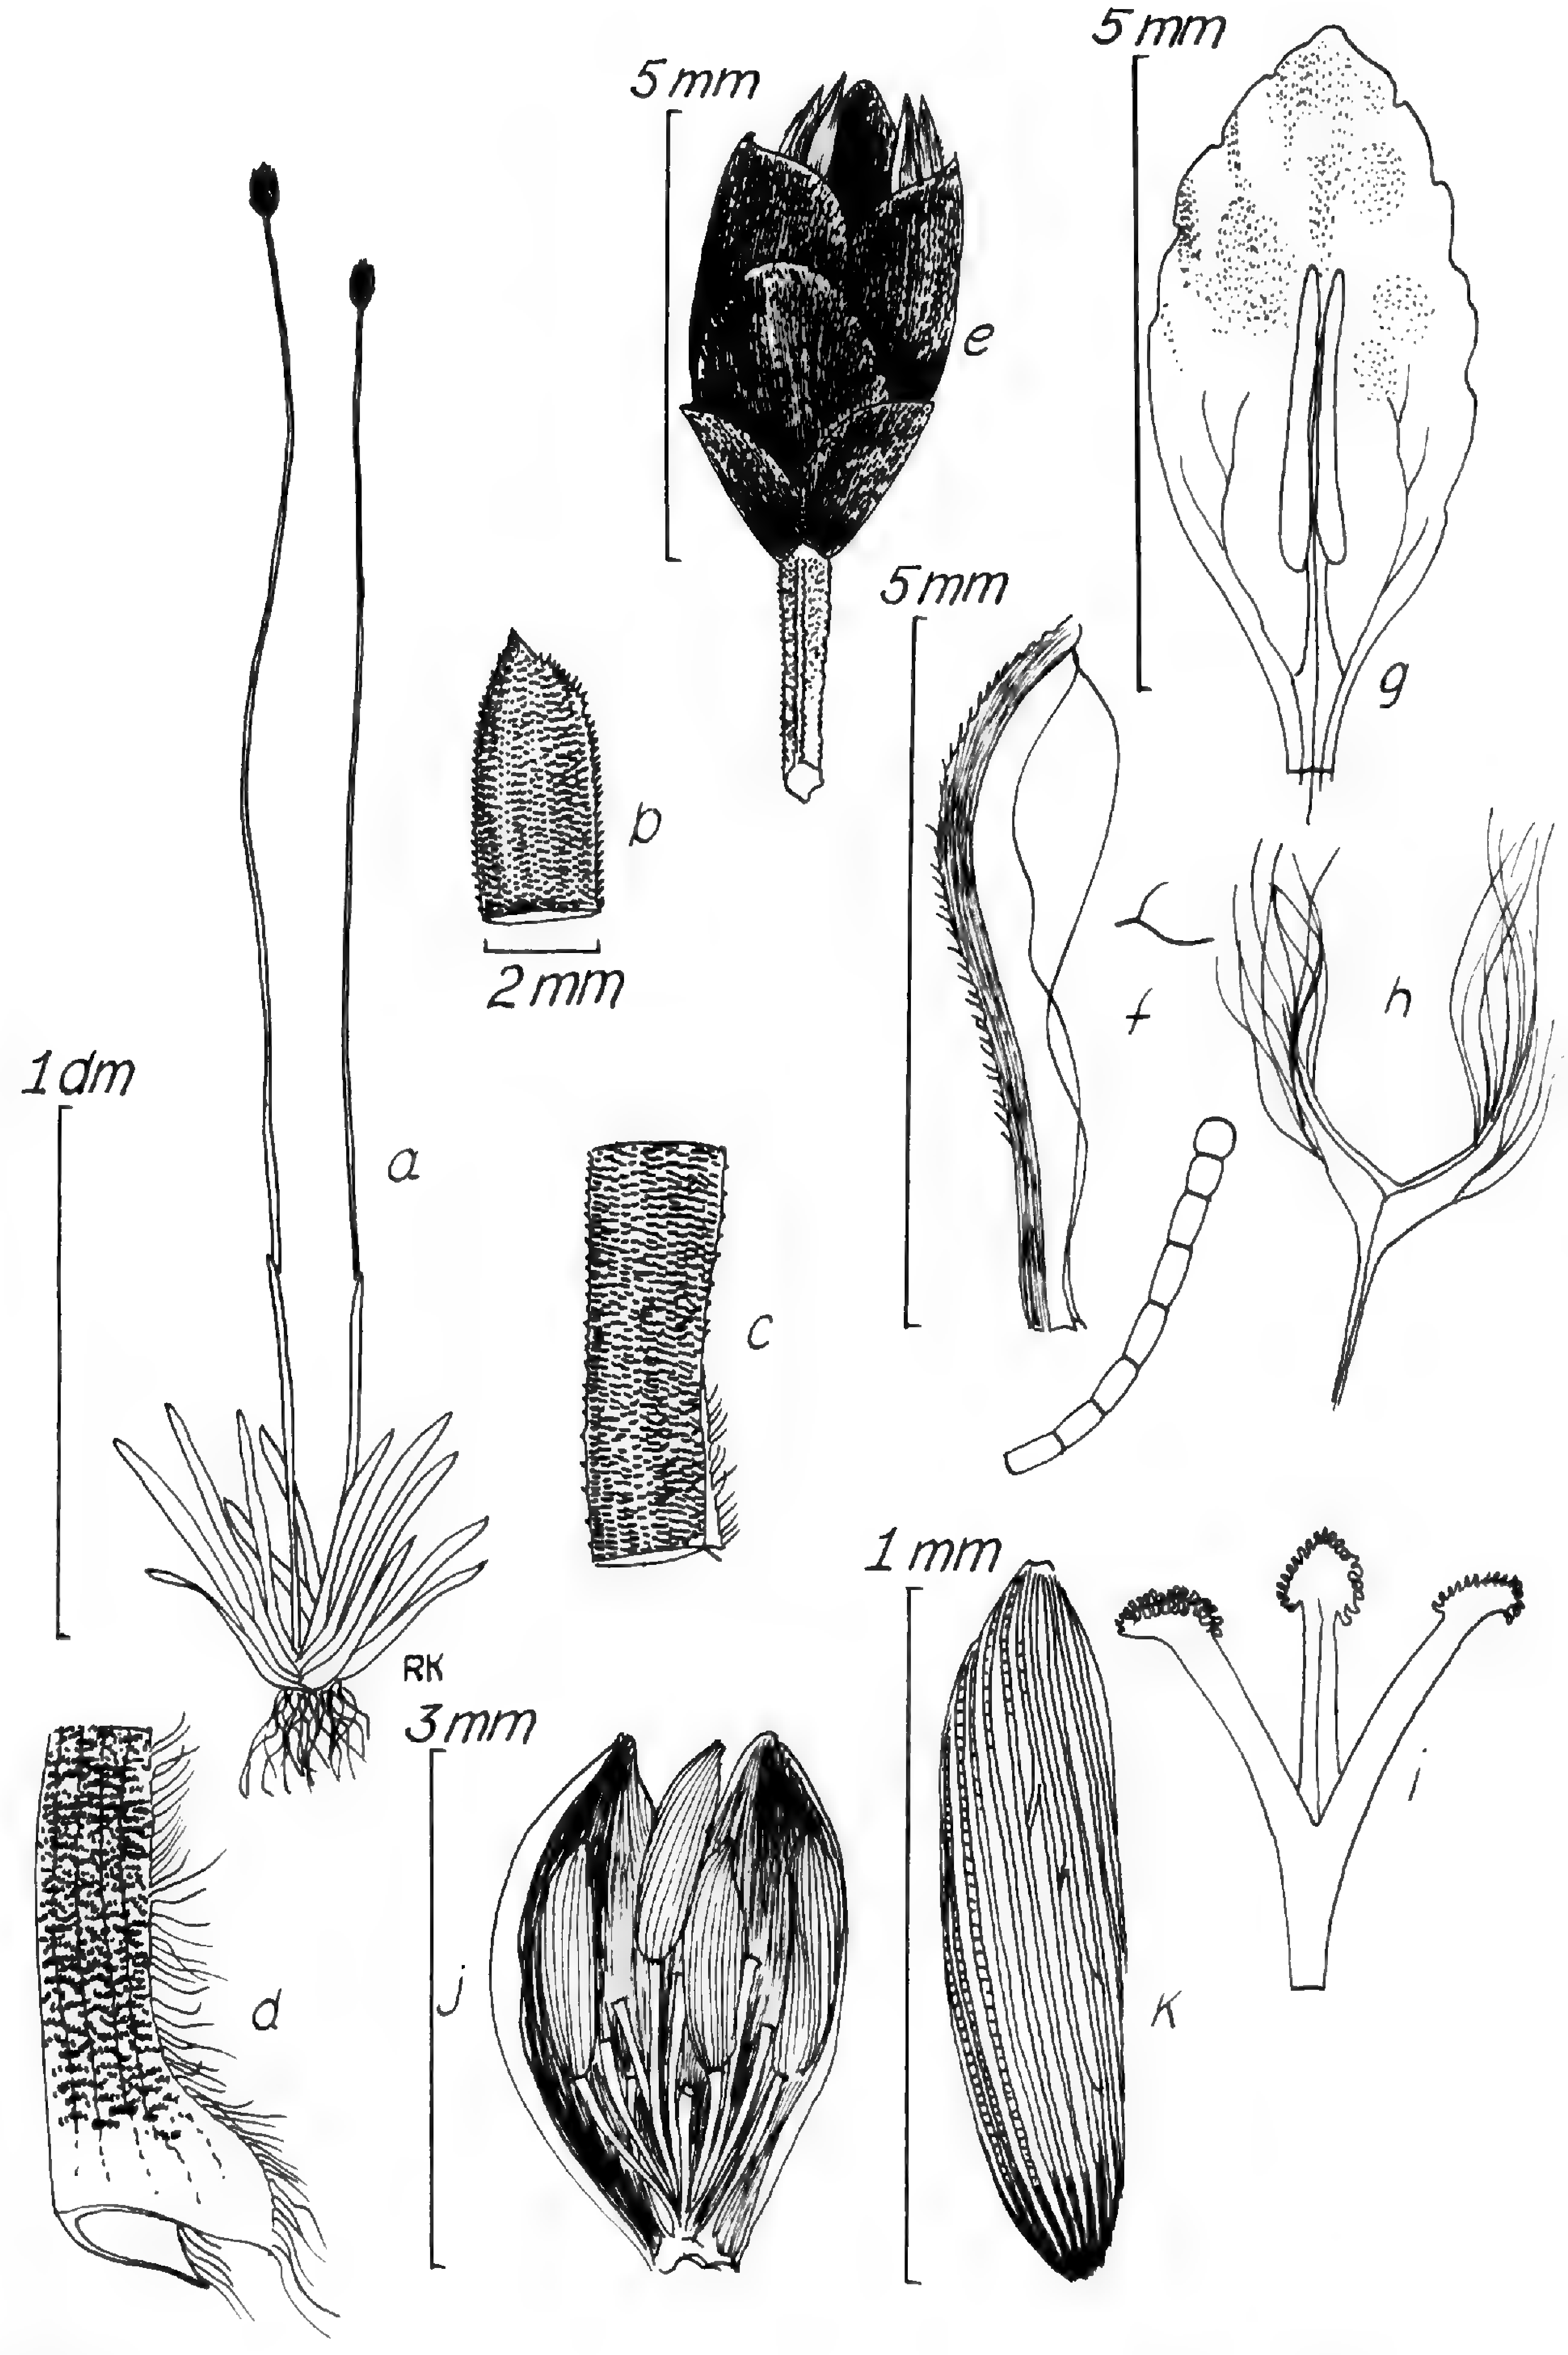

FIGURE 84. Xyris schneeana (Steyermark et al. 128918).—*a. Habit sketch.—b. Leaf apex.—c. Leaf at blade-sheath junction.—d. Leaf base.—e. Spike.—f. Lateral sepal.—g. Petal blade, stamen.—h. Staminode.—i. Stylar apex.—j. Capsule, dehiscing, showing two valves, placentation.—k. Seed.*

the margin sinuate. Staminodia bibrachiate, the branches long-penicillate. Anthers lance-oblong, ca. 1.7–2 mm long, deeply bifid and sagittate, on filaments 0.8–0.9 mm long. Capsule broadly ellipsoid or nearly obovoid, ca. 3 mm long, placentation basal-central. Seeds narrowly ellipsoid or cylindric, ca. 1 mm long, amber, longitudinally finely but distinctly multiribbed.

Distribution. High, sandy, rocky savanna-plain, Chimantá Massif and related tepuis, Estado Bolívar, Venezuela.

Additional specimens examined. VENEZUELA. BOLÍVAR: altiplanicie meridional Acapá-tepui, ubicada en el sector SW del Macizo, 2,200 m, 31 Jan.–Feb. 1984, *Huber & Dezzeo 8636* (NY); cumbre Aprada-tepui, sector sur, ca. 30 km al E de Urimán, ca. 2,500 m, 30 June 1984, *Huber 9580* (MYF, VDB); NW part of summit of Abacapa-tepui, 2,125–2,300 m, 13 Apr. 1953, *Steyermark 74920* (F, NY); sector centro-noreste del Chimantá-tepui, cabeceras orientales del Caño Chimantá, 2,000 m, 26–29 Jan. 1983, *Steyermark et al. 128162* (VDB, VEN); Apacara-tepui, sector Norte del Macizo, 2,200 m, *Steyermark et al. 128372* (VDB, VEN); sección oriental del Chimantá-tepui, cabeceras del afluente derecho superior del Río Tirica (Caño del "Grillo"), 2,450 m, *Steyermark et al. 128918* (VDB, VEN).

The stubby, low habit of the leaves, dull green and papillose-rugulose foliage, small and dark-bracted spikes, and strongly septate capsule valves combine to distinguish this high-tepui endemic.

85. **Xyris consolida** Kral & Lyman B. Smith, Phytologia 53(6): 434–435, figs. 3, 4. 1983. TYPE: Venezuela. Bolívar: Uaipan-tepui, the summit of west Peak, 1,980 m, small, wet grassy swamp on sandstone, 4 Mar. 1967, *G. Agostini & T. Koyama 7462* (holotype, VEN; isotypes, NY, US). Figure 85A, B.

Plants perennial, solitary or in small tufts; leaf and scape surfaces scabrid; habit lax; roots slender; stems contracted. Leaves all basal, ensiform-linear, 1.5–2 dm long, longer than scape sheaths, spreading flabellately; blades flat, strongly compressed, 3–5 mm wide, olivaceous, multinerved longitudinally, transversely rugose; apices abruptly narrowed, incurved-acute at tip, slightly thickened; margins slightly thickened, minutely tuberculate-ciliate to strigo-ciliate or entire; sheaths gradually narrowed from base to apex, carinate, the carinae ciliate with spreading to retrorse hairs, the sides transversely rugulose, dull olive, multinerved longitudinally, lustrous at base, deeply red-brown, the edges narrow, pale, hirsute-ciliate with sordid trichomes. Scape sheaths twisted, carinate, prominently multicostate with carinae and submarginal costae strongly tuberculate and ciliate, the sheath apex with a short, erect, flat blade. Scapes linear, twisted, 4–6 dm high, subterete or slightly compressed, 1–1.5 mm thick, olive, multicostate, with costae scabrous. Spikes ovoid to broadly obovoid or subglobose, 8–10 mm long, 6–7 mm wide, several-flowered, the bracts loosely spirally imbricate, ecarinate, convex-backed, the margins narrowly scarious; sterile bracts several, gradually passing larger into the fertile bracts, 3.5–4.5 mm long, broadly obovate to obovate, rounded, the margins narrowly scarious; fertile bracts broadly obovate, ca. 5 mm long, rounded-convex; dorsal area absent. Lateral sepals ca. ⅓ connate, inequilateral, ca. 5.5 mm long, the lobes oblong, broadly acute or obtuse; keel wide, thin, entire from base to middle, ciliolate-lacerate from middle to apex. Petal blades obovate, 4–4.5 mm long, yellow, the narrowed apex erose. Staminodia bibrachiate, the branches apically long-penicillate. Ripe capsule ellipsoid, 3.5 mm long, the valves without septa, the placentation basal-central. Seeds oblong-ellipsoid, ca. 1 mm long, amber, strongly multiribbed longitudinally.

Distribution. Known only from the type collection (Uaipan-tepui) and from Ptari-tepui, in Estado Bolívar, Venezuela.

Additional specimens examined. VENEZUELA. BOLÍVAR: Ptari-tepui, cumbre; al norte de la Misión de Santa Teresita de Kavanayen, 2,360–2,420 m, 23 Feb. 1978, *Steyermark et al. 115729* (F, MO, US, VEN).

The scabrous foliage, small, dark-bracted spikes, and connate lateral sepals distinguish this rather low plant. At the beginning of the study it was thought that the two collections represented tepui-summit endemics; a closer

examination revealed that, other than the smooth-margined leaves of the Ptari-tepui material, there are no other significant differences between them.

86. Xyris kukenaniana Kral, sp. nov. TYPE: Venezuela. Bolívar: Dist. Roscio Kukenán-tepui, cumbre del sector más septentrional algo separado del macizo principal. Vegetación herbáceo-arbustiva sobre rocas de arenisca y alrededor de lagunas, 5°16′N, 60°48′W, 2,500 m, 28 Apr. 1984, *O. Huber 9460* (holotype, VEN; isotypes, MYF, NY, VDB). Figure 86.

Planta perennis, caespitosa, humilis. Folia linearia, solum basalia, 6–10 cm longa, erecta vel leviter expansa, vaginis scaporum longiora. Laminae folia principalia vaginis 3–5-plo longiores, planae, leviter compressae, 1–1.5 mm latae, pallidae virides, ad apicem abrupte incurvato-acutae, aliquantum incrassatae, a basin gradatim contractae; margines prominente albociliati aut scabrociliati; paginae longitudine grosse nervatae, glabrae vel papillosae; vaginae ciliato-carinatae, pluricostatae, rugulosae, pallide ferrugineae, marginibus a basin ad apicem longiciliatis, in laminas gradatim convergentibus aut ad apicem curtam pilosam ligulam fascientibus. Vaginae scaporum prominente ciliato-carinatae, grosse nervatae, laminis similis laminis foliorum sed brevibus. Scapi recti vel leviter tortae, 1–2 dm longi, distaliter in sectio transversali elliptici, ca. 1 mm lati, anguste ancipiti, 2–3(–4) costati, costis dense pallide scabrociliatis. Spicae ovoideae, atroferrugineae vel fuliginosae, 7–8 mm longae, pluriflorae, obtusae, bracteis subdecussatis, laxe imbricatis, sine area dorsali, minute papillosis; bracteae steriles plures, triangulatae vel oblongae, 2–3.5 mm longae, ad apicem albociliatae, obtusae, fertilibus breviores et in eas gradatim transientes; bracteae fertiles late obovatae, ca. 5 mm longae, vadose convexae, ecarinatae, apice rotundatae, integrae tum laceratae. Sepala lateralia libera, leviter curvata, subaequilatera, late lanceolata, 4.5–5 mm longa, acuta; ala carinali angusta, parce longiciliata. Laminae petalorum late obovatae, ca. 4 mm longae, luteolae, ad apicem erosae. Antherae oblongae, 1.5 mm longae, profunde bifidae et sagittatae; filamenta ca. 1 mm longa. Staminodia bibrachiata, dense longipenicillatis. Capsula immatura septa efferentes. Semina non visa.

The plant perennial, cespitose, low. Leaves linear, strictly basal, 6–10 cm long, erect to slightly spreading, longer than the scape sheaths. Blades of principal leaves 3–5 times longer than the sheaths, plane, slightly compressed, 1–1.5 mm wide, pale green, at apex abruptly incurved-acute, somewhat thickened, gradually narrowed toward base; margins prominently white ciliate or scabro-ciliate; surfaces coarsely nerved longitudinally, smooth or papillose; sheaths ciliate-carinate, several-ribbed, rugulose, pale red-brown, the margins long-ciliate from base to tip, gradually narrowing into the blades or producing a short, pilose ligule at apex. Scape sheaths prominently ciliate-carinate, coarsely nerved, with blades similar to leaf blades but shorter. Scapes straight or slightly twisted, 1–2 dm long, distally elliptic in cross section, ca. 1 mm wide, narrowly ancipital, 2–3(–4) costate, the costae densely pale scabrociliate. Spikes ovoid, dark red-brown or sooty brown, 7–8 mm long, several-flowered, obtuse, the bracts subdecussate, loosely imbricate, without dorsal area, minutely papillose; sterile bracts several, triangular to oblong, 2–3.5 mm long, white ciliate at apex, obtuse, smaller than the fertile bracts and grading into them; fertile bracts broadly obovate, ca. 5 mm long, shallowly convex, ecarinate, rounded apically, entire, aging lacerate. Lateral sepals free, slightly curvate, subequilateral, broadly lanceolate, 4.5–5 mm long, acute; carinal keel narrow, sparsely long-ciliate. Petal blades broadly obovate, ca. 4 mm long, yellow, erose at apex. Anthers oblong, 1.5 mm long, deeply bifid and sagittate; filaments ca. 1 mm long. Staminodia bibrachiate, densely long-penicillate. Immature capsule producing septa. Seeds not seen.

Distribution. Known only from the type locality.

Superficially *Xyris kukenaniana* resembles *X. setigera* in general spike bract character and color, and in the coarsely ciliate leaf blades, but the former lacks the excentrically spinulose leaf blade apex of *X. setigera*, and its scapes are definitely sharp-edged and ciliate, very unlike the lustrous and ecostate scapes of *X. setigera*.

87. Xyris delicatula Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 23, fig. 7A–F. 1963. TYPE: Venezuela. T. F. Amazonas: frequent in wet hummocks, Camp Savanna, Campo Grande, 1,500 m, Cerro Sipapo (Pa-

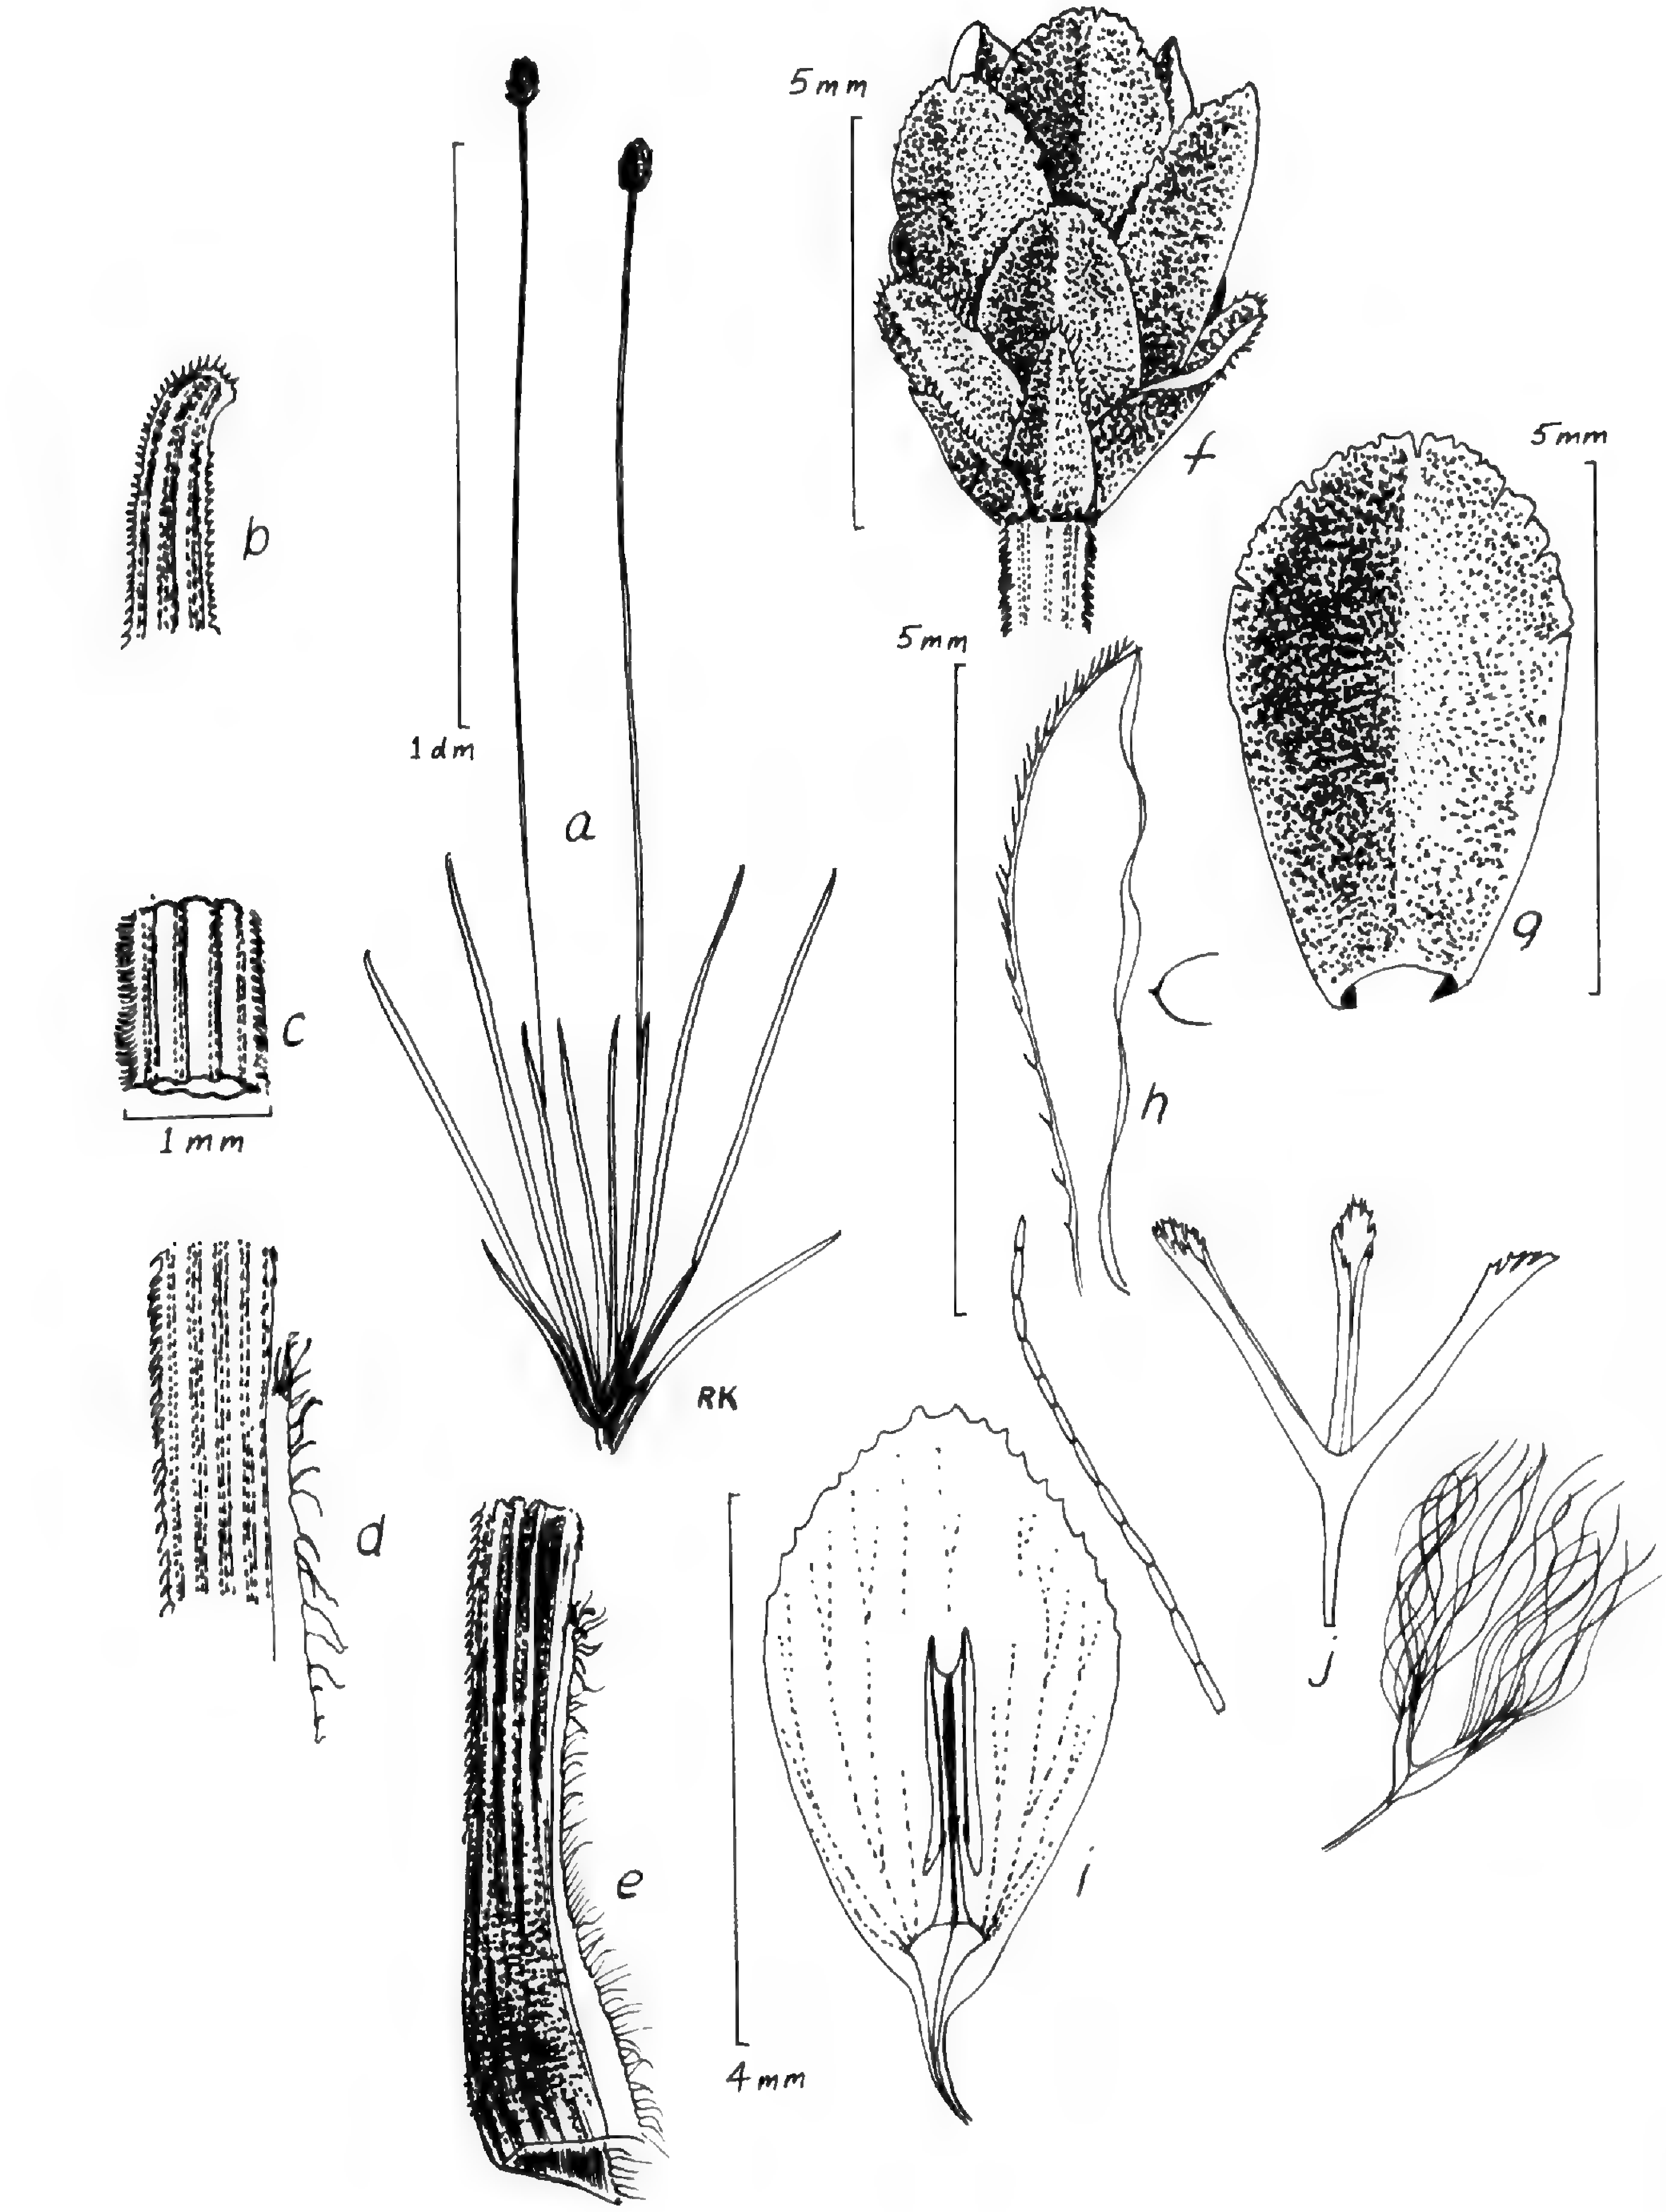

FIGURE 86. Xyris kukenaniana (O. Huber 9460).—*a. Habit sketch.—b. Leaf tip.—c. Sector of leaf at midblade.—d. Leaf blade–sheath junction.—e. Leaf base.—f. Spike.—g. Fertile bract.—h. Lateral sepal.—i. Petal blade, stamen.—j. Stylar apex, staminode, staminodial beard hair, enlarged.*

raque), 10 Dec. 1948, *B. Maguire & L. Politi 27580.* Figure 87.

Slender, densely cespitose perennial 3–5 dm high, the stems contracted. Leaves erect or ascending, 1.5–3 dm long; sheaths less than ½ length of blade, long-ciliate, slightly dilated at very base, ecarinate, pale brown, papillate-rugulose, gradually narrowing, carinate, roseate, at apex producing a narrow

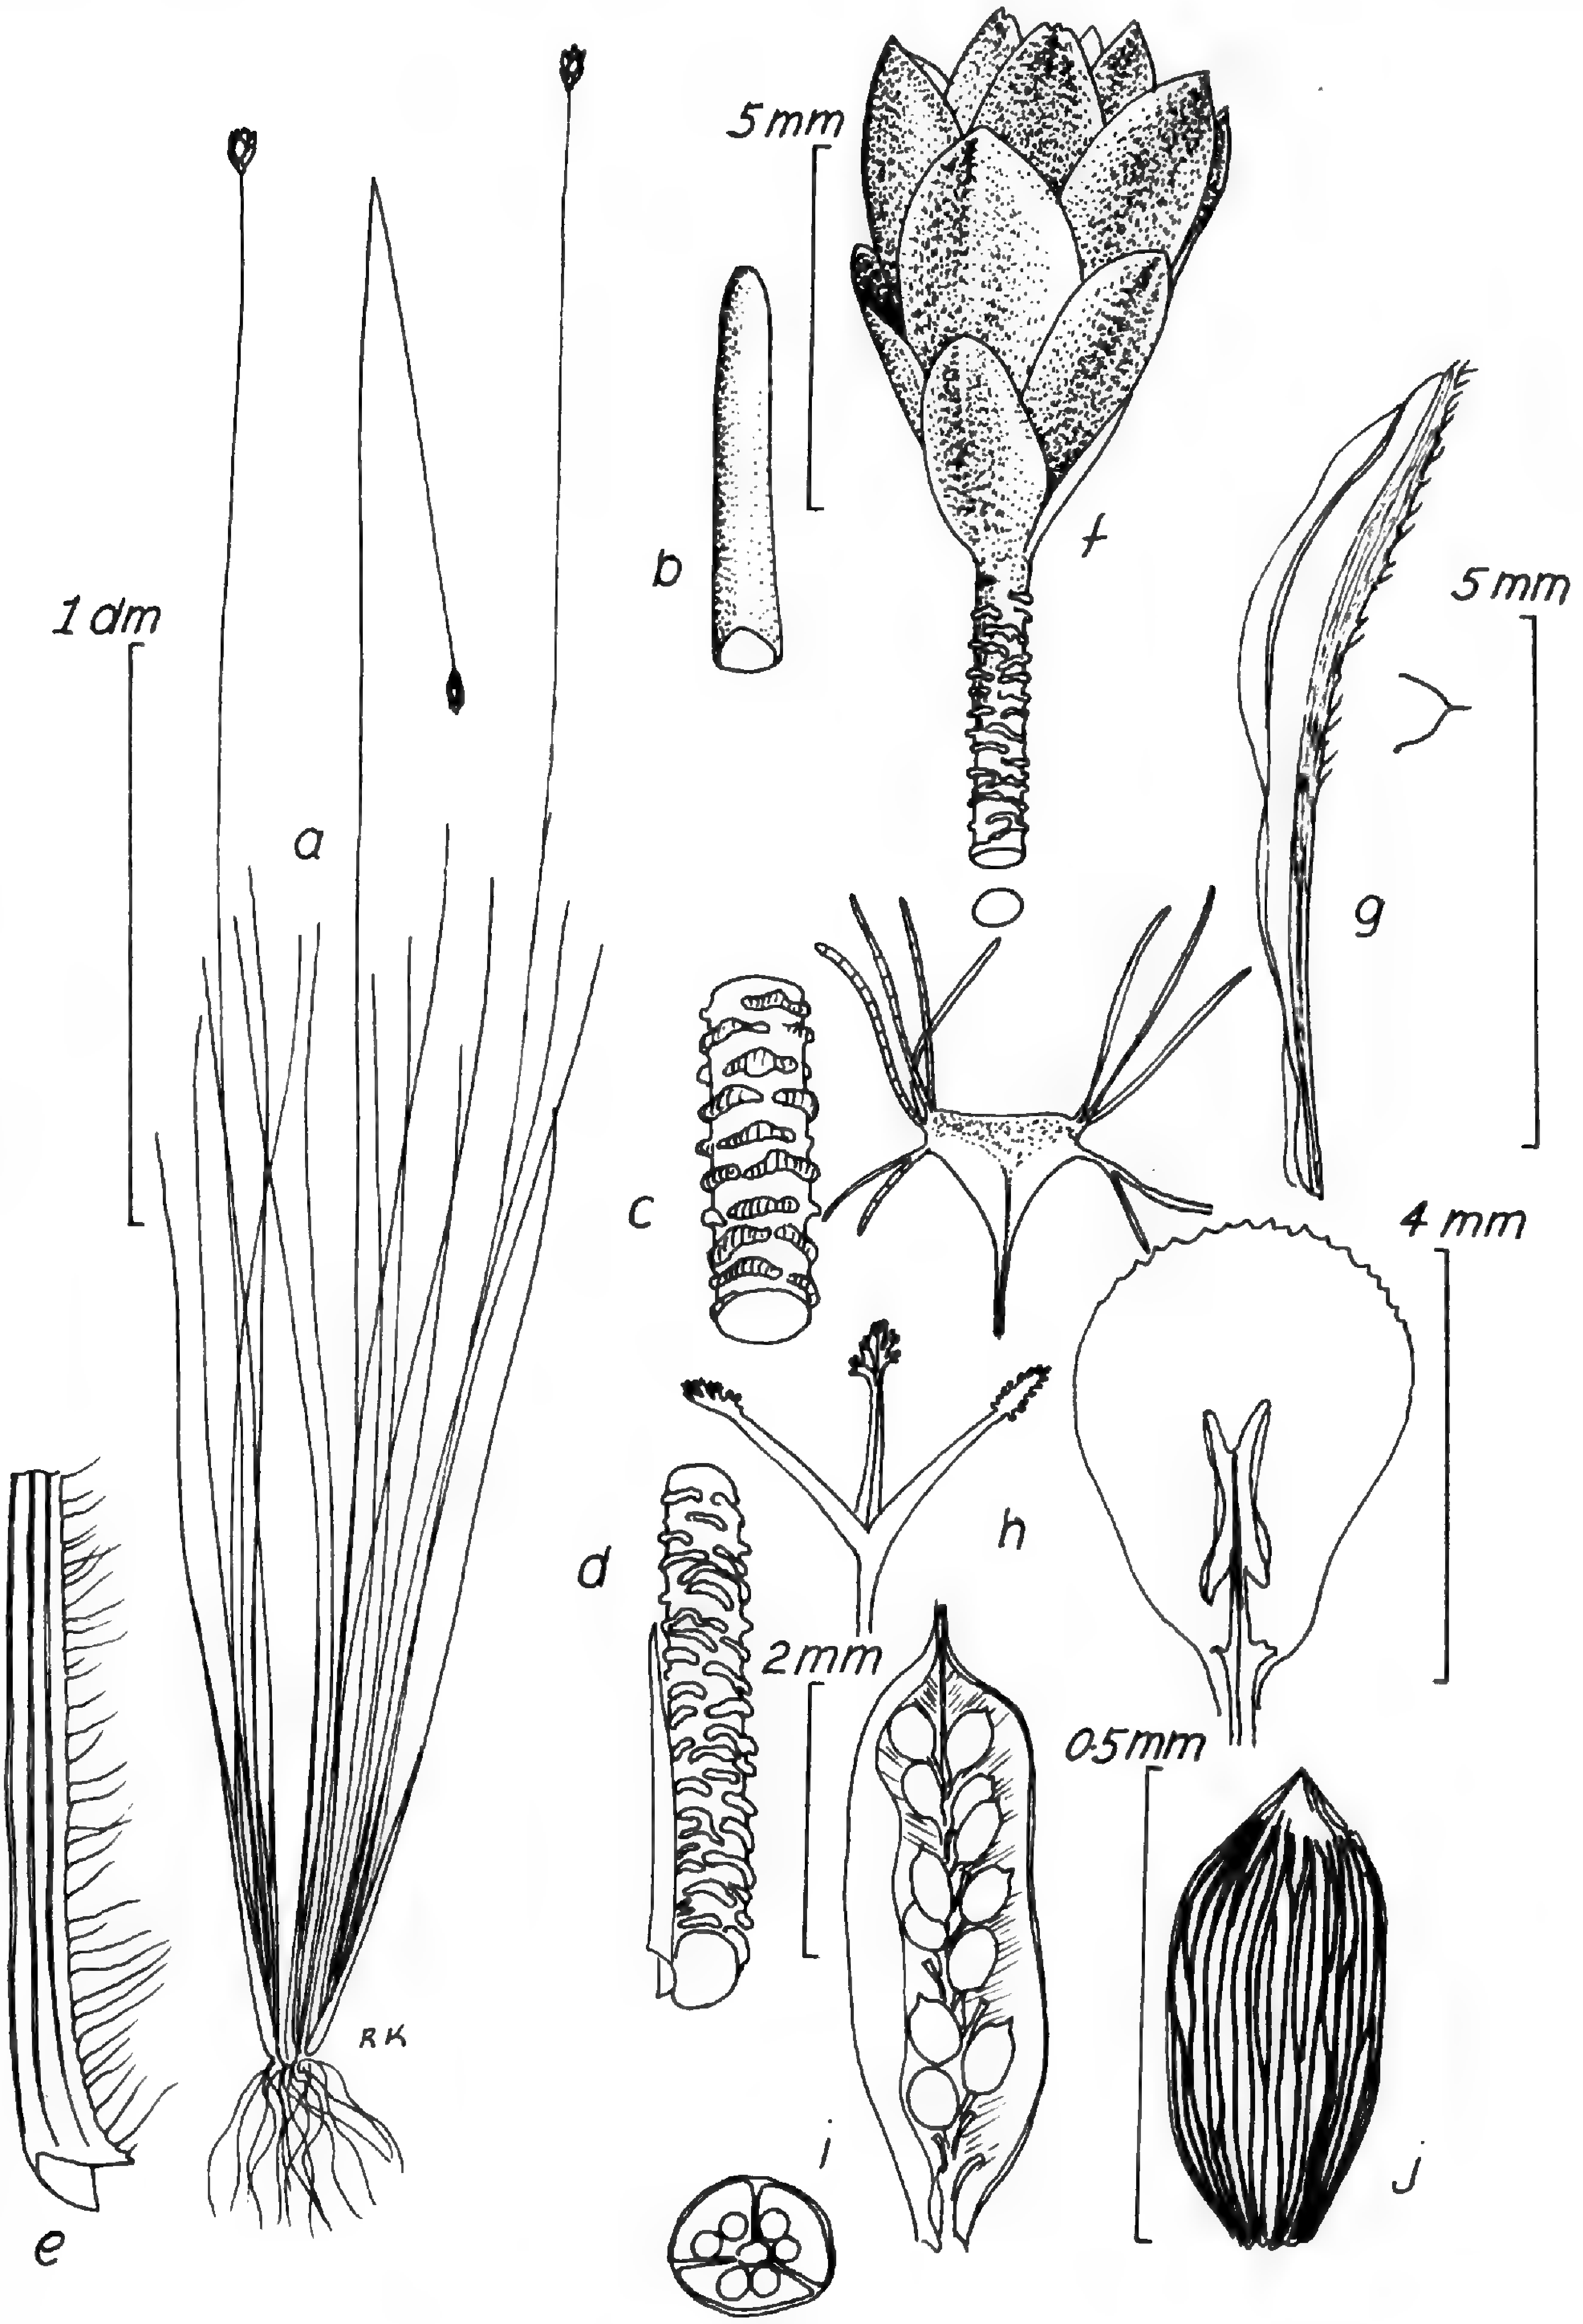

FIGURE 87. Xyris delicatula *(from the type).—a. Habit sketch.—b. Leaf tip.—c. Sector of leaf, midblade.—d. Leaf sheath-blade junction.—e. Leaf base.—f. Spike.—g. Lateral sepal.—h. Stylar apex, petal and stamen, staminode.—i. Capsule, one valve removed.—j. Seed.*

narrowly acute or blunt, scarious, erect ligule to 2 mm long; blades filiform, mostly terete, sometimes slightly flattened, ca. 0.5 mm wide, tapering to a bluntly short-conic, smooth tip above middle, otherwise completely rugose or verrucose, the nerves not evident. Scape sheaths shorter than leaves, strongly rugose, ecarinate, with a very short, blunt cusp above. Scapes straight to flexuous, twisted, distally terete, ca. 0.4–0.5 mm thick, papillose-rugulose. Spikes ellipsoid, drying obovoid, ca. 7–8 mm long, of several firm, erect but loosely spirally imbricate, brown bracts lacking distinct dorsal areas and grading from the smaller, narrowly ovate, slightly carinate sterile bracts to the slightly larger, oblong to narrowly obovate fertile ones, these ca. 6.5–7 mm long, narrowly rounded or broadly acute at apex and with very short apical carinae, the backs convex-rounded, papillate. Lateral sepals free, subequilateral, linear-oblanceolate, ca. 5.5 mm long, acute, erect or excurved, the dark firm keel lacerociliate from middle to apex. Petal blades broadly obovate, ca. 4 mm long, yellow, the broadly rounded apex irregularly denticulate. Anthers oblong, ca. 1.5 mm long, deeply bifid, sagittate, on filaments 0.5 mm long. Staminodes somewhat reduced, broadly bibrachiate, the branches apically sparsely penicillate. Capsule cylindric, ca. 4 mm long, trilocular, the deep septa pulling away from the axis at maturity, thus placentation appearing free-central but really axile. Seeds broadly ellipsoid or ovoid, ca. 0.5 mm long, apiculate, amber, longitudinally finely but distinctly ribbed, some ribs anastomosing.

Distribution. High-elevation tepuis, Territorio Federal Amazonas and Estado Bolívar, southern Venezuela, infrequent.

Additional specimens examined. VENEZUELA. BOLÍVAR: Auyan-tepui, sect. SSE, ca. 12 km al SE del Churun-meru (Salto Churun) 5°47′N, 62°28′W, 2,250 m, *Huber & Medina 8521* (MYF, VEN); Serranía Guanay, sector nororiental, cabeceras mas orientales del Río Paraguaza, 5°55′N, 66°23′W, ca. 1,700 m, 20–28 Oct. 1985, *Huber 11055* (MYF, VDB); altiplanicie del Auyantepui, sector centro-oeste del Brazo Occidental ca. 15 km al WSW Salto Angel, 1,860 m, 19 Jan. 1986, *Huber 11248* (MYF, NY, VDB); Auyan-tepui, sector suroriental, 2,140 m, 26 Feb. 1978, *Steyermark et al. 116055* (a mix with *X. setigera*—US).

This species is peripheral to *X. setigera* and, along with *X. carinata* and *X. byssacea*, develops populations at high elevations that are homogeneous but at the same time distinctive on the basis of fine characters. *Xyris delicatula* is indeed close to *X. setigera* but, while its leaves are harsh as in that species, their tips lack the setiform apex so common in the latter, and its scapes are rugose rather than smooth. Interestingly, this is another taxon in which placentation is evidently axile.

NOTES

A NEW SPECIES OF *OCOTEA* (LAURACEAE) FROM NICARAGUA AND A NOTE ON *OCOTEA JORGE-ESCOBARII*

The *Ocotea* species in Central America form a difficult and incompletely known group. Reasons for this are that the genus is not clearly separated from *Nectandra* and *Phoebe*, that there is a scarcity of flowering collections, and that decisions by earlier botanists are sometimes difficult to understand and the species they described are hard to interpret.

During the preparation of the Lauraceae treatment for the *Flora de Nicaragua*, one undescribed *Ocotea* species was found and is here published. The affinities of the new species, *O. strigosa*, are not clear. It is so inconspicuous that one wonders how it was ever found. Several Nicaraguan collections are referred to *O. jorge-escobarii*, a species recently described from Honduras. An English description and an illustration of this poorly known species are provided.

Ocotea strigosa van der Werff, sp. nov. TYPE: Nicaragua. Matagalpa: W slope and summit of Cerro El Picacho, cloud and elfin forest, 1,350–1,590 m, *Stevens 22181* (holotype, MO; isotype, HNMN). Figure 1.

Frutex vel arbor parva. Ramuli teretes, glabri, sed apicibus strigis brunneis munitis. Gemma terminalis dense cinereo-sericea. Folia alterna, chartacea, 6–9 × 2–3.5 cm, ovata vel anguste ovata, basi obtusa vel acuta, apice acuminata; juvenalia strigosa, vetustiora glabrescentia; super opaca, venatione non manifesta; subtus venatione leviter elevata; domatiis carentia sed infrequenter in axillis venarum pilis erectis praedita. Nervi laterales utroque costae latere 3–6. Inflorescentiae axillares, foliis breviores, strigosae, ad 6 cm longae. Flores albi. Petala 6, aequalia, ca. 1.5 mm longa, extus basi strigosa, apice glabrescentia, intus glabra praeter apicem tepalorum interiorum papillosam. Stamina 9, 4-locellata, glabra, 6 exterioribus filamentis ca. 0.5 mm longis, antheris ca. 0.5 mm longis, apicibus truncatis locellis introrsis, 3 interioribus filamentis ca. 0.7 mm longis, antheris ca. 0.8 mm longis, locellis extrorsis; glandulae staminum interiorum magnae, breviter stipitatae, ca. 0.6 cm diametro; staminodia 3, ca. 0.7 mm longa, apice triangulari. Ovarium glabrum, ellipsoideum, ca. 0.8 mm longum. Fructus ellipsoideus, cupula brevi, ad 1 cm lata, sensim in pedicellum angustata.

Shrubs or small trees. Twigs terete, glabrous at maturity, but the tips with varying amounts of brown, appressed hairs, these sometimes giving a brown cast to the twigs. Terminal bud densely gray-sericeous. Leaves alternate, chartaceous, 6–9 × 2–3.5 cm, ovate or narrowly ovate, the base obtuse or acute, the apex acuminate; strigose above and below when young, becoming glabrescent; upper leaf surface smooth, the venation scarcely or not at all visible; lower leaf surface with venation slightly elevated; lateral veins 3–6 pairs; domatia generally lacking, although occasionally a few erect hairs present in the vein axils. Inflorescences axillary, shorter than the leaves, to 6 cm long, grayish strigose, paniculate. Flowers white; petals 6, equal, ellipsoid, ca. 1.5 mm long, the outside strigose near the base, less so towards the apex, the inside glabrous, but the inner 3 tepals with a papillose tip; stamens 9, 4-celled, the outer 6 with introrse cells, the filament ca. 0.5 mm long, the anther ca. 0.5 mm long, the cells arranged in 2 horizontal rows, apex of anther truncate; inner 3 stamens with extrorse cells, the filaments ca. 0.7 mm, the anther ca. 0.8 mm; staminal glands globose, short-stalked, ca. 0.6 mm diam.; staminodia 3, ca. 0.7 mm long, the head small, triangular. Ovary glabrous, ellipsoid, ca. 0.8 mm long; style robust,

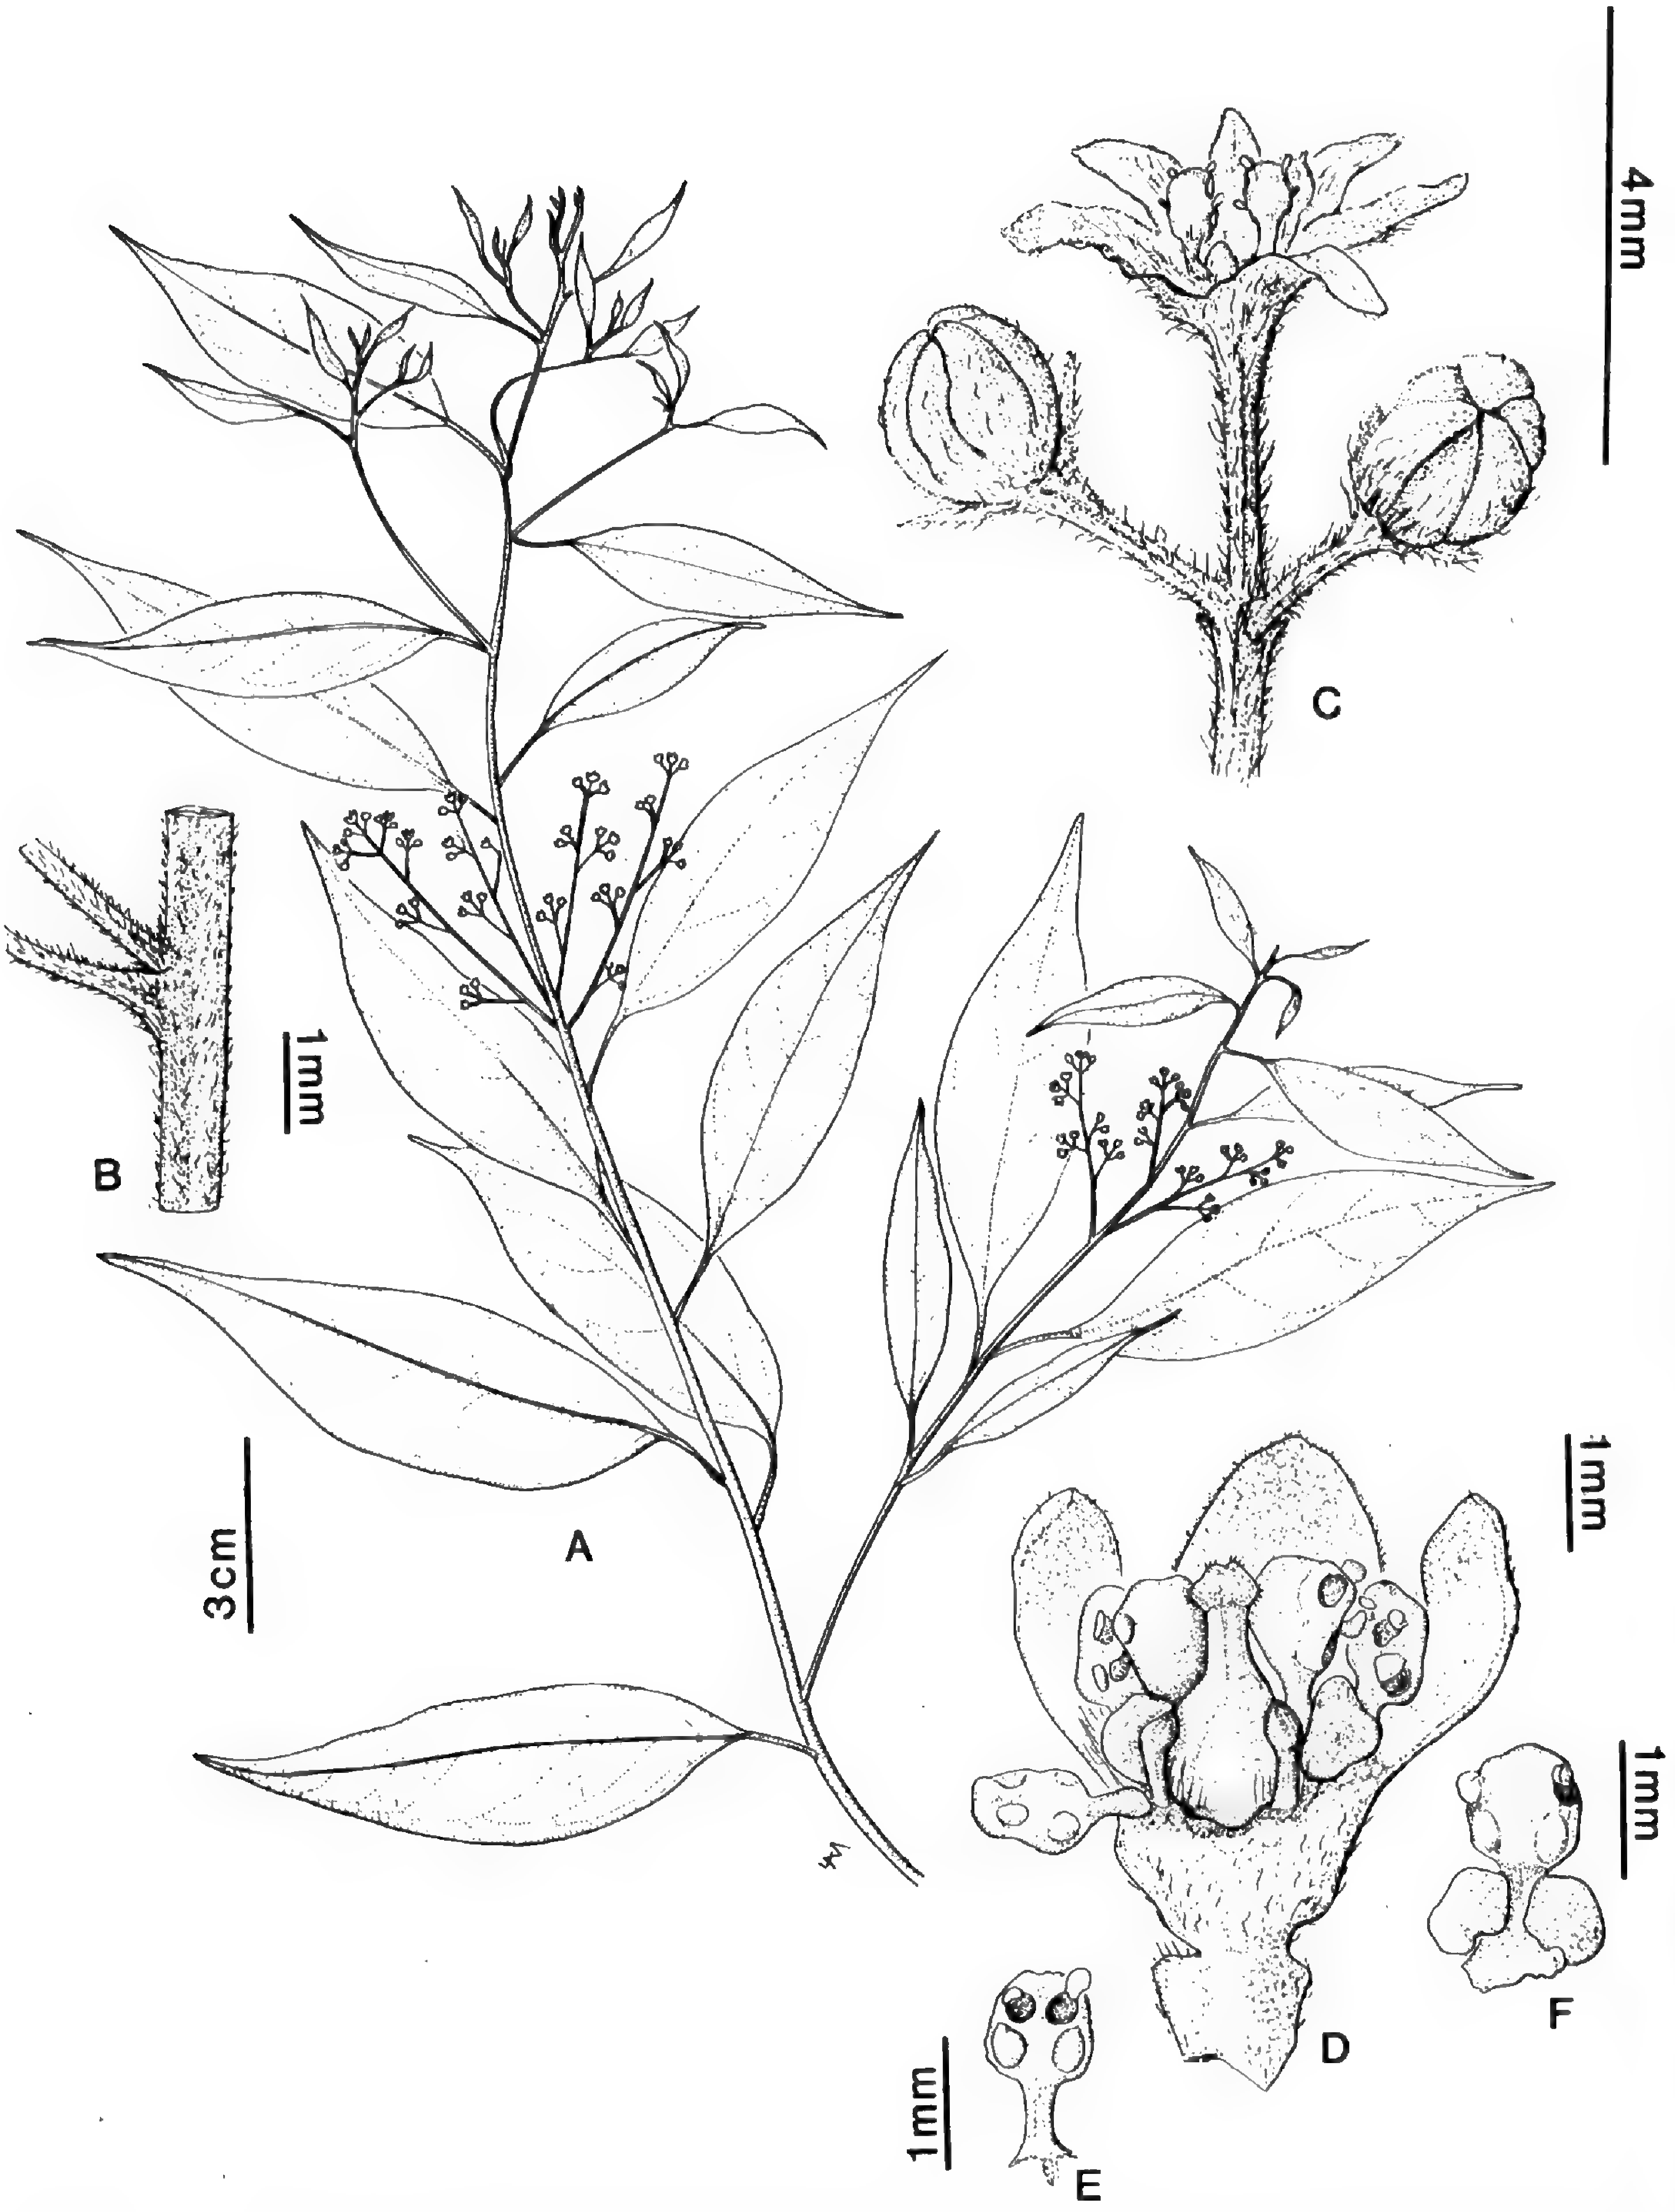

FIGURE 1. Ocotea strigosa.—*A. Habit.—B. Detail of twig, showing pubescence.—C. Detail of inflorescence.—D. Flower, tepals removed, showing stamens, staminal glands, staminodia, and ovary.—E. Outer stamen.—F. Inner stamen with basal glands.*

ca. 0.7 mm long, the stigma triangular. Fruit an ellipsoid berry, ca. 1 cm long, seated on a shallow cupule, ca. 1 cm wide, with a gradually thickened pedicel.

Paratypes. NICARAGUA. BOACO: entre Cerro Alegre y El Roblar, *Moreno 20201* (MO), *20212 B* (MO). JINOTEGA: Montaña Cuspire, *Moreno 8045* (MO); Fila Piedra Pelona, *Moreno 7794* (MO); Volcán Yali, *Moreno 7944, 7965* (both MO). MATAGALPA: El Picacho, *A. Molina R. 30512* (F, MO); Hacienda Santa Maria de Ostuma, *Tomlin 141, 142, 154, 156* (all MO).

Ocotea strigosa is known only from cloud forests between 1,000 and 1,600 m elevation in Nicaragua. One of the most inconspicuous *Ocotea* species in Central America, it can be recognized best by its strigose pubescence and acuminate leaves. Domatia are generally lacking, but occasionally some erect hairs can be found in the axils of the lateral veins. Some leaves of *Stevens 22181* have minute, insect-built cocoons in the vein axils, which are partly covered by stiff hairs. This collection also has a stronger raised reticulation on the lower leaf surface than the other collections.

Ocotea is a difficult genus, not always clearly separated from *Nectandra* and *Phoebe*, and it includes several poorly known species based on incomplete specimens. In Allen's (1945) *Ocotea* treatment of the Central American Lauraceae, *O. strigosa* keys to *O. effusa* (Meissner) Hemsley or *O. klotzschiana* (Nees) Hemsley, both known from Mexico and adjacent areas. *Ocotea strigosa* can be separated from those species by its strigose pubescence, ovate leaves (widest below the middle), and absence of domatia. In Allen's (1945) *Phoebe* treatment, it keys to the vicinity of *P. mollicella* Blake or *P. acuminatissima* Lundell. The first can be immediately recognized by its yellowish tomentum and is probably not closely related. *Phoebe acuminatissima* differs from *O. strigosa* by its narrower leaves, domatia in the lower vein axils, raised reticulation on the upper leaf surface, papillose anther tips, and denser pubescence consisting of shorter hairs. The papillose anthers and tepals and the glaucous cast of the flowers suggest that *P. acuminatissima* does not belong in *Phoebe* but might better be placed in *Ocotea* near the group of *O. helicterifolia* (Meissner) Hemsley.

Ocotea jorge-escobarii Nelson, Ceiba 25: 173. 1984. Figure 2.

Ocotea jorge-escobarii Nelson was recently described and was only known from Honduras. Because the description and discussion of this species were brief, its identity remained problematical. During preparation of the treatment of the Lauraceae for the *Flora de Nicaragua*, several *Ocotea* collections from cloud forests in Nicaragua were found to represent an unknown species. A search in the MO herbarium produced several collections from Honduras, distributed as *Phoebe* species, which belonged in this unknown species. Because one of these collections (*Escobar 247*) was cited as a paratype of *O. jorge-escobarii*, and the specimens agree with the brief description, I place the Nicaraguan collections in *O. jorge-escobarii.* I present here an English description and an illustration of this species.

Trees, to 20 m tall. Twigs ridged or terete, glabrous except for a few appressed hairs near the tip, the terminal bud white-sericeous pubescent. Leaves alternate, glabrous, evenly distributed along the twigs, firmly chartaceous or coriaceous, 10–20 × 4–8 cm, slightly obovate or narrowly obovate, widest above the middle, mature leaves drying pale green, the base cuneate-attenuate, the apex obtuse or slightly acute, the venation scarcely visible on upper surface but visible and slightly raised on lower surface; lateral veins 6–9 pairs; pit domatia present along the midvein and along lateral veins, these without hairs; margin thickened, greenish and often slightly inrolled. Inflorescences axillary, glabrous or with few hairs near base, shorter than the leaves, ca. 6 cm long; flowers glabrous, greenish white; tepals 6, equal, ca. 2 mm long, broadly elliptic; stamens 4-celled, the outer 6 ca. 2 mm long, glabrous, except for some hairs at base of filaments, with introrse cells; inner 3 stamens ca. 2 mm long, the cells extrorse, the filaments glabrous but base of anther densely

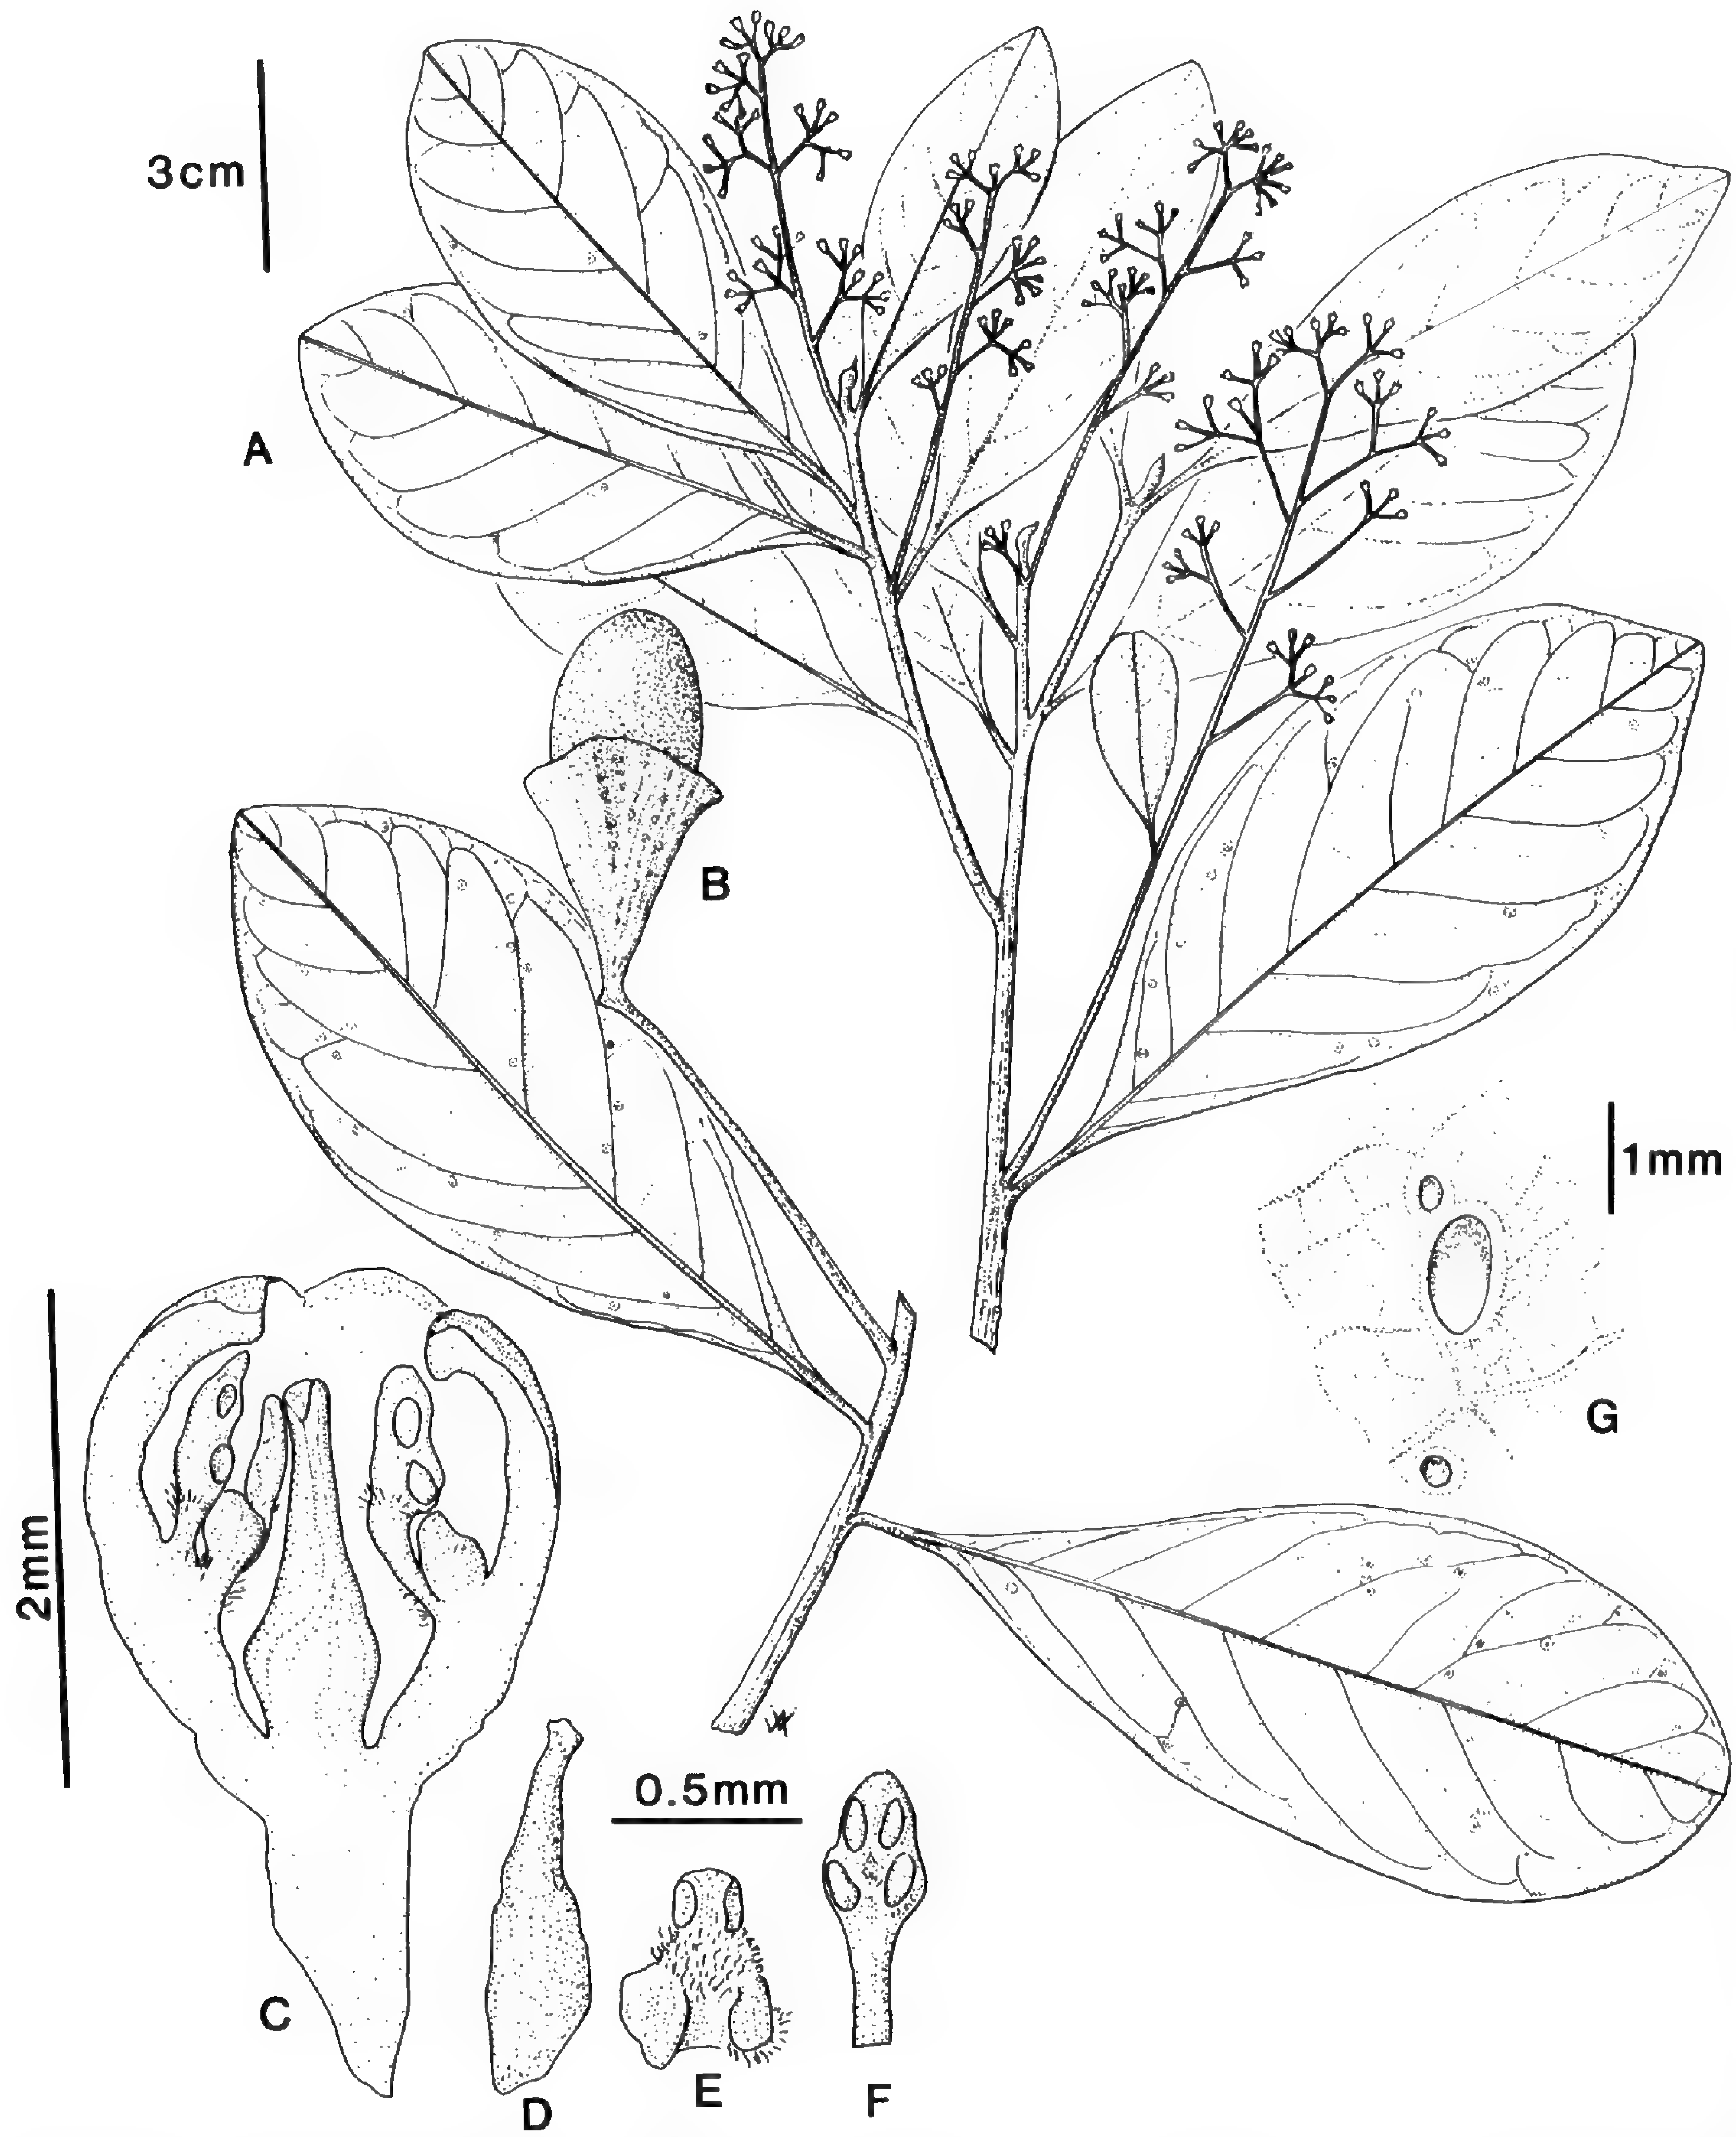

FIGURE 2. Ocotea jorge-escobarii.—*A. Habit.—B. Twig with cupule and fruit.—C. Cross section of flower.—D. Ovary.—E. Inner stamen with basal glands.—F. Outer stamen.—G. Detail of leaf, showing pitlike domatia.*

pubescent on the side facing the ovary, staminodia lacking; staminal glands large, ca. 0.8 mm diam.; floral tube ca. 1 mm deep, glabrous except for a ring of hairs at the upper margin; ovary glabrous, ellipsoid, gradually narrowed into style, the ovary and style ca. 2 mm long. Fruit an ellipsoid berry, ca. 3 cm long, 2 cm wide, cupule a large, thick cup, ca. 2.5 cm wide at rim and 1 cm deep, with many small warts and a few longitudinal ribs, which may be a drying artifact.

Specimens seen. HONDURAS. OLANCHO: Montaña Los Zapotes, *Mejia 138* (MO); same locality, *Sosa 191* (MO); same locality, *Alverado 130* (MO); same locality, *Escobar*

247 (MO); same locality, *Mejia Orduñez 146* (MO). NICARAGUA. MATAGALPA: El Arenal, between Aranjuez and Santa Martha, *A. Molina 20345* (F, MO). JINOTEGA: Ocotillo near Sta. Lasthenia, *L. Williams et al. 27783, 20794* (F); Sta. Maria de Ostuma, *L. Williams et al. 23435* (F). ZELAYA: Cerro El Hormiguero, *Pipoly 5166* (MO); Cerro La Pimienta, *Grijalva 363* (MO).

Ocotea jorge-escobarii, known only from cloud forests in Nicaragua and Honduras between 1,000 and 1,600 m elevation, is closely related to such species as *O. meziana* Allen from Panama and Costa Rica, *O. barbatula* Lundell from Guatemala, *O. viridiflora* Lundell from Chiriquí, Panama, and possibly to other species, such as *O. laetevirens* Standley & Steyerm., *O. verapazensis* Standley & Steyerm., and *O. eucymosa* Lundell. Characters shared by most species in this group are pale green drying leaves and the presence of pit domatia away from the midrib. The new species can be recognized easily by its leaf shape (widest above the middle), unusually large cupules, and thickened, slightly inrolled leaf margin. Specimens have been annotated earlier as *O. meziana* vel aff., *O.* aff. *laetevirens*, and *O. veraguensis* and may be found in additional herbaria under these names. The material from Honduras was all annotated as *Phoebe* species. Nelson compares this species with *Ocotea bernoulliana* Mez; this species differs in its dark green drying leaves and in its inflorescences, which are longer than the leaves. *Ocotea bernoulliana* is a rarely collected species, to me known only with certainty from the type.

I thank Dr. J. Dwyer for correcting the Latin description and Dr. J. Rohwer for bringing the publication of *O. jorge-escobarii* to my attention. John Myers skillfully made the illustrations.

A NEW AND ENDANGERED SPECIES OF *DAPHNOPSIS* (THYMELAEACEAE) FROM ECUADOR

Six species of *Daphnopsis* C. Mart. & Zucc. are known to occur in Ecuador (Nevling, 1959, 1978). The species are distinctive, but sterile collections may be confused with sterile collections of *Schoenobiblus* C. Mart. & Zucc. There is no reliable way to distinguish sterile *Daphnopsis* from *Schoenobiblus* other than by direct comparison of specimens. Fertile specimens of *Daphnopsis* are easily distinguished from *Schoenobiblus* C. Mart. by the presence of a calyx tube.

The following species was discovered in 1980. Since then, the forests at the only known locality have been cleared for farmland (Dodson, pers. comm.). Only scattered groups of trees persist along the creekbeds. The individuals from which the type was collected have been destroyed. With continued development of the lowland forest of Ecuador, it is likely that the species will soon be eliminated, if it is still extant.

Daphnopsis grandis Nevling & Barringer, sp. nov. TYPE: Ecuador. Los Rios: El Centinela, Montas de 11a road from Patricio Pilar to 24 de Mayo, km 12, 600 m, 6 Apr. 1980, *Dodson & Gentry 10295* (holotype, SEL; isotype, MO).

Species insignis foliis 45–65 cm longis 15–18 cm latis, inflorescentiis saepe caulifloris, hypanthio anguste obconico 10–12 mm longo, staminibus alternisepalo sessilibus.

Small tree to 5 m tall; young stems glabrous; older stems covered by a smooth gray-brown cortex. Leaves alternate; petioles 1.5–2 cm long, terete, wrinkled; blade narrowly obovate, 45–65 cm long, 15–18 cm wide, subcoriaceous, glabrous above and below, the base cuneate, the margin revolute when dry, the apex acuminate, the venation pinnate, prominent, the secondary veins straight, subparallel. Staminate inflorescence on leafless stems or rarely terminal, umbelliform, sericeous; primary peduncle 3–4 cm long; rachis 1–3 mm long; secondary peduncle 3–4 mm long. Staminate flowers 20–30 per inflorescence, white, sericeous; pedicel 3–4 mm long; hypanthium narrowly obconic, 10–12 mm long, glabrous within; calyx lobes triangular, reflexed, 3–4 mm long, 2–3 mm wide; petals absent; stamens 8, obdiplostemonous, the antisepalous whorl inserted on the calyx lobes, the filaments 1 mm long, the anthers 1 mm long, the alternisepalous whorl inserted 1–1.5 mm below the mouth of the hypanthium, sessile, anthers less than 1 mm long; disk cupuliform to tubular, 1–2 mm long, free, undulate; pistillode 2 mm long, glabrous, on a gynophore less than 1 mm long. Pistillate inflorescence on leafless stems or rarely terminal, umbelliform, sericeous; primary peduncle 1.2–1.7 cm long; rachis 2 mm long; secondary peduncle 1–1.5 mm long. Pistillate flowers not seen. Immature drupe ovoid, 6–7 mm long, the style and base of the hypanthium persistent, the pedicel to 5 mm long.

Additional specimen examined. ECUADOR. LOS RIOS: El Centinela, Montas de 11a road from Patricio Pilar to 24 de Mayo, 2 Oct. 1979, *Dodson, Gentry & Schupp 8694* (F, MO, SEL).

Daphnopsis grandis is known only from the type locality in northern Los Rios Province, Ecuador. It is easily distinguished from all other species of *Daphnopsis* by its obovate leaves 45–65 cm long, cauliflorous inflorescences, and long, tubular-funnelform hypanthia. It is also unusual to find the upper whorl of stamens with filaments while the lower whorl is sessile. The species is so distinctive that it is difficult to establish its affinities. The cauliflorous inflorescences, free disk, and appar-

ANN. MISSOURI BOT. GARD. 75: 728–729. 1988.

ent lack of true dichotomous branching place the species in subgenus *Neivira* (Griseb.) Nevling (1959). It appears to be most closely related to *D. gemmiflora* (Miers) Domke from Brazil but differs by its large leaves, pistillode 2 mm long, and sessile whorl of anthers. *Daphnopsis grandis* can be distinguished from all other known Ecuadorean species by the following key.

KEY TO THE SPECIES OF *DAPHNOPSIS* IN ECUADOR

1a. Young growth tomentose to sericeous; disk annular; shrubby tree growing above 2,400 m .... *D. macrophylla* (Kunth) Gilg
1b. Young growth glabrous or glabrescent; disk cupuliform or coroniform.
  2a. Calyx tube more than 7 mm long; trees growing below 1,500 m.
    3a. Leaves over 40 cm long, over 10 cm wide; inflorescences umbelliform; branching monopodial .... *D. grandis* Nevling & Barringer
    3b. Leaves under 30 cm long, under 10 cm wide; inflorescences racemose, sessile, 3–8-flowered; branching dichotomous .... *D. occulata* Nevling
  2b. Calyx tube under 5 mm long.
    4a. Petioles 4–6 cm long; inflorescence umbelliform; rudimentary petals present; branching dichotomous; small tree growing below 1,500 m .... *D. americana*, subsp. *ecuadorensis* (Domke) Nevling
    4b. Petioles 1–4 cm long; inflorescence racemiform; rudimentary petals absent; branching monopodial.
      5a. Petioles 1–2 mm long; leaves 18–27 cm long; inflorescences 8 cm long; small tree growing below 1,500 m .... *D. zamorensis* Domke
      5b. Petioles 2–4 mm long; leaves 3–8 cm long; inflorescences 1–2 cm long; shrubby tree growing above 2,400 m .... *D. espinosae* Monachino

We thank Dr. Calaway H. Dodson and the curators of F, MO, and SEL for providing material and information. Research was funded in part by the Tieken Fund of the Field Museum.

A NEW SPECIES OF *DIOCLEA* KUNTH (DIOCLEINAE, FABACEAE) FROM THE VENEZUELAN GUAYANA

Study of collections with fruit from the Venezuelan Guayana, particularly those of Steyermark, has resulted in the identification of a new species of *Dioclea*. Prior to the availability of these collections many specimens of this new species were determined incorrectly as *D. macrocarpa* Huber (1909).

Dioclea ruddiae R. H. Maxwell, sp. nov. TYPE: Venezuela. Amazonas: Cerro Huachamacari, Río Cunucunuma. Occasional in slope forest near Camp 2, 1,100 m, 16 Dec. 1950, *Maguire, Cowan & Wurdack 29930* (holotype, US; isotypes, F, K, GH, IAN, MO, NY, P, RB, S, U, US). Isotypes may have been annotated *Dioclea macrocarpa* Huber by me from 1969 to 1980. Figure 1.

Foliola subcoriacea, subconduplicata, elliptica, ad ca. 12.5 × 8 cm, basi rotundata; stipulis non productis, acutis. Flores ca. 1.5 cm longi, calycis lobis 4, supero lobo calycis integro; vexillum valde reflexum, orbiculari; carinis obtusis rostratis; staminibus 10, antheris perfectis; ovario 4-ovulato. Legumina turgida, ad ca. 13 × 4 × 3 cm, indehiscentia, seminibus 1–4; seminibus ellipsoideis; hilo oblongo, ca. 5.5 mm longo.

Lianas, to 30 m tall; stems terete, the younger stems with mostly appressed, ferruginous pubescence, the older bark glabrous, splitting horizontally, the lenticels light brown and conspicuous. *Leaves* trifoliolate, the leaflets subcoriaceous, subconduplicate, the lamina mostly elliptic, the terminal leaflet lamina to ca. 12.5 × 8 cm, the laterals to ca. 11 × 6 cm, the upper surface reticulate, somewhat sulcate, glabrous or glabrescent on the primary veins, the lower surface with light brown pubescence, the apices acute or with drip tips to 2 cm long, the bases rounded, the primary lateral veins in 6–9 pairs; petioles 4–9 cm long, the rachis 5–25 mm long, this and petiole with sparse, mostly ascending pubescence, the pulvinules ca. 7 mm long, densely pubescent; stipules not produced below insertion, acute, 1–3 mm long; stipels caducous or possibly absent. *Inflorescence* axillary, single, 11–35 cm long, ferruginous pubescent, flowering to ca. ⅘ its length; tubercles short-clavate; bracts acute, ca. 2.5 mm long, semipersistent, inserted at the base of the tubercle stalk; bracteoles ovate, ca. 2 × 1.5 mm, persistent; pedicels ca. 5 mm long. *Flowers* with buds straight, the lower calyx lobe upcurved, flowers ca. 1.5 cm long, the calyx tube ca. 7 mm long, ferruginous pubescent, black velutinous inside extending up the lobes, the upper lobe obtuse, entire, ca. 7 × 5 mm, the lateral lobes slightly falcate, ca. 8 × 3 mm, the lower lobe lanceolate, ca. 10 × 4 mm; standard strongly reflexed, orbicular, ca. 9 × 10 mm with a claw ca. 4 mm; wings obliquely oblong, ca. 6 × 7 mm with a claw ca. 5 mm long; keels obliquely oblong, 4–6 mm long with a claw ca. 5 mm long, the upper margin basally auriculate, unlobed, the beak obtuse; stamens 10, pseudomonadelphous, the base of the vexillary filament free ca. 2 mm, sparsely pubescent, the anthers perfect, ca. 1 mm long; pistil straight ca. 10 mm then geniculate, rising distally ca. 6 mm, the ovary ca. 5 mm long, sessile, ca. 4-ovulate, hirsute with mixed canescent, fuscous and ferruginous pubescence, the hairs to 1 mm long, the style hirsute, swollen distally then narrowing to the incurved, somewhat subterminal stigma. *Fruit* turgid, fleshy, oblong, to ca. 13 × 4 × 3 cm, indehiscent, the exocarp with brown pubescence, becom-

ANN. MISSOURI BOT. GARD. 75: 730–732. 1988.

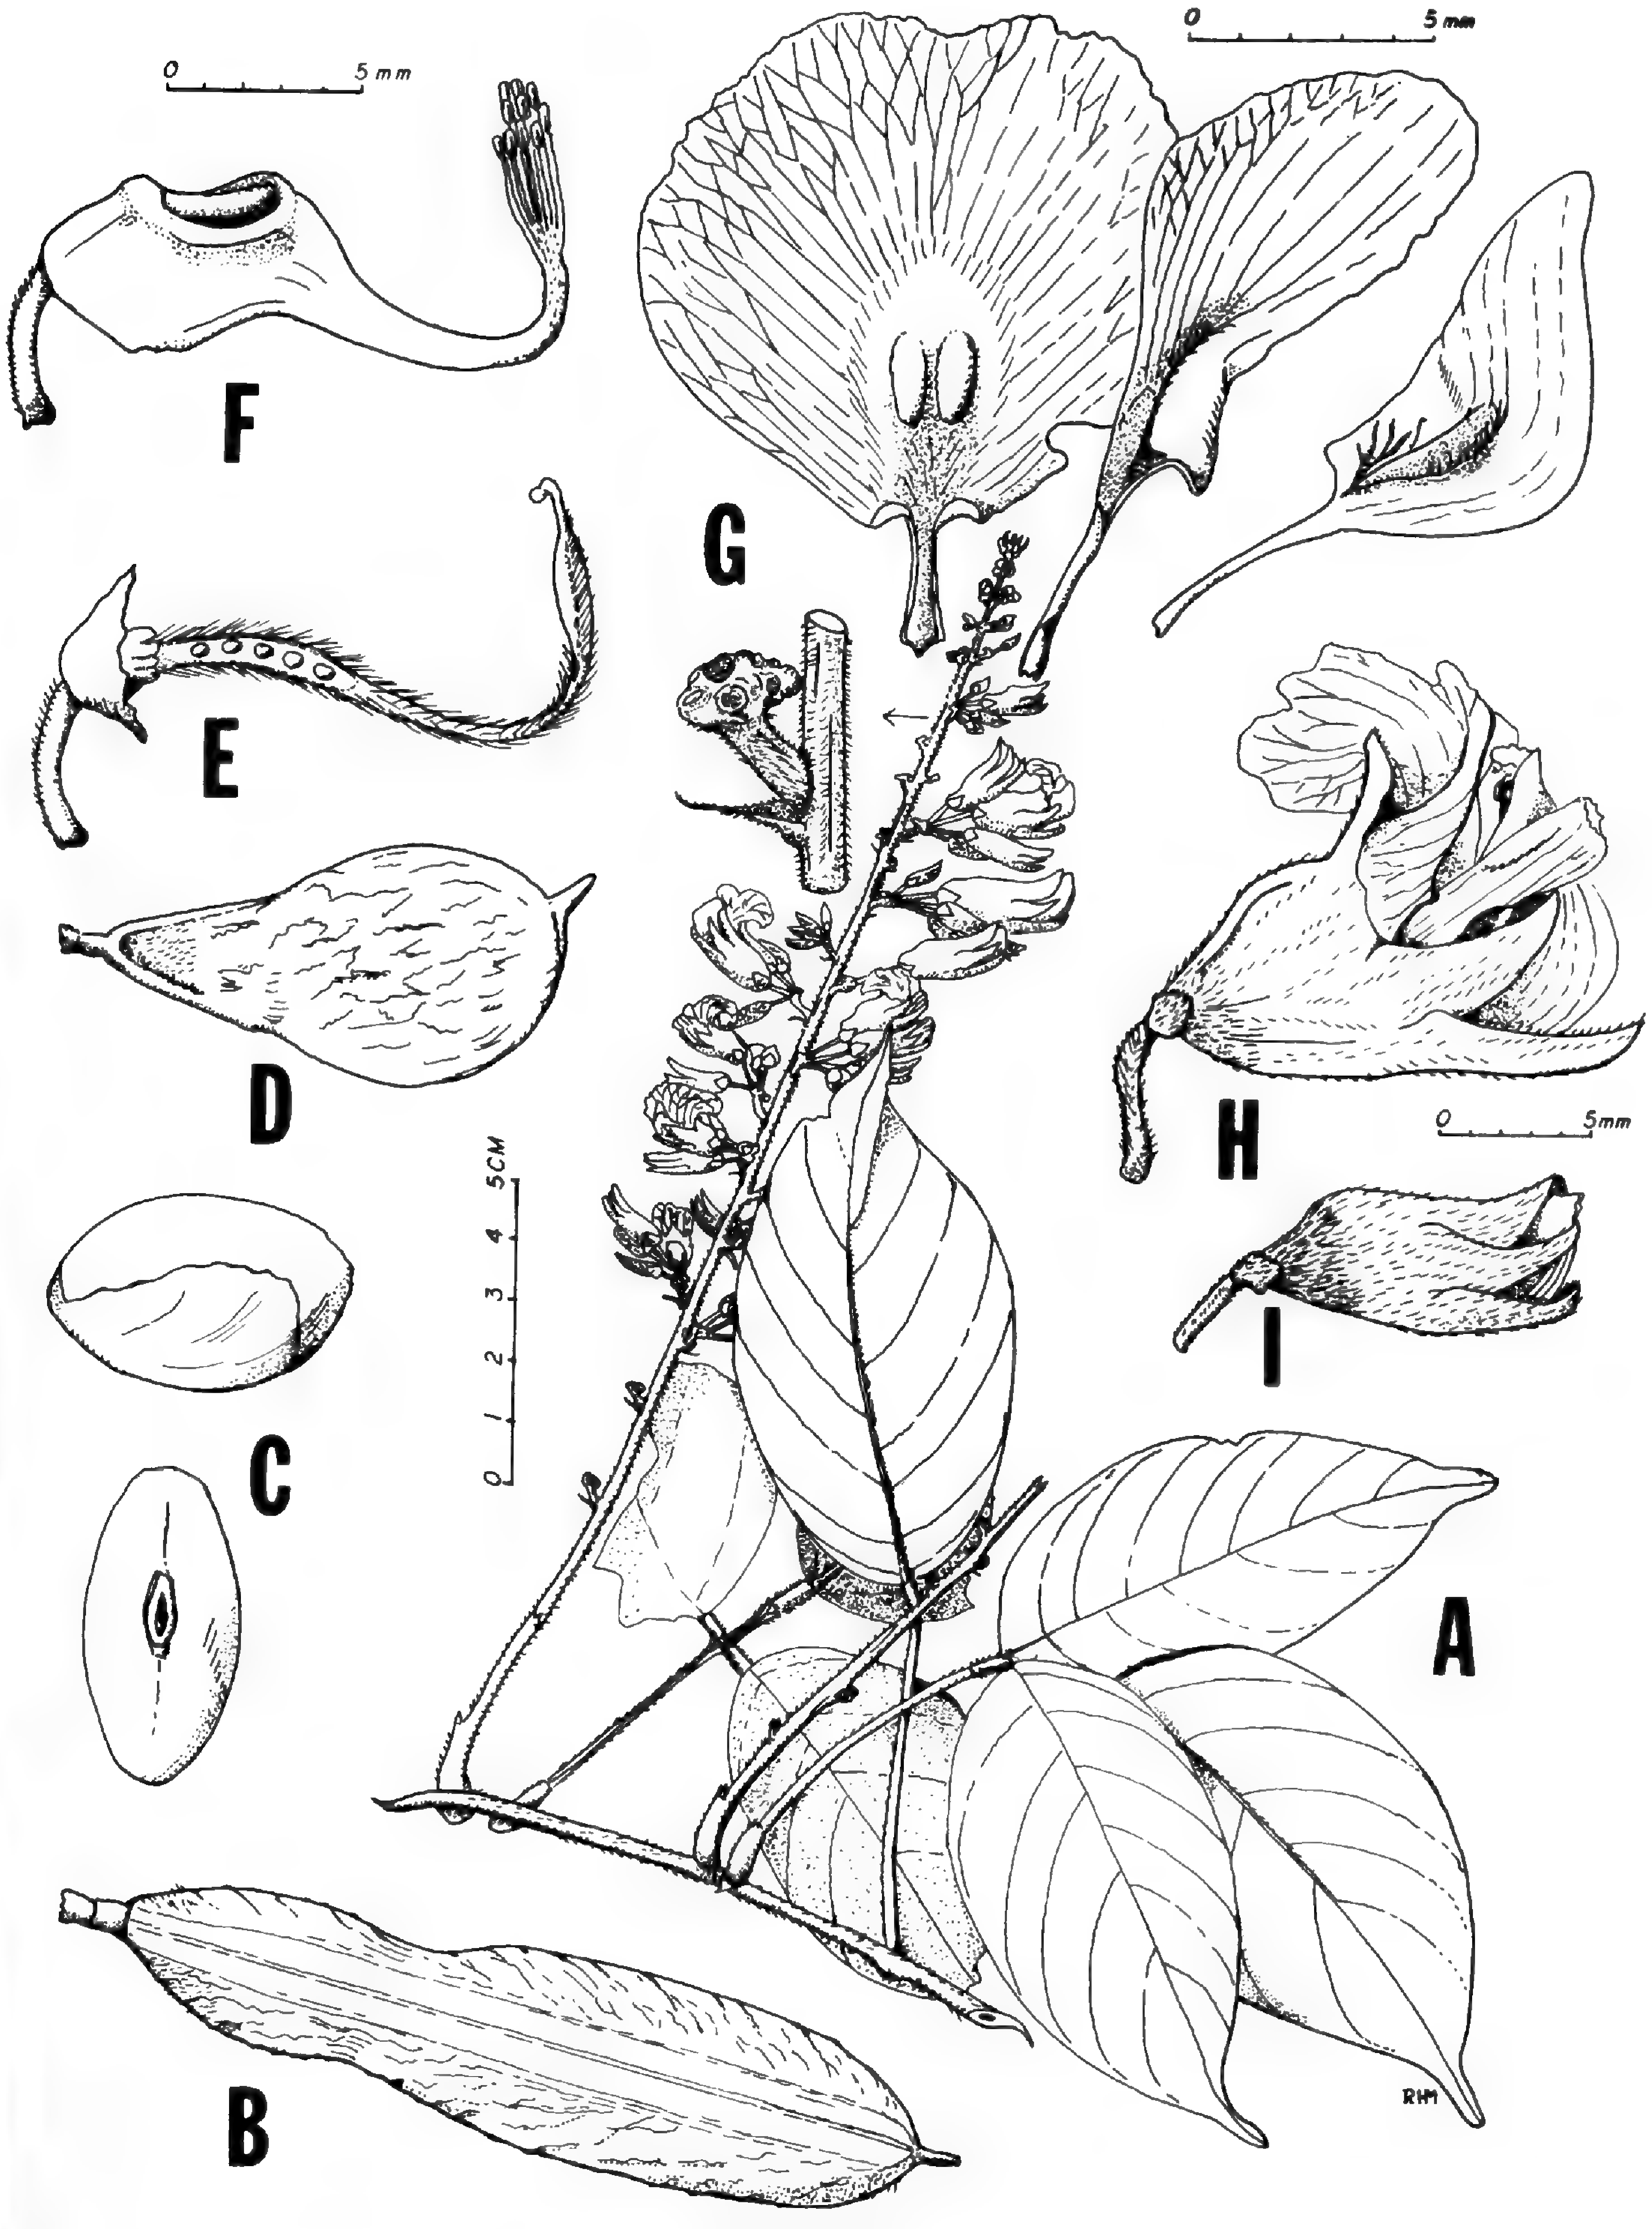

Figure 1. Dioclea ruddiae.—*A. Flowering branch,* Steyermark et al. 92713 *(US).—B. Fruit, 3-seeded, dorsal view,* Steyermark 107174 *(US).—C. Seeds, dorsal and lateral views (with packing attached),* Steyermark 107174 *(NY).—D. Fruit, 1-seeded,* Steyermark 107174 *(NY).—E. Pistil showing ovule position,* Maguire et al. 29930 *(S).—F. Staminal sheath with pseudomonadelphous stamens,* Maguire et al. 29930 *(S).—G. Petals, standard, wing and keel,* Steyermark et al. 92713 *(K).—H. Flower,* Maguire et al. 29930 *(US).—I. Flower bud,* Maguire et al. 29930 *(US).*

ing glabrescent, the upper suture raised, culminating in a persistent, upturned beak, the lower suture indistinct, 1–4-seeded; seeds soft, ellipsoid, to ca. 4.5 × 3.2 × 2.2 cm, the hilum oblong, ca. 5.5 mm long.

Selected specimens examined. VENEZUELA. AMAZONAS: Sierra Parima, a unos 6–7 km al Oeste de la frontera Venezolana-Brasilera, *Steyermark 107174* (NY, US). BOLÍVAR: south of El Dorado, *Gentry et al. 10464* (JEF, MO); Distr. Roscio, sabanas y arbustales en la cumbre del Cerro Chirikayen, *O. Huber & Alarcón 7628* (JEF, MYF); Cerro Venamo (parte Sur-Oeste), Cerca de los Limites con la Guayana Inglesa, *Steyermark et al. 92713* (K, US).

Flowering collections date from January, March, and June in Bolívar, Venezuela. December flowering is reported in Amazonas, with fruit appearing 18 April through 23 May. Collectors report the calyx magenta, the petals lavender or magenta to purple, with the target spot on the standard yellow.

Collectors further report the species occasional to locally frequent from roadsides, savannas, and wooded hills and slopes to upland, humid forest. The altitude range is 795–1,580 m. Habitat may separate *Dioclea ruddiae* from the closely related *D. macrocarpa* Huber, where the habitat is noted as from floodplains and riverbanks in Brazil, Colombia, Ecuador, Guyana, Peru, and Surinam in addition to Venezuela.

The distinguishing characters within *Dioclea* of this new species are the stipules not produced below insertion, 10 perfect anthers, and the oblong seed hilum. These characters place the species in section *Macrocarpon* Amshoff (1939). The turgid, fleshy fruit, however, is distinct within section *Macrocarpon* and the closely related section *Platylobium* Benth. (1859) but similar to several species in section *Pachylobium* Benth. (1839), such as *D. malacocarpa* Ducke and *D. pulchra* Moldenke.

Dioclea macrocarpa differs from *D. ruddiae* by possessing papyraceous leaflets, mostly glabrous or glabrecent beneath; inflorescences frequently in cauliflorous clusters; calyx tube glabrous or canescent puberulent; 4–8 ovules; and fruit flat, ca. 1 cm thick, frequently over 20 cm long, 3–8-seeded, with both sutures raised and with closely parallel ribs, the upper suture culminating in a short downturned beak. Fruit and seed have been illustrated by Ducke (1925).

In contrast, *Dioclea ruddiae* has subcoriaceous, subconduplicate leaflets, pubescent beneath; inflorescences seen are axillary and single; calyx tube with ferruginous pubescence; ca. 4 ovules; and fruit turgid, ca. 3 cm thick, to ca. 13 cm long, 1–4-seeded, with the sutural ribs indistinct, the upper suture culminating in a slender, upturned beak.

It is probable that reexamination of collections determined *Dioclea macrocarpa* from the Venezuelan Guayana will yield additional *D. ruddiae.*

The new species is named in honor of Dr. Velva E. Rudd, a renowned legume specialist and source of encouragement and support for other legume workers. I wish to thank Dr. Julian Steyermark for the opportunity to work on the *Flora of the Venezuelan Guayana* and for commenting on this mansucript. For the opportunity to study *Dioclea* material, I also thank the herbaria directors and curators of MO, NY, and US, in particular, as well as A, F, GH, IAN, MYF, S, and VEN.

A NEW SPECIES OF *ILEX* (AQUIFOLIACEAE) FROM CENTRAL AMERICA

While preparing a treatment of the Aquifoliaceae for *Flora de Nicaragua*, several specimens not referable to any described species of *Ilex* were encountered. The specimens were obviously related to the widespread *Ilex guianensis* (Aublet) O. Kuntze but differed in several key characters of leaf venation and fruit morphology. Further study of the material available in European and American herbaria proved these to represent a new species, described below.

Ilex tectonica Hahn, sp. nov. TYPE: Belize. Toledo, Columbia Forest Reserve, vicinity of forest camp, ca. 6 miles due south of Cabro, in upper Río Grande drainage area, ca. 1,000 ft., high forest, tree, 45 m tall, dbh 70 cm, 5–9 May 1976, *G. R. Proctor 36093* (holotype, MO; isotype, BM). Figure 1.

Ex affinitate *I. guianensis* et *I. belizensis* ab utroque praecipue natura foliorum, laminis chartaceis, marginibus planis, apicibus caudatis, venationibus subtus distincte reticulatis luteisque, etiam fructibus ovoideis, stigmatum vestigiis prominentibus, conice angularibus, elevati supra pericarpia distincta.

Tree to 45 m tall, to over 1 m dbh, laxly branched; trunk reportedly buttressed; bark pale brownish gray on mature stems, with oval lenticels 1 mm long, the new stems drying black or dark brown with white spots; stipules triangular, 2 mm long, 1 mm wide, subtending inflorescences or not. Leaves elliptic, chartaceous, the apex shortly caudate, the base acute, slenderly attenuate, 7–10 cm long, 3.5–4.5 cm wide, the margin usually entire, sometimes minutely spinulose toward the apex, epunctate, venation elevated abaxially, brochidodromous, semicraspedodromous, reticulate, the veins yellow and obvious; petiole thickened, adaxially channeled, 4–8 mm long. Inflorescence of axillary dichasia branched to 2–3 orders, clustered on reduced stems while in flower, later expanding when in fruit, the main rachis and rachillae winged or flattened, the primary rachis 8–13 mm long, the secondary rachillae 3–5 mm long, the tertiary rachillae 1–3 mm long; bracts triangular, paired, 1–1.5 mm long, sometimes deciduous; bracteoles similar but smaller. Flowers (4–) 5-merous, regular, actinomorphic, unisexual; staminate flowers with sepals acute, 1 mm long, sometimes irregular at the apex; petals broadly elliptic, obtuse-rounded at the apex, thinner along the margin, basally united with the filaments, 2–2.5 mm long, 1.5 mm wide; stamens antisepalous; filaments 2–3 mm long; anthers 1 mm long; pistillodium conical, 1 mm long; carpellate flowers not seen. Fruit ovoid, 5–6 mm long, 4 mm diam.; pericarp thin, red at maturity; stigma persistent and conspicuous in profile, conical; mesocarp fleshy but scant; pyrenes crescent-shaped, triangular in cross section; endocarp ligneous, striated abaxially.

Additional specimens examined. HONDURAS. ATLANTIDA: Reserva Forestal de Lancetilla, *Hazlett 2928* (MO, F); Lancetilla Valley near Tela, *Standley 53191, 54736* (A), *55449* (A, F). YORO: SW of La Florida, 8 km by Agua Zarca, *Hazlett 3105* (F, MO). NICARAGUA. CHONTALES: 4 km al NW de Santo Domingo, *Aranda et al. 83* (MO). MATAGALPA: near Peñas Blancas, *Molina s.n.* (F). ZELAYA: Kurinwasito, 50 km SE de Rio Blanco, *Sandino 4845* (MO); ca. 5 km al S de Waslala, *Grijalva & Moreno 1205* (MO).

Common names. San Juan macho, sibuc che, powder stick (Belize), camibar, areno (Nicaragua), San Juan campano, San Juan arenillo (Honduras).

Typically found in tall moist forests, *I. tectonica* is sometimes found with pines in drier mixed forests. Throughout its known range, the species flowers in the dry season of April and May and fruits through July. According

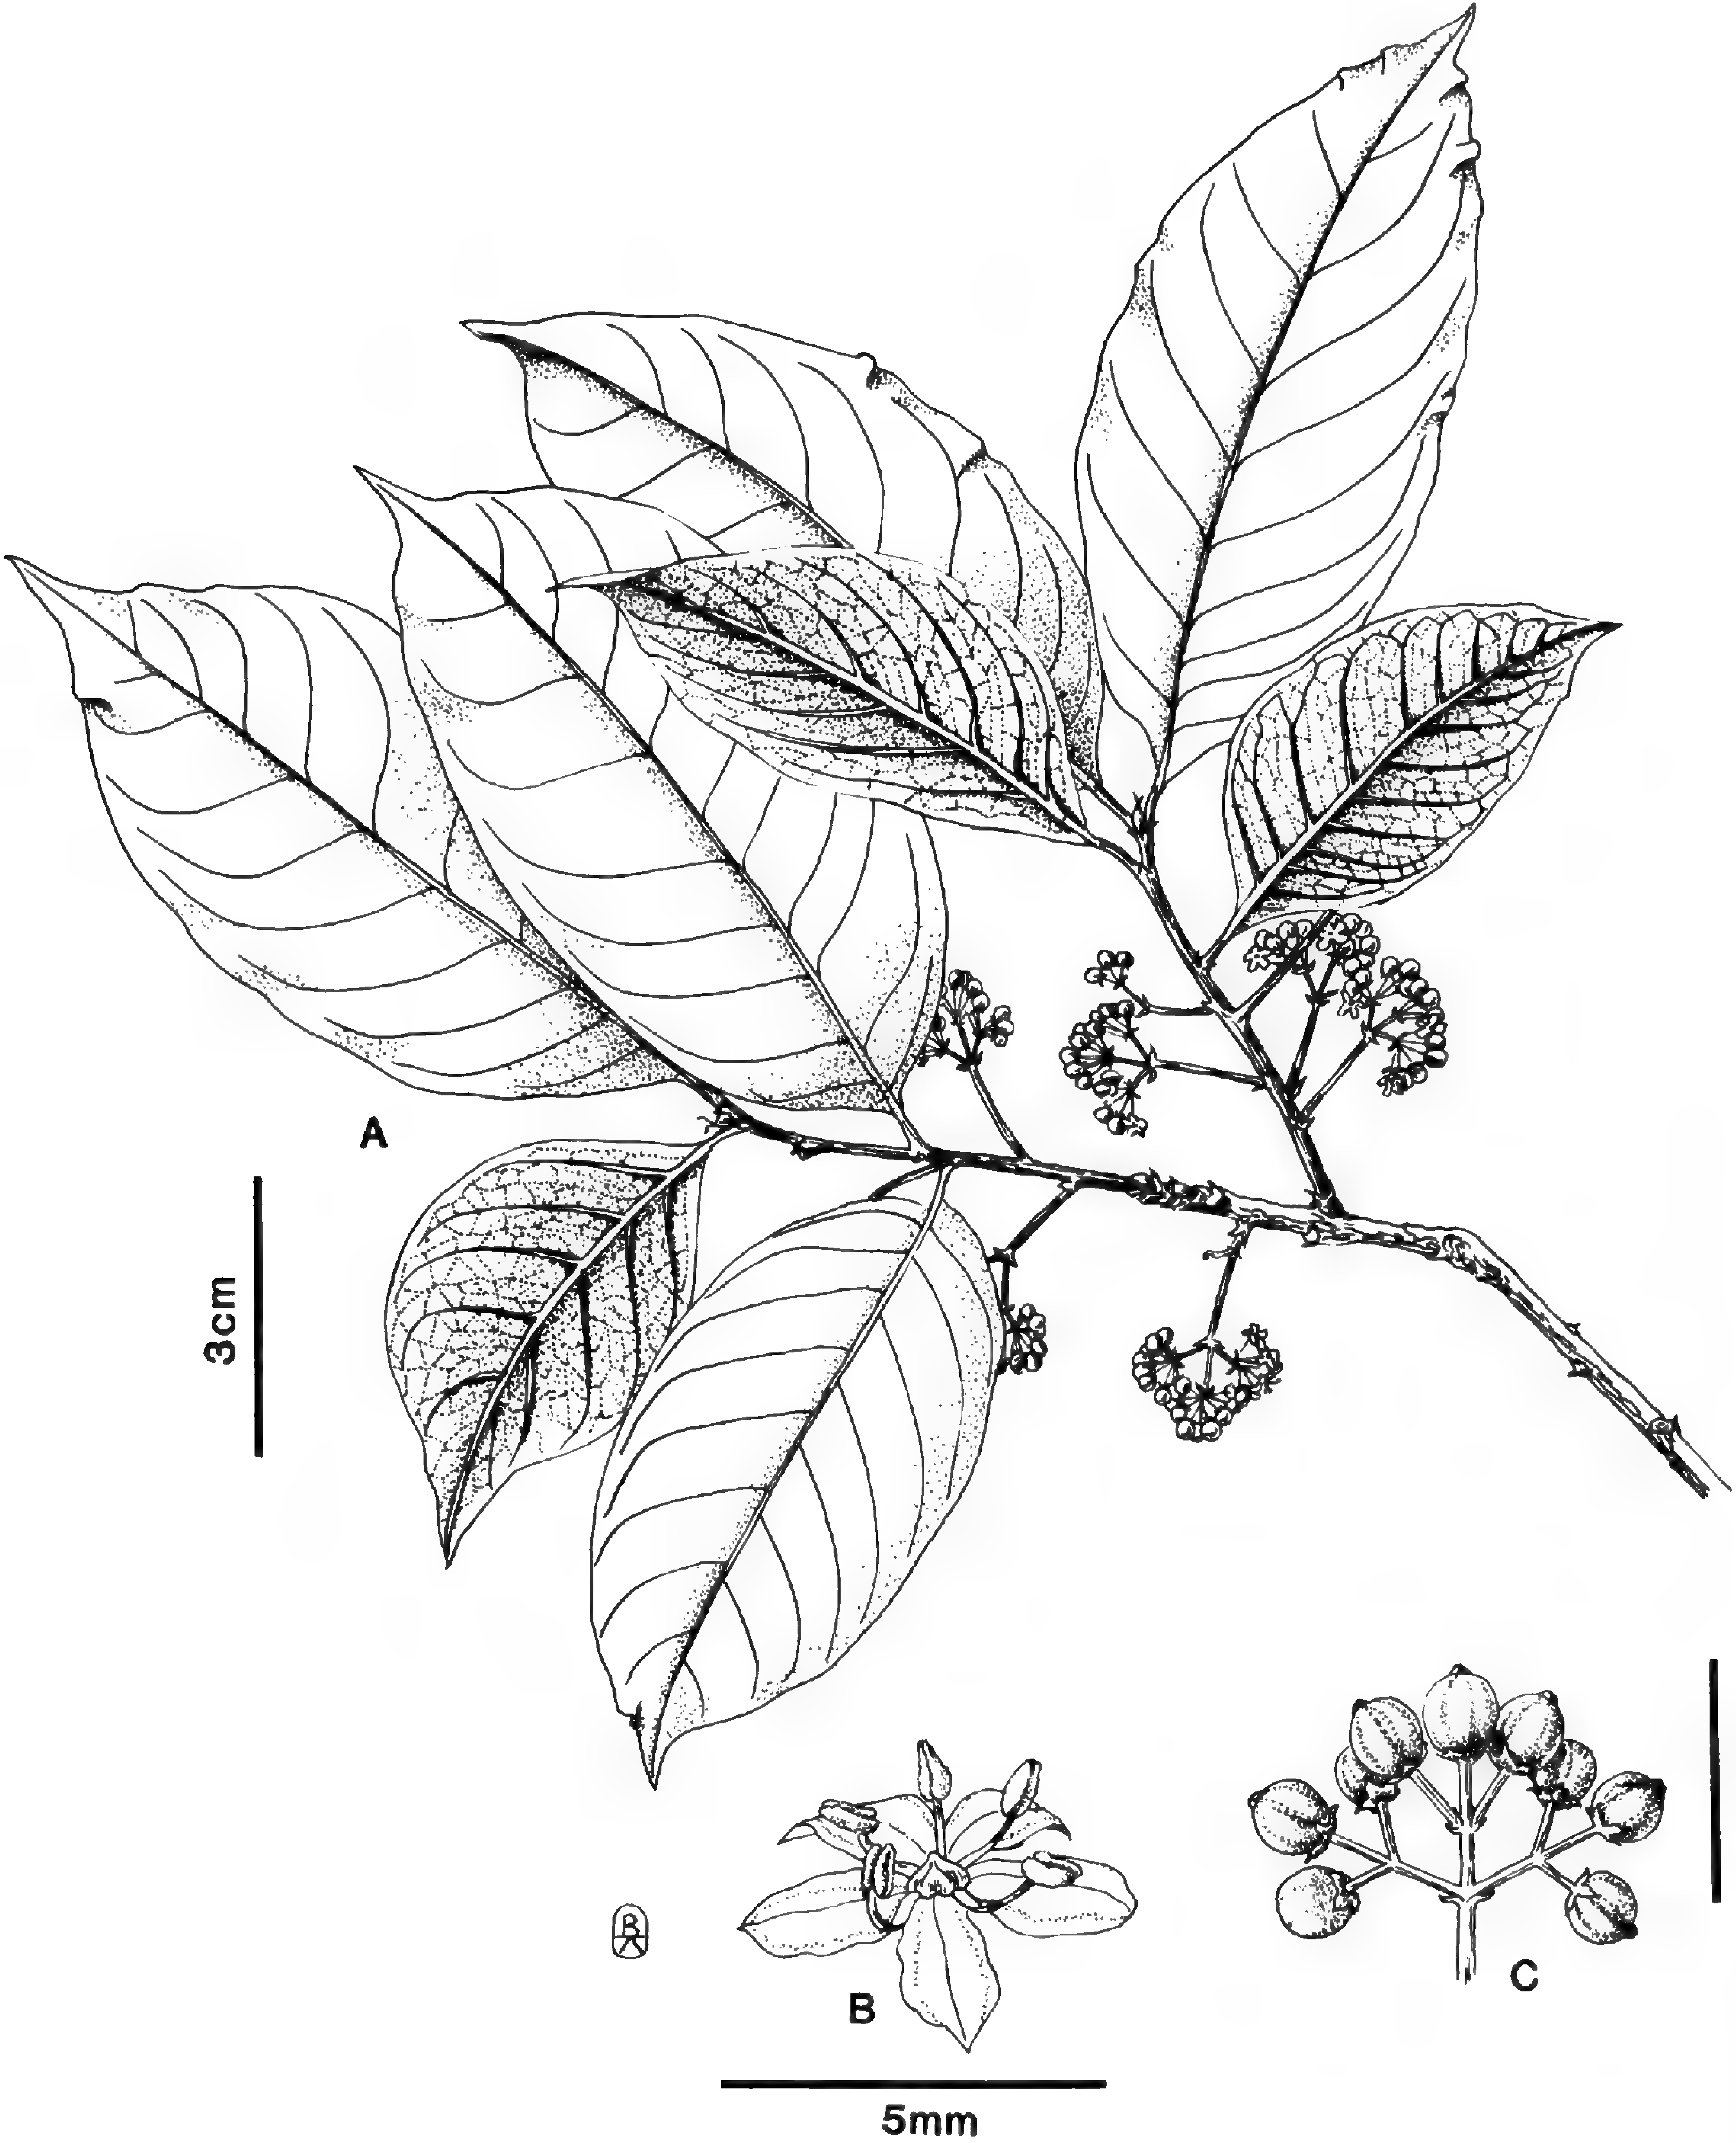

FIGURE 1. Ilex tectonica.—*A. Flowering branch (*Proctor 36093*).—B. Staminate flower (*Proctor 36093*).—C. Infructescence (*Grijalva & Moreno 1205*).*

to label information (*Molina s.n.* and *Hazlett 3105*), it is utilized for timber. In recognition of this, the specific epithet, derived from the Greek *tektonikos* (used for construction), is applied.

Components of the *Ilex guianensis* species complex are found throughout the Caribbean and present some of the most difficult taxonomic problems among neotropical members of the genus. The widespread distribution and relatively homogeneous morphology typical of many coastal strand and scrub species hold true for individuals of this complex growing in such associations. A considerable amount of the confusion, therefore, is due solely to the insular distribution of this group and the synonymy common to pan-Caribbean taxa. However, the ability of the group to invade recently disturbed areas in the highlands of Central America and the Caribbean Islands and apparent hybridization with native upland congeners present additional taxonomic challenges. A key to the Central American members of the *Ilex guianensis* complex is presented below.

1a. Leaves coriaceous, margins usually revolute, apex usually obtuse or retuse, sometimes slightly acute; new stems drying gray or green; coastal scrub, inland savannas, occasionally moist forests and disturbed upland clearings; Atlantic coast of Central America and northern South America, Gulf of Panama, and the Greater Antilles .... *Ilex guianensis*

1b. Leaves chartaceous, margins flat, apex acute; new stems drying black or brown.
    2a. Young stems drying black; secondary leaf venation obscure; fruits spherical; stigmatic residue spreading, not prominent in profile above the pericarp; advanced forest on limestone; Belize .... *Ilex belizensis*
    2b. Young stems drying brown with white lenticels; secondary leaf venation distinct, reticulate, the veins yellow; fruits ovoid; stigmatic residue angular-conical, raised above the pericarp; moist forest or mixed with pines; Belize, Honduras, and Nicaragua .... *Ilex tectonica*

I thank Bente King for providing the illustration, Harold Robinson for suggesting the specific epithet, and John Dwyer for supplying the Latin diagnosis.

NOTES ON *OLDENLANDIA FILICAULIS* AND *OLDENLANDIA TENUIS* (RUBIACEAE)

During an expedition to the northwestern portion of the state of Bolívar, Venezuela, in 1985, collections were made of a slender-stemmed, rubiaceous annual belonging to the genus *Oldenlandia.* An attempt to identify the material led to a study of *O. filicaulis* Schum. and *O. tenuis* Schum. Both species were described originally from the state of Piauhy, northeastern Brazil, at a considerable distance from the Venezuelan locality.

As first described by Schumann (1889), *O. filicaulis* has heterostylous flowers with infundibuliform corollas 4 mm long, whereas *O. tenuis* has homostylous flowers with broader-tubed corollas 2 mm long equaling or slightly exceeding the calyx lobes. Further examination of these taxa showed that the isosyntypes of *O. filicaulis* (*Blanchet 2703, 2742,* and *Martius 2476*) have the stems much more branched with opposite branching and relatively smaller capsules, as contrasted with the rather few, flexuous, alternately branched stems and broader fruiting capsules of *O. tenuis.* Moreover, the isosyntypes of *O. filicaulis* have filiform stems, filiform-acicular leaves 0.1–0.3 mm wide, and minute capsules 1.2–1.5 mm wide, whereas *O. tenuis* has slightly broader stems, leaves up to 1 mm wide, sometimes varying to subspatulate and broadened above the middle, and broader capsules mainly 2 mm wide. The long-exserted anthers of the isosyntypes of *O. filicaulis,* furthermore, are in contrast to the sessile and included ones of *O. tenuis.*

The Venezuelan specimens from northwestern Bolívar state differ from both Brazilian taxa in having a mainly solitary, simple, or slightly branched stem above with more numerous and shorter internodes averaging (6–)8–12 on a stem and 13–17 mm long, instead of, as in the Brazilian taxa, 3–8 to a stem and (12–)15–30 mm long. The leaves and calyx lobes of the Venezuelan plants have the margins more abundantly setulose-aculeate, but this character appears variable in the Brazilian taxa, from entire to varying numbers of aculeae.

Contrary to Schumann's description of the corolla length of 4 mm for *O. filicaulis,* examination of isosyntype and other material of this species showed corolla length variation usually to be 2–2.5 mm. A specimen of *Ule 7419* (F) from Bahia showed the longest length of 2.5–3 mm. In general, the corolla of *O. filicaulis* has a narrower, more elongated infundibuliform corolla tube than *O. tenuis.*

When compared with the corollas of the Brazilian taxa, the Venezuelan plant agrees with the type of corolla exhibited by *O. tenuis,* showing a broad tubular, short corolla 1.8–2 mm long, which is only slightly longer than the calyx, with sessile anthers included at the summit of the corolla tube. Additionally, the Venezuelan specimens also have the alternate branching of the stem characteristic of *O. tenuis.* A specimen collected by *Otto Huber et al. 1399* (VEN) from Territorio Federal Amazonas, Venezuela, has the short broad corolla and sessile, included anthers of *O. tenuis,* but the slender stem with opposite branches, few internodes, and minute capsules, sharing the characters common to *O. filicaulis.*

If one relies on the characters of few-branched stems with alternate branching, sessile included anthers, and capsules ca. 2 mm wide, then most of the specimens of this *Oldenlandia* complex would fall into *O. tenuis.* Such specimens are known from the Brazilian states of Ceará, Piauhy, Parahyba, Rio Bran-

co, and Terr. do Roraima, from Guyana, and from northwestern Venezuela, if we include the collections obtained in the latter area. *Oldenlandia filicaulis*, on the other hand, appears to be rarer and occurs in the Brazilian states of Piauhy, Bahia, and Pará and in Venezuela from Territorio Federal Amazonas. Both taxa were collected from the Brazilian state of Piauhy.

Although it is possible that only one variable species is represented among the specimens studied, the two taxa may be considered as separate and distinct until more intensive investigation has been completed.

KEY TO THE SPECIES

1a. Corolla slightly longer than the calyx, 1.8–2 mm long, broadly cylindric; anthers included, sessile; branching of stem alternate, irregular, with relatively few axes; capsule 1.5–2 mm wide; leaves 0.5–0.7(–1) mm wide, linear-subulate to subspatulate, sometimes broader near the middle; stem 0.5–0.7 mm thick .... *O. tenuis*

1b. Corolla ca. 2½ times longer than the calyx, 2–3 mm long, infundibuliform; anthers long exserted; branching of stem opposite, with numerous axes; capsule 1.2–1.5 mm wide; leaves 0.1–0.3 mm wide, linear-acicular, uniform in width; stem 0.3–0.5 mm thick .... *O. filicaulis*

THE GENERA OF EUPATORIEAE (ASTERACEAE)

R. M. King & H. Robinson
Smithsonian Institution

Starting in 1966 the authors have provided a series of partial revisions of the Eupatorieae, publishing over 200 papers on the group. *The Genera* provides a synthesis of their contributions to our understanding of this species-rich group: one in every 150 species of flowering plants belongs to the Eupatorieae.

This new work treats all 180 genera of the tribe with a description, full-page illustration, discussion, and listing of recognized species and their distributions. Keys to all the subtribes and genera and regional keys for portions of tropical America are included. A nomenclator of the over 6,000 specific and infraspecific names that have been placed in the tribe at one time or another indicates their present disposition.

REPRODUCTIVE BIOLOGY OF FRESHWATER AQUATIC ANGIOSPERMS: AN INTRODUCTION

Aquatic flowering plants have long held a special appeal for plant biologists. Many features of aquatics, such as convergent reduction of vascular systems and reproductive structures, vegetative polymorphism, widespread asexual propagation, and unusual pollination systems, contribute to some of the most perplexing phylogenetic, evolutionary, and taxonomic problems in angiosperm systematics. The study of the mode of operation and diversity of reproductive systems is fundamental to understanding the evolution of taxa, but unfortunately these systems continue to be less well known in aquatics than in terrestrial groups. In the now classic book, *The Biology of Aquatic Vascular Plants* (1967; Edward Arnold Publishers, Ltd., London), Sculthorpe reviewed the literature on reproductive systems of aquatic angiosperms. There have been significant contributions to our understanding during the 20 years since Sculthorpe's book; the purpose of this series of papers is to present some of these contributions.

Invasion of the aquatic habitat has occurred numerous times throughout angiosperm evolution. A diverse array of monocot and dicot taxa are "aquatic," although the precise definition of the term can be debated. Differences of opinion notwithstanding, approximately 18 monocot and 10 dicot families comprise principally aquatic members. In addition, there are numerous examples of aquatic genera in largely terrestrial families (e.g., *Pistia, Orontium, Peltandra,* Araceae; *Armoracia, Cardamine,* Cruciferae; *Megalodonta,* Asteraceae) and aquatic species in otherwise terrestrial genera (e.g., various species of *Polygonum,* Polygonaceae). The greatest diversity of aquatic angiosperms is found in freshwater environments: 104 genera (ca. 90%) in the principally aquatic families occur in freshwater, whereas only 12 genera are marine. The high frequency of freshwater aquatics could well reflect the comparative ease of adapting to freshwater versus marine conditions.

"It is in their reproductive phase that vascular hydrophytes betray their terrestrial ancestry most clearly." This statement by Sculthorpe (1967) illustrates an obvious aspect of aquatic angiosperms: the vast majority produce aerial flowers and share general features of pollination with their terrestrial counterparts. The evolutionary or perhaps phylogenetic constraint to retain aerial flowers is especially well illustrated in *Utricularia* (Lentibulariaceae), where aerial flowers are produced even though the rest of the plant is submerged and highly modified for life under water.

There can be little question that the aquatic environment imposes a strong and unique set of physical and biotic constraints on its inhabitants. For instance, the high specific heat of water, manifested in slow vernal warming and autumnal cooling, undoubtedly influences flowering patterns as well as the spectrum and availability of pollen vec-

tors. Thus, it is not unreasonable to expect reproductive patterns or "strategies" in aquatics that are different from those of terrestrial plants. These expectations are best realized in taxa that exhibit hydrophilous pollination systems. In hydrophily, a suite of characters has evolved that allow for the aquatic medium itself to play an intimate role in pollen transfer; these reflect strong evolutionary concessions to life in the aquatic milieu. This plethora of specialized features makes phylogenetic and evolutionary interpretations of hydrophilous taxa difficult because affinities with any presumably ancestral, aerial pollination systems are obscured. Few such reproductive patterns have been deciphered in aerial-flowered aquatics, where much of our understanding derives from the general similarity with terrestrial relatives. The role that flower production in close proximity to the water has played in molding reproductive systems is seldom addressed; we possess limited insight into reproductive features of aerial flowers that are consequential to an aquatic existence.

This series of papers covers a range of topics concerning reproductive systems in aquatic angiosperms. Barrett and Ornduff consider evolutionary aspects of heterostyly in *Eichornia* (Pontederiaceae) and *Villarsia* (Menyanthaceae), respectively. The importance of anemophily is addressed in two contributions: Cook presents an overview of anemophilous aquatic taxa, and Osborn & Schneider discuss the evolution of anemophily from entomophilous systems in *Brasenia* (Nymphaeaceae). Wiersema surveys the diversity of reproductive strategies in *Nymphaea* (Nymphaeaceae), and Haynes addresses the importance of reproductive systems and how they pertain to the problem of aquatic weeds. Papers by Cox & Knox, Les, and Philbrick present various aspects of the evolution and diversity of hydrophilous breeding systems. Cox & Knox present evidence for the importance of two-dimensional pollination in *Amphibolis antarctica* (Potamogetonaceae) and *Ruppia polycarpa* (Ruppiaceae). Possible relationships between hydrophily, genetic variability, and evolution are addressed by Les, and in the last contribution, Philbrick proposes a hypothesis for the evolution of underwater outcrossing from aerial pollination systems.

These papers were presented at the annual meeting of The Botanical Society of America and The American Society of Plant Taxonomists, The Ohio State University, Columbus, Ohio, August 1987. The contents of the published papers may be modified from the oral presentations. Financial support for the symposium was provided in part by The Botanical Society of America.

EVOLUTION OF BREEDING SYSTEMS IN *EICHHORNIA* (PONTEDERIACEAE): A REVIEW[1]

Spencer C. H. Barrett[2]

ABSTRACT

Eichhornia *is of New World origin and comprises eight species of freshwater aquatics in the monocotyledonous family Pontederiaceae.* Eichhornia *flowers display a broad range of morphological specializations associated with their pollination mechanisms and breeding systems. These range from large-flowered, outcrossing, tristylous populations to small-flowered, predominantly self-fertilizing, semi-homostylous populations. Two sources of evidence indicate that the major pathway of breeding system evolution in the genus involves the repeated breakdown of tristyly to give rise to selfing semi-homostylous populations: the occurrence of semi-homostylous forms in each of the primarily tristylous species (*E. azurea, E. crassipes, E. paniculata*) and the presence of residual heteromorphisms, associated with the tristylous syndrome, in the largely autogamous semihomostylous species (*E. diversifolia, E. heterosperma, E. paradoxa*). It is suggested that genetic bottlenecks associated with long-distance dispersal and colonization of aquatic habitats with uncertain moisture regimes play major roles in disrupting the maintenance of tristyly. This leads to the breakdown of the polymorphism and the evolution of semi-homostyly.*

Eichhornia (Pontederiaceae) is a small genus comprised of eight species of freshwater aquatics and palustrial herbs. All species, with the exception of the exclusively African *E. natans*, are native to the New World tropics. *Eichhornia azurea* and *E. paniculata* are used as pond ornamentals, and *E. crassipes* (water hyacinth) has spread, with man's aid, from lowland tropical South America to become one of the world's most noxious aquatic weeds.

The flowers of *Eichhornia* are usually mauve-blue and showy, and are pollinated primarily by bees and butterflies. They display a broad range of morphological specializations associated with their pollination mechanisms and breeding systems. The variation ranges from large multicolored tristylous flowers adapted to outcrossing to small uniformly colored self-fertilizing homostylous flowers. This diversity provides suitable experimental material for studies of breeding system evolution. The present review summarizes work on this topic with special attention to the evolutionary breakdown of tristyly and the responsible ecological and genetic factors.

Heterostyly is a genetically controlled floral polymorphism in which plant populations contain two (distyly) or three (tristyly) morphs that differ primarily in style and stamen length, pollen size, and incompatibility behavior. The polymorphism promotes disassortative mating between the floral morphs and is reliably reported from 24 angiosperm families of which just three (Lythraceae, Oxalidaceae, Pontederiaceae) contain tristylous members (Ganders, 1979). A common feature of heterostylous breeding systems is their propensity to become evolutionarily modified in the direction of increased self-fertilization. The main pathway is by the formation of self-compatible homostyles. Plants in these groups possess anthers and stigmas at the same level within a flower and, as a result, are largely autogamous. In tristylous species homostyles often have only one of their two anther sets adjacent to the stigma and as a result are referred to as semi-homostylous (Stout, 1925; Ornduff, 1972). The breakdown of heterostyly to homostyly represents a paradigm for studies of the evolution of self-fertilization in plants, because the direction of change is readily interpretable, genetic modifications are often simply inherited, and alterations in the floral polymorphisms that influence mating behavior can usually be detected without difficulty under field conditions (Barrett, 1988a).

We have investigated the pathways and mechanisms of breeding system evolution in *Eichhornia*

by adopting the comparative approach employed by many plant systematists and evolutionists (e.g., Stebbins, 1957; Baker, 1966; Grant & Grant, 1965; Lloyd, 1965; Moore & Lewis, 1965; Raven, 1979). Here the working hypothesis is that among closely related taxa of outcrossers and selfers the former condition is usually ancestral and the latter derived. Stebbins (1974) has argued that this pathway has been followed by more lines of evolution in the flowering plants than has any other.

To test this hypothesis in *Eichhornia* two types of evidence were sought. Population studies of outcrossing taxa were conducted to establish whether, under present conditions, the shift from outcrossing to selfing is occurring. Of primary importance in these studies is to determine whether genetically based differences in mating patterns occur both within and between populations of the tristylous taxa. A second line of enquiry has involved interspecific studies of the floral biology of selfing taxa to discover whether residual tristylic traits are evident (see Crowe, 1964). Their occurrence can be taken as evidence of descent from tristylous ancestors, unless we are prepared to accept that tristyly is in *statu nascendi* within different selfing lineages of the genus. Given the rarity of the polymorphism in the angiosperms as a whole, this evolutionary scenario seems unlikely (see Eckenwalder & Barrett, 1986).

This review summarizes evidence in favor of the derived nature of selfing taxa and evaluates several hypotheses concerned with the selective mechanisms responsible for the breakdown of tristyly. Before this is done, however, a brief summary of the systematic and ecological characteristics of the genus is required.

SYSTEMATICS AND ECOLOGY

Taxonomy. Most floristic works and regional floras follow Solms-Laubach (1883) and Schwartz (1927, 1930) in their treatments of *Eichhornia* (e.g., Alexander, 1937; Schulz, 1942; Castellanos, 1958; Agostini, 1974; Rosatti, 1987). Schwartz recognized two sections in the genus, the primitive *Protoeichhornia* composed of *E. paniculata* and *E. paradoxa*, and the more advanced *Eichhornia* ("*Eueichhornia*") containing *E. azurea*, *E. crassipes*, *E. natans*, and *E. diversifolia*. More recently, two frequently overlooked species, *E. heterosperma* and *E. meyeri*, have come to be recognized. *Eichhornia heterosperma*, first described in 1939 from Venezuela by Alexander (Smith, 1939) and very similar in vegetative traits to *E. azurea*, is widely distributed in Central and South America and is misidentified in most collections (Horn, 1987). Similarly, *E. meyeri* has most often been treated as a synonym of *E. paniculata*, which it resembles closely. It is known from a few localities in Paraguay and from the type locality in the Chaco of Argentina (Schulz, 1942).

Phylogeny. A recent cladistic analysis of the Pontederiaceae by Eckenwalder & Barrett (1986) is of interest because most cladograms produced were in conflict with Schwartz's sectional treatment of *Eichhornia* and the genus was paraphyletic under most methods of cladogram construction. Of particular relevance to breeding system evolution was the placement of tristylous and homostylous taxa. Two contrasting patterns emerged from the analyses, neither of which is supported by microevolutionary studies presented below. Most cladograms separated homostylous species of *Eichhornia* as a clade not closely associated with tristylous *Eichhornia* and *Pontederia* but allied instead to *Heteranthera*. This seems unacceptable because of the clear relationships among species such as *E. azurea* (tristylous) and *E. heterosperma* (homostylous), and *E. paniculata* (tristylous) and *E. meyeri* (homostylous). A second pattern derived homostylous taxa from tristylous ancestors, but in this case all homostylous taxa were united as a monophyletic group implying a single origin for homostyly. However, evidence presented below indicates that tristyly has broken down repeatedly within *Eichhornia*, implying multiple origins for homostyly in the genus. These disparities probably result from the choice of characters used in cladogram construction. The parallel evolution of the selfing syndrome in different homostylous taxa may provide enough characters to unite species during tree construction. This difficulty has been recently discussed at length by Wyatt (1988) in his review of phylogenetic aspects of the evolution of self-pollination.

Genetic systems. Breeding systems and chromosome numbers of *Eichhornia* species are given in Table 1. Three of the eight species are primarily tristylous, and the remaining five are semi-homostylous. However, because of considerable intraspecific variation in floral traits, it is important to note that these terms refer to the most common condition within each species. In *Eichhornia* polyploidy and aneuploidy are derived from an original base number of $x = 8$. Unlike other heterostylous groups (e.g., *Turnera ulmifolia* L., Barrett & Shore, 1987), there is no evidence of an association between breeding system and ploidal level. Tristyly and semi-homostyly occur at the diploid and tetraploid level.

TABLE 1. *Genetic systems, life forms, and distributions of* Eichhornia *species. Breeding systems indicated are the most common condition within each species.*

Taxon	Major Breeding System	Chromosome Number (n)	Life Form	Clonal Propagation	Native Distribution
E. azurea (Swartz) Kunth	tristylous	16	floating-leaved aquatic, long-lived perennial	++	widespread, Neotropics
E. crassipes (Mart.) Solms-Laub.	tristylous	16	free-floating aquatic, long-lived perennial	+++	widespread, lowland South America
E. paniculata (Spreng.) Solms-Laub.	tristylous	8	emergent aquatic, short-lived perennial or annual	−	locally abundant, northeast Brazil, Cuba, Jamaica, Nicaragua, Ecuador
E. heterosperma Alex.	semi-homostylous	15	floating-leaved aquatic, perennial	++	widespread, Neotropics
E. diversifolia (Vahl) Urb.	semi-homostylous	15	floating-leaved aquatic, perennial or annual	+	widespread, Neotropics
E. natans (Beauv.) Solms-Laub.	semi-homostylous?	—	floating-leaved aquatic, perennial or annual	+	widespread, Africa
E. paradoxa (Mart.) Solms-Laub.	semi-homostylous	8	emergent aquatic, annual	−	rare, Guatemala, Venezuela, Brazil
E. meyeri Schulz	semi-homostylous?	8	emergent aquatic, annual	−	rare, Paraguay, Argentina

Distribution. The three diploids of *Eichhornia* have narrower distributions than the tetraploids (Table 1) have. In particular, *E. paradoxa* and *E. meyeri* are rare with relatively few known localities. The distribution patterns of the three diploids support Schwartz's (1927) view that the species are phylogenetically old and that their current distributions may represent relict areas of previously wider ranges. The remaining New World *Eichhornia* species all have widespread distributions throughout lowland South America, Central America, and parts of the Caribbean. Unlike the diploids, which are annual or short-lived perennial emergent aquatics with no clonal propagation, all tetraploids exhibit extensive lateral growth either through a branching internode system or by stolons. Fragmentation facilitates clonal regeneration, and all tetraploid species, particularly *E. crassipes*, are capable of prolific vegetative spread. The ability to disperse by seeds and floating vegetative fragments may contribute to the wider distributions of tetraploid than diploid taxa.

The Pontederiaceae are of New World origin with all but one species of *Eichhornia* native to the Neotropics. The African *Eichhornia natans* is likely descended from New World ancestors following long-distance dispersal. Its homostylous breeding system would favor establishment and subsequent spread in Africa following long-distance dispersal from the New World. The most likely progenitor of *E. natans* is *E. diversifolia*, which is very similar in appearance and has been considered conspecific by some taxonomists. The small seeds of *Eichhornia* species and their occurrence in habitats frequented by migratory water birds provide opportunities for long-distance dispersal. This may account for the disjunct and scattered distributions of many of the species.

Ecology and life history. There have been no detailed ecological studies of the life history, demography, or habitat preferences of *Eichhornia* species in their native ranges. The following field observations, while rudimentary, may stimulate more in-depth work as well as providing the necessary ecological background from which to discuss the reproductive biology and evolution of breeding systems in the genus.

Eichhornia species are exclusively freshwater aquatics. They occupy a diversity of wetland habitats ranging from large water bodies, such as major river systems, lakes, and reservoirs, to extensive marshlands, seasonal pools, and low-lying pastures. Several species are also capable of colonizing sites disturbed by man, such as rice fields, irrigation canals, and drainage ditches. It is not uncommon to find two or three species of *Eichhornia* at the same site. Significant features of aquatic habitats that determine the presence of individual taxa appear to be permanency of the habitat, water level fluctuations, and overall water depth. These factors not only influence the type of regeneration strategy employed by *Eichhornia* species, but also the composition of the aquatic community and hence the degree of interspecific competition.

Eichhornia azurea is a large, long-lived, mat-forming perennial which most commonly occurs in permanent water bodies such as rivers, lakes, and extensive marshlands. The long duration of its pre-reproductive phase restricts the species from colonizing habitats subject to seasonal desiccation. The mat-forming *Eichhornia crassipes* possesses a similar ecology, although it is capable of reaching reproductive maturity more rapidly (Barrett, 1980a) and is often found in more seasonal environments. Unlike *E. azurea*, which is a rooted, floating-leaved aquatic, the free-floating *E. crassipes* is able to colonize environments that experience large fluctuations in water level (Barrett, 1977a, 1979). *Eichhornia heterosperma* commonly occurs in shallow lakes and ponds. Its abundance in the highly seasonal environments of the Llanos of Venezuela and in the caatinga of northeast Brazil indicates that it is capable of withstanding habitat desiccation, presumably as rhizomes or seed. *Eichhornia paniculata* occurs in seasonal pools, rice fields, and low-lying pastures. In comparison with the preceding species, it is capable of colonizing more terrestrial environments that experience only limited periods of inundation. The life history of *E. paniculata* depends largely on available moisture. When available for extended periods, plants perennate; however, at many locations in northeast Brazil and in Jamaica, populations are annual and regenerate from seed (Barrett, 1985a). An annual life history is also implicated for *E. meyeri* in the seasonal environment of the Chaco of Argentina (Schulz, 1942).

Owing to the rarity of *E. paradoxa*, little is known of its ecology. I have observed two populations in northeast Brazil. At one site in Paraiba state the species was growing in a roadside depression with *E. paniculata*; at the other location it occupied a low-lying floodplain of the São Francisco River. These observations suggest that the species prefers seasonally inundated sites.

Eichhornia diversifolia is most commonly found in seasonal ponds that experience large water-level fluctuations. During the vegetative growth period it is often in water 1–2 m deep, and as the water level drops, plants flower and mature seed. The species usually behaves as an annual and may require water-level fluctuations for successful seed germination and establishment. *Eichhornia diversifolia* colonizes rice fields and can be considered a fugitive species adapted to temporary aquatic environments. Habitat descriptions on herbarium specimens and flora accounts of *E. natans* in Africa suggest a similar ecology. The species is reported as a rice field weed in Nigeria (Vaillant, 1967).

Reproductive biology. The contrasting breeding systems and life histories of *Eichhornia* species are associated with diverse reproductive attributes (Table 2). In general, the outcrossing species possess large showy flowers, inflorescences with many flowers, high pollen–ovule ratios, and heavier seeds in comparison with selfing species. It is important to emphasize that each *Eichhornia* species shows considerable variation in reproductive traits. The values presented in Table 2 are from a single population of each species and were chosen to illustrate overall trends in reproductive traits among species. With the exception of data presented for *E. meyeri*, all values are based on field-grown plants. Exceptions to the trends discussed above are apparent, however, such as in *E. paniculata*, where individual flowers are similar in size to several of the selfing taxa. Inflorescences of this species contain many more flowers (up to 300) than other *Eichhornia* species so that the overall floral display of plants is by no means diminished because of their smaller flowers. Figure 1 illustrates the dramatic difference in floral display of tristylous *E. crassipes* and semi-homostylous *E. paradoxa*.

TRISTYLY IN THE PONTEDERIACEAE

The tristylous syndrome. To understand the evolutionary modifications of tristyly in the Pontederiaceae it is necessary to describe the morphological, physiological, and functional aspects of trimorphic incompatibility. Populations of tristylous plants are composed of three floral morphs known as the long-, mid-, and short-styled morphs (hereafter referred to as L, M, S). Each plant possesses flowers with two anther levels that correspond to the stigma levels in the remaining two morphs. Thus, as illustrated in Figure 2, there is a reciprocal positioning of anthers and stigmas in the three floral morphs. Pollinations between anthers and stigmas of equivalent height result in seed set and are termed "legitimate" following Darwin (1877). The remaining pollinations are referred to as "illegitimate" and result in little or no seed set.

A unique feature of tristylous plants is the pro-

duction, by the two anther levels within a flower, of distinct pollen phenotypes that differ in their size and incompatibility behavior. Associated with pollen heteromorphism are differences in the amount of pollen produced by the three stamen levels. Long-level anthers produce small numbers of large-sized pollen grains; mid-level anthers produce intermediate amounts of mid-sized pollen grains; and short-sized anthers produce large numbers of small-sized pollen grains. Several other floral polymorphisms often accompany the stamen–style trimorphism (e.g., stigmatic papillae length, style coloration, pollen exine sculpturing). These traits often vary among taxa in their occurrence and expression.

Genetic studies of the inheritance of tristyly in the three tristylous families indicate that the most common mode of control is by two diallelic loci (*S*, *M*) with *S* epistatic to *M* (Fig. 2). With this genetic control and legitimate mating among the morphs, an isoplethic equilibrium (1 : 1 : 1) is the only possible condition in large populations, provided that the morphs are of equal fitness (Fisher, 1941, 1944; Heuch, 1979). This expectation provides a "standard" for a fully functional tristylous system, and surveys of style morph frequencies in natural populations can be viewed as the logical starting point for studies directed toward understanding the causes of modification in tristylous systems.

In no species of *Eichhornia* or *Pontederia*, the two tristylous genera of Pontederiaceae, does the expression of tristyly conform to all of the features described above. The tristylous syndrome of *Pontederia* most closely resembles this hypothetical state with the major departure involving the self-incompatibility system. In the four taxa of *Pontederia* that have been examined experimentally the M morph is moderately self-compatible when pollinated with pollen from long-level anthers, whereas incompatibility expression in the L and S morphs is considerably stronger (Ornduff, 1966; Barrett, 1977b; Glover & Barrett, 1983; Barrett & Anderson, 1985). The significance of this variation to the functioning of tristyly is unclear, since it is not associated with modifications in the stamen–style polymorphism or features of pollen trimorphism.

While trimorphic incompatibility is a stable feature of populations of *Pontederia* species (see Price & Barrett, 1982; Barrett et al., 1983), this is not the case in *Eichhornia*. Only in *E. azurea* do populations occur that possess self-incompatibility, strong pollen trimorphism, and the three style morphs (Barrett, 1978). Even in this species, however, monomorphic populations are common, and genetic modifications favoring self-fertilization occur in Central America. In the remaining tristylous taxa, self-compatibility occurs and is associated with weak heteromorphisms of pollen size. Differences in the degree of pollen heteromorphism among *Eichhornia* species are illustrated in Figure 3. The greatest difference in the mean size of pollen originating from the two anther levels within a flower occurs in the self-incompatible *E. azurea*. Differences are less evident in the two self-compatible tristylous species, *E. crassipes* and *E. paniculata*. In the remaining homostylous species there is evidence of slight differences in pollen size distributions in *E. heterosperma* and *E. diversifolia*, whereas in *E. paradoxa* pollen originating from the two anther levels is uniform in size.

Self-compatible tristyly. In the vast majority of heterostylous plants the floral polymorphisms are associated with a sporophytically controlled self-incompatibility system (Ganders, 1979). Absence of such a system in most *Eichhornia* species raises the issue as to whether illegitimate matings are frequent under field conditions and whether the stamen–style polymorphism functioning alone is effective at promoting disassortative mating among the floral morphs. Two studies involving

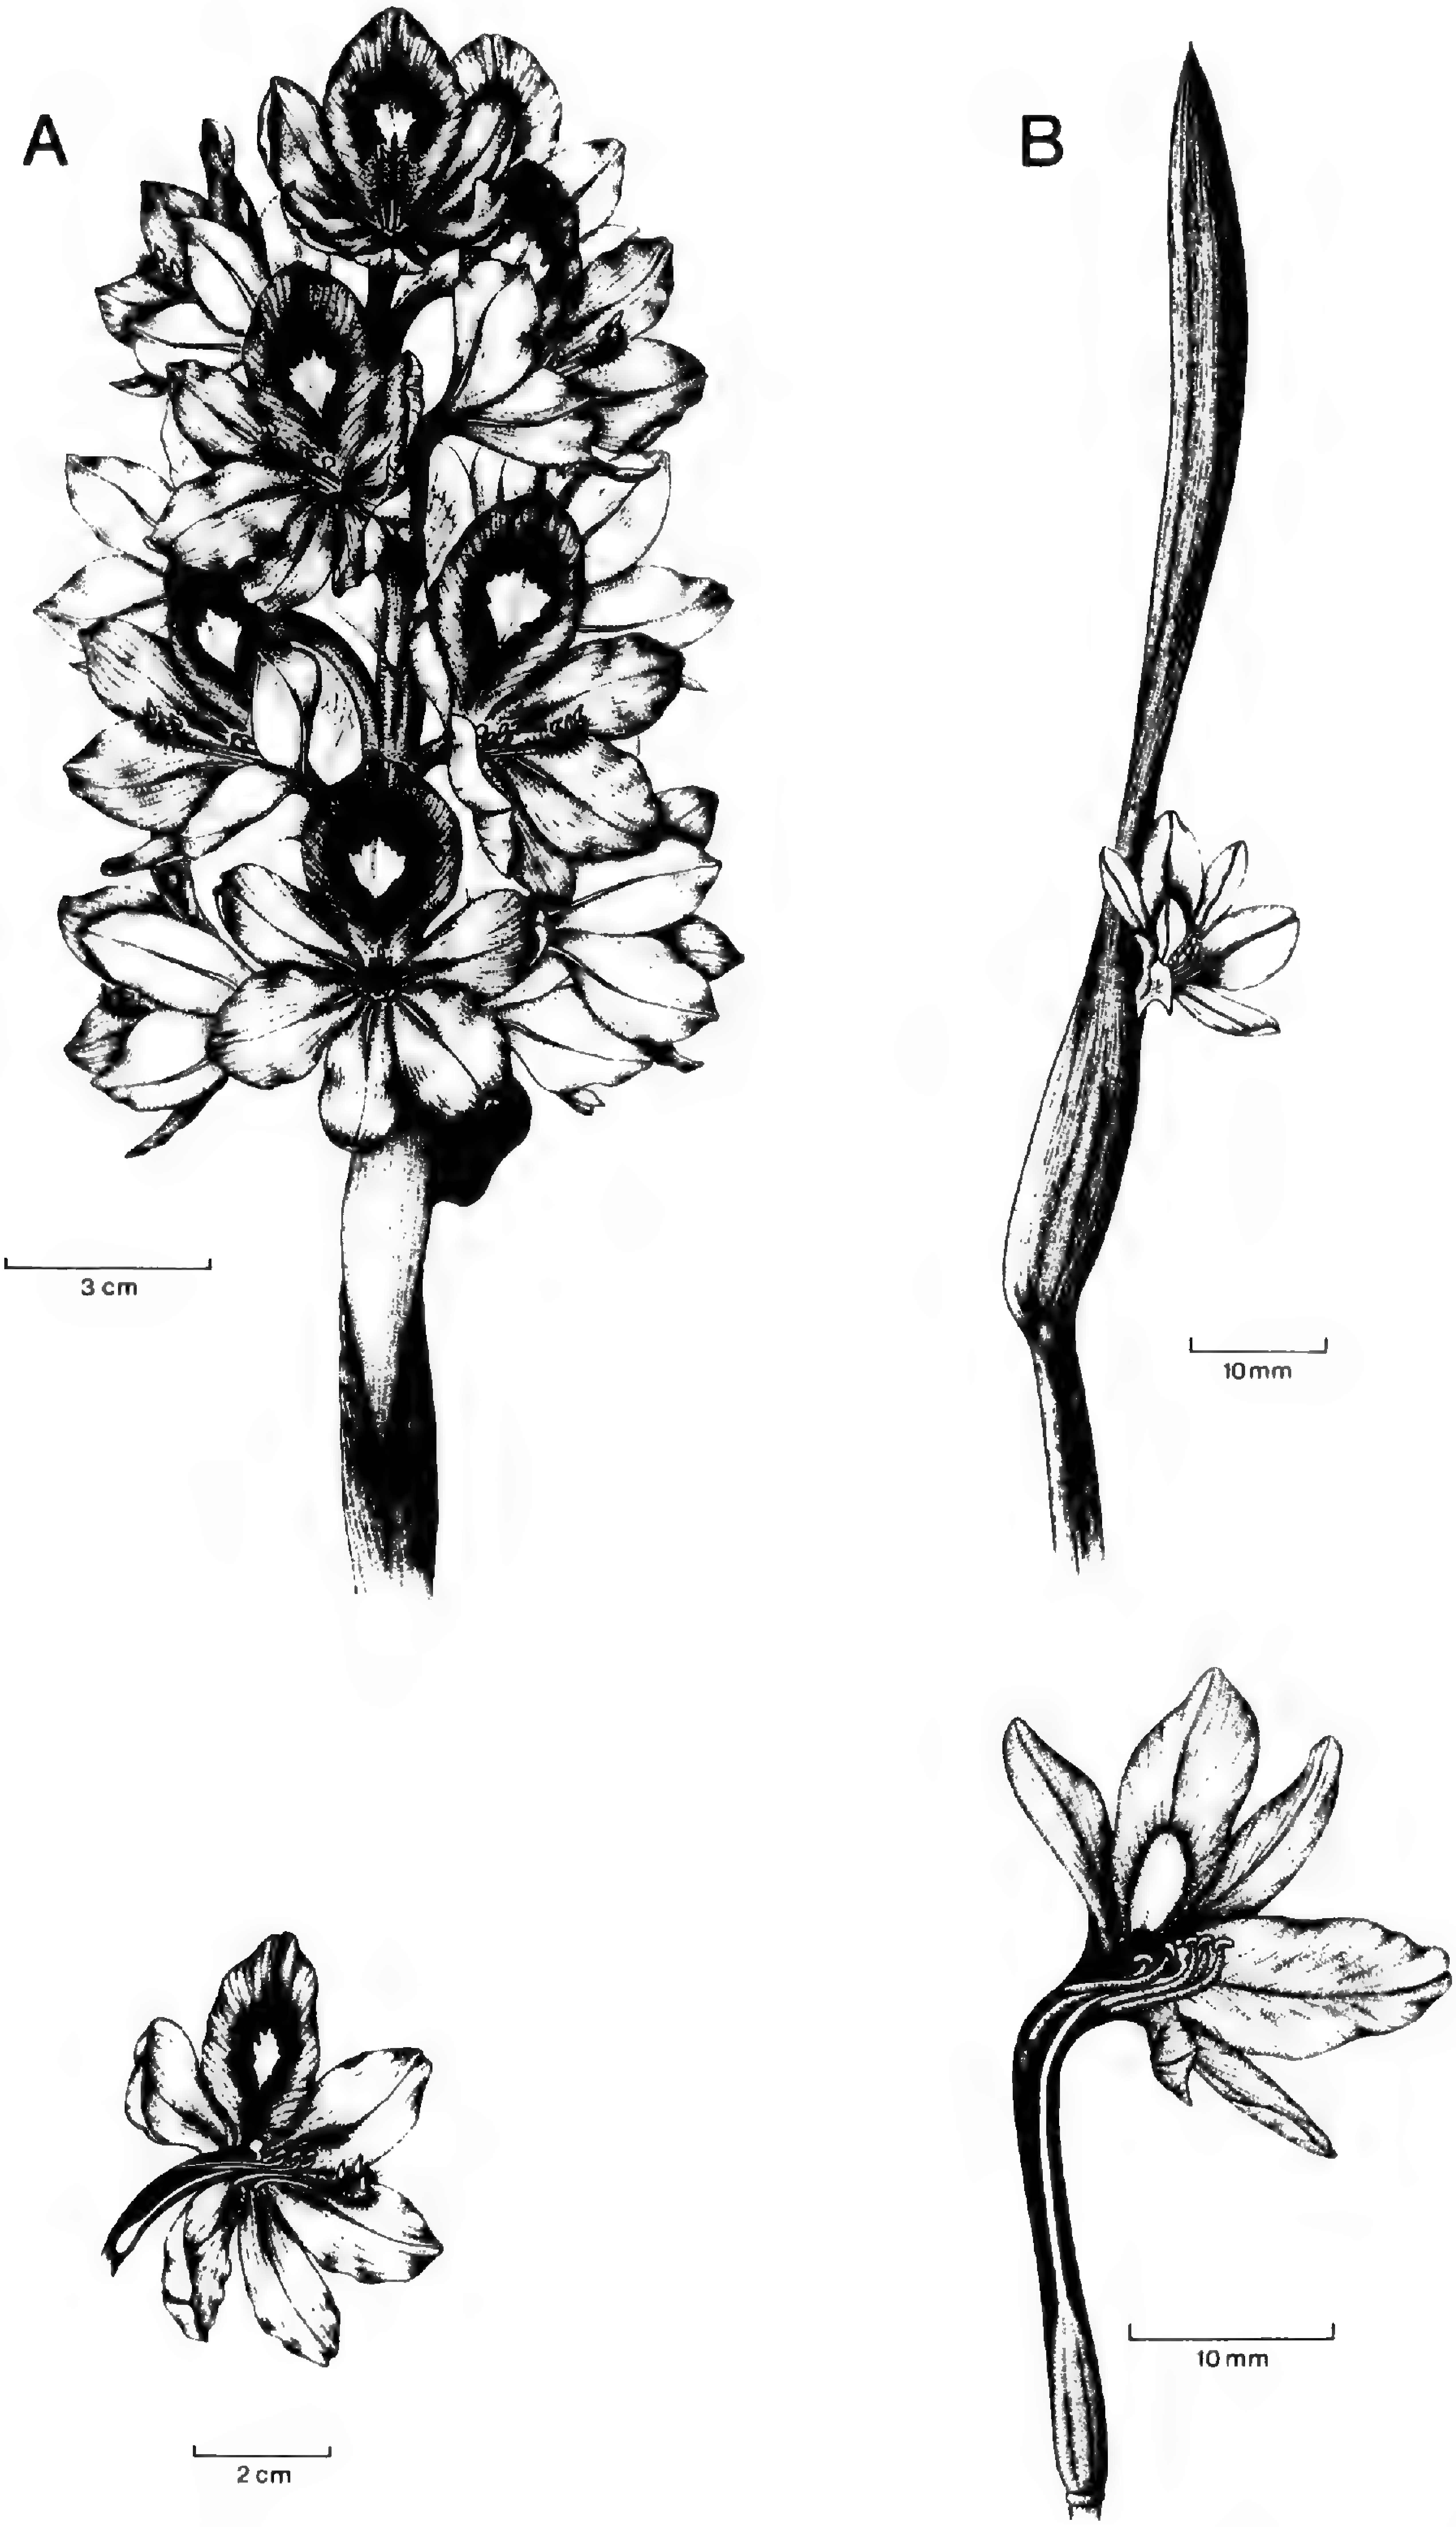

FIGURE 1. *Floral displays in a tristylous and a semi-homostylous species of* Eichhornia.—*A.* Eichhornia crassipes, *S morph from Boca de Jari, Lower Amazon, Brazil.*—*B.* E. paradoxa, *semi-homostylous M morph from Propriá, Sergipe, northeast Brazil.*

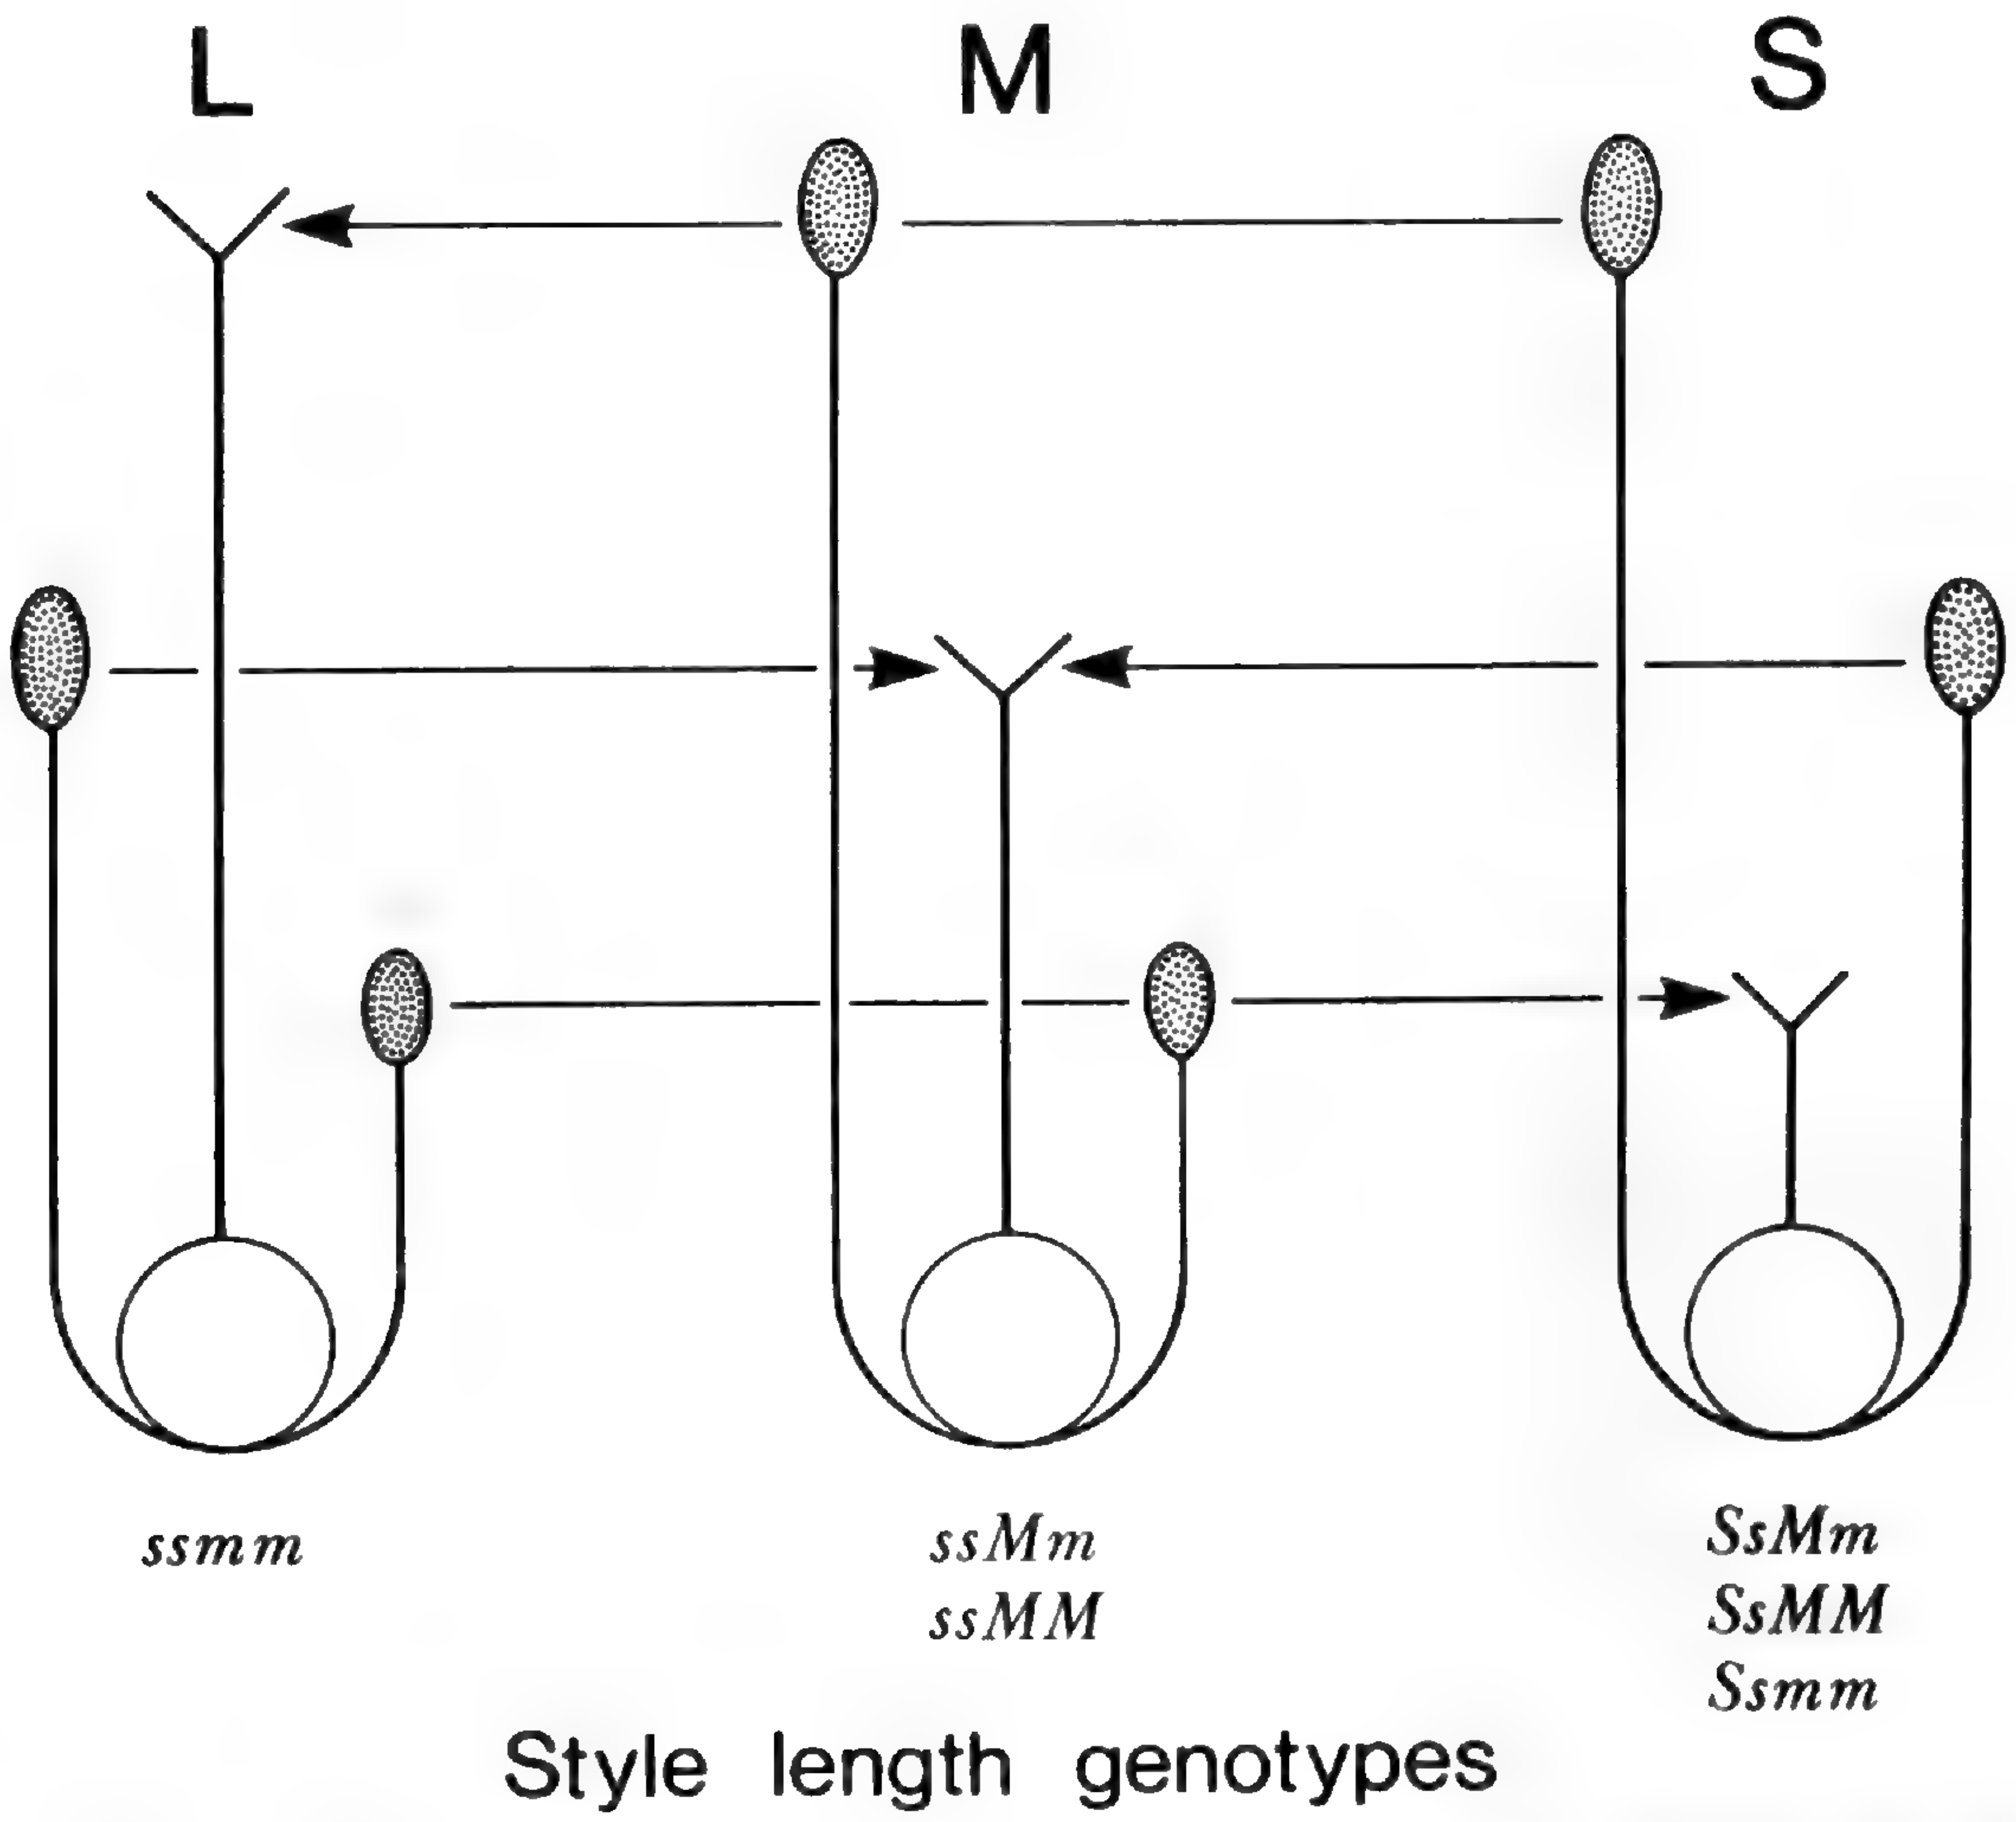

FIGURE 2. *Schematic diagram of the relative positions of styles and stamens in the floral morphs of a tristylous species. Legitimate pollinations are indicated by arrows. Genotypes of the floral morphs under the two-locus model (*S, M*) for the inheritance of tristyly in* Eichhornia *are shown.*

marker genes indicate that the mating system of floral morphs in self-compatible tristylous populations can involve a high level of outcrossing (Glover & Barrett, 1986a; Barrett et al., 1987). Progeny test data from *E. paniculata* (Table 3) reveal that the floral morphs are largely outcrossing and that most matings are disassortative in nature. This indicates that self and intramorph matings occur infrequently in this population. Such an effect could result from the operation of a cryptic heteromorphic incompatibility system of the type demonstrated in *Amsinckia* (Weller & Ornduff, 1977; Casper et al., 1988). However, this does not appear to be the case. In a controlled pollination experiment on *E. paniculata* that compared the competitive ability of self, illegitimately outcrossed, and legitimately outcrossed pollen, using the *GOT-3* marker locus, Glover & Barrett (1986a) found no evidence of a residual or cryptic trimorphic incompatibility system. Outcrossed progeny were always favored over selfed progeny irrespective of whether they were legitimate or illegitimate.

The results from *E. paniculata* are relevant to the question of whether self-compatibility in tristylous *Eichhornia* species is a derived condition involving relaxation of self-incompatibility. Following this view we might have anticipated some residual influence of the ancestral incompatibility system favoring legitimate over illegitimate matings. However, this was not detected, perhaps because the action of numerous modifier genes has removed all traces of the functional aspects of trimorphic incompatibility. The prepotency of cross-pollen over self-pollen might then be explained as a manifestation of inbreeding depression operating via extensive pollen–pistil interactions and genetically unrelated to the original incompatibility system (Barrett, 1988b).

Comparative evidence from other heterostylous families indicates that self-compatibility is commonly derived from self-incompatibility (Ganders, 1979). Most workers (e.g., Charlesworth & Charlesworth, 1979) have favored the idea that the evolution of self-incompatibility precedes the development of the stamen–style polymorphism in heterostylous groups (although see Richards, 1986).

Function of tristyly. Although the progeny test data from Recife demonstrate high levels of disassortative mating in *E. paniculata*, this does

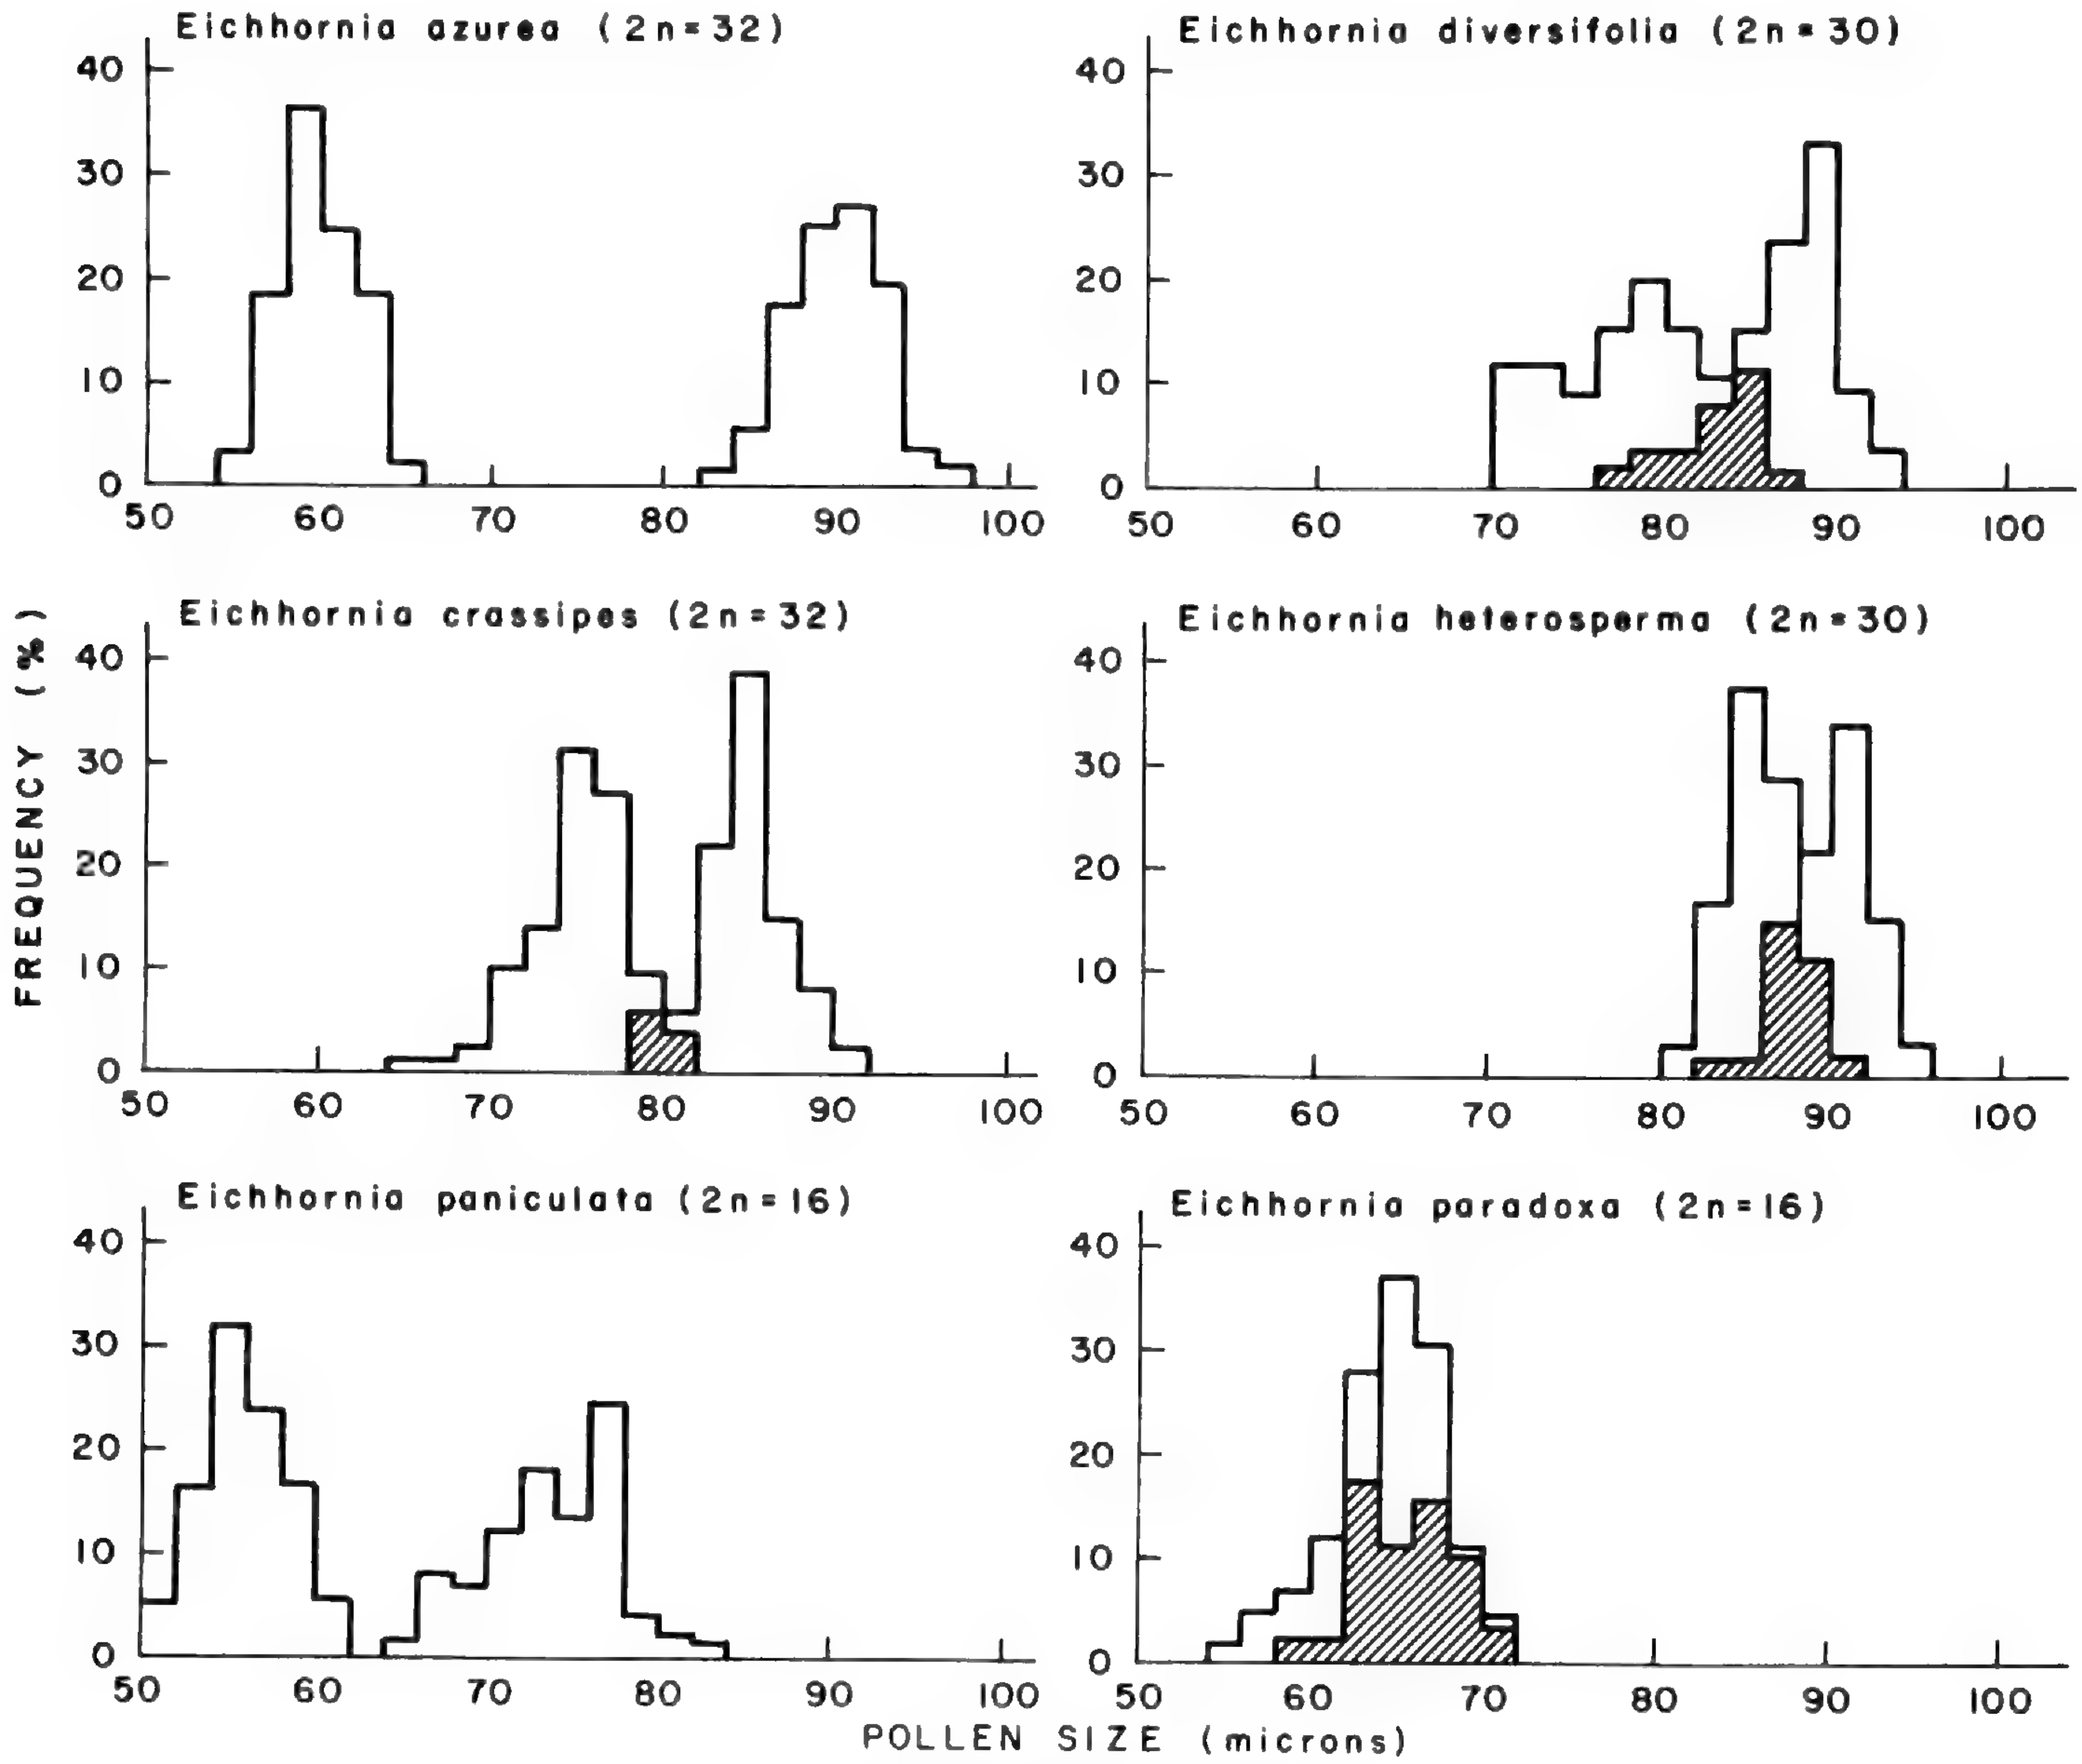

FIGURE 3. *Patterns of pollen-size heteromorphism in six species of* Eichhornia *with contrasting breeding systems. The distributions for each species were obtained by measuring the equatorial axis of 200 dry pollen grains originating from the two stamen levels of a flower. To facilitate comparisons among species, all measurements were conducted on the M morph (*E. azurea, E. crassipes, E. paniculata*) or semi-homostylous derivatives of the M morph (*E. diversifolia, E. heterosperma, E. paradoxa*). Note the overall differences in pollen size between diploid and tetraploid species.*

not prove that tristyly promotes legitimate pollination, as Darwin (1877) originally proposed. This is because in a self-compatible species intermorph illegitimate matings contribute towards estimates of disassortative mating. Using the progeny test method, it is not possible to distinguish between cross-pollinations involving legitimate and illegitimate pollen that originate from the same plant (Barrett et al., 1987). However, in some heterostylous species, these pollen types differ in size, and it is therefore possible to measure the magnitude of legitimate and illegitimate pollination in natural populations by inspecting the pollen loads of open-pollinated stigmas (Ganders, 1979). The extensive overlap in the size of pollen that originates from different anther levels of self-compatible *Eichhornia* species (Fig. 3) precludes this method. However, stigmatic pollen loads have been examined in *Pontederia* species, where size trimorphism is well developed, and significant levels of legitimate pollination were recorded in several natural populations (Glover & Barrett, 1983, 1986b; Price & Barrett, 1984; Barrett & Glover, 1985). These studies therefore provide support for the Darwinian hypothesis of the adaptive significance of tristyly.

BREAKDOWN OF TRISTYLY

Disruption of population structure. For tristyly to function effectively, populations should contain the three floral morphs and provide sufficient pollen and nectar rewards to attract specialized long-tongued pollinators, usually bees. Several influences can disrupt population structure to yield populations composed of one or two morphs. In *E. crassipes* and *E. azurea*, founder effects and rampant clonal propagation are major disruptive influences on tristyly. This is well illustrated by the geographical distribution of floral morphs in *E. crassipes* (Fig. 4). The S morph is absent from many parts of the New World range as well as from the Old World. In the latter case genotypes of the S morph were not among clones transported to the Old World by man. The M morph predominates in most regions, while the L morph appears sporadically (Barrett, 1977a). In a survey of 196 sites throughout the New World range of *E. crassipes*, Barrett & Forno (1982) found that 77% of the colonies located were monomorphic for style length, 18.4% were dimorphic, and only 4.6% were trimorphic. The rarity of *E. crassipes* populations containing the three floral morphs results from the high dispersal of the free-floating life form coupled with rapid clonal propagation. These factors result in inequalities of representation of founding genotypes. In addition, the short-lived nature of many populations and ecological restrictions on seedling establishment (Barrett, 1980a, b) retard further progress toward isoplethic population structure.

Founder events have also played a disruptive effect on the maintenance of tristyly in *E. paniculata*. Although clonal propagation is absent from this species, repeated colonizing episodes and stochastic influences on population size play a major role in determining morph frequencies in populations. Surveys of population structure in northeast Brazil and Jamaica (Barrett, 1985b and unpubl. data) have revealed a pattern reminiscent of that found in *E. crassipes* (Table 4). The S morph is absent from Jamaica and underrepresented in many populations from Brazil. The M morph predominates in dimorphic populations and, with one exception (see below), is the only morph that has been observed in monomorphic populations.

Absence of the S morph from parts of the range of *E. crassipes* and *E. paniculata* and its underrepresentation in Brazilian populations of *E. paniculata* may be explained by founder events and fluctuations in population size. Since both species are highly self-compatible, polymorphic populations can arise from selfing and segregation of genotypes heterozygous at the *S* and *M* loci. However, since the dominant *S* allele governing the expression of short styles is only carried by the S morph, separate introduction(s) of this morph are necessary for it to become established in a region. In contrast, the *m* allele can be carried by all three morphs and the *M* allele by the M and S morphs. Computer simulation studies by Heuch (1980) on the effects of random fluctuations of population size in tristylous systems confirm that the S morph is most often lost from populations. The same processes, on a neighborhood scale, may also account for the low average frequency of the S morph in trimorphic populations of *E. paniculata* (Table 4). Thus a genetic constraint imposed by the inheritance of tristyly interacting with random ecological processes plays a major role in disrupting the maintenance of population trimorphism.

TABLE 3. *Estimates of the mating system of floral morphs in a tristylous population (B5) of* Eichhornia paniculata *at Recife, northeast Brazil. Outcrossing rates and levels of disassortative mating were estimated from open-pollinated progeny arrays using six isozyme loci or the two loci governing style length, respectively. After Glover & Barrett (1986a) and Barrett et al. (1987).*

Measurement	Floral Morphs L	M	S
Outcrossing rate	0.98	0.97	0.93
N	480	520	480
Standard error	0.021	0.018	0.022
Disassortative mating	0.90	0.93	0.83
N	652	721	665
Standard error	0.034	0.052	0.052

Disruptions of trimorphic population structure in *Eichhornia* may not necessarily lead to genetic modifications of the breeding system. In *E. azurea* and *E. crassipes*, clonal regeneration and the low frequency of sexual reproduction in many monomorphic and dimorphic populations limit opportunities for evolutionary change. However, under conditions where sexual reproduction is favored, e.g., in strongly seasonal aquatic environments, there may be strong selection pressures to increase fecundity, particularly if pollinating agents are scarce (Barrett, 1979).

Semi-homostyle formation. In each of the three tristylous species of *Eichhornia* there is evidence of the breakdown of tristyly and the evolution of semi-homostyly (Barrett, 1978, 1979, 1985a). Semi-homostyles in *Eichhornia* occur primarily at the geographical margins of the neotropical ranges of species either as local populations (*E. azurea*, *E. paniculata*) or as variants in otherwise unmodified population systems (*E. crassipes*). In each species, semi-homostyles are highly autogamous be-

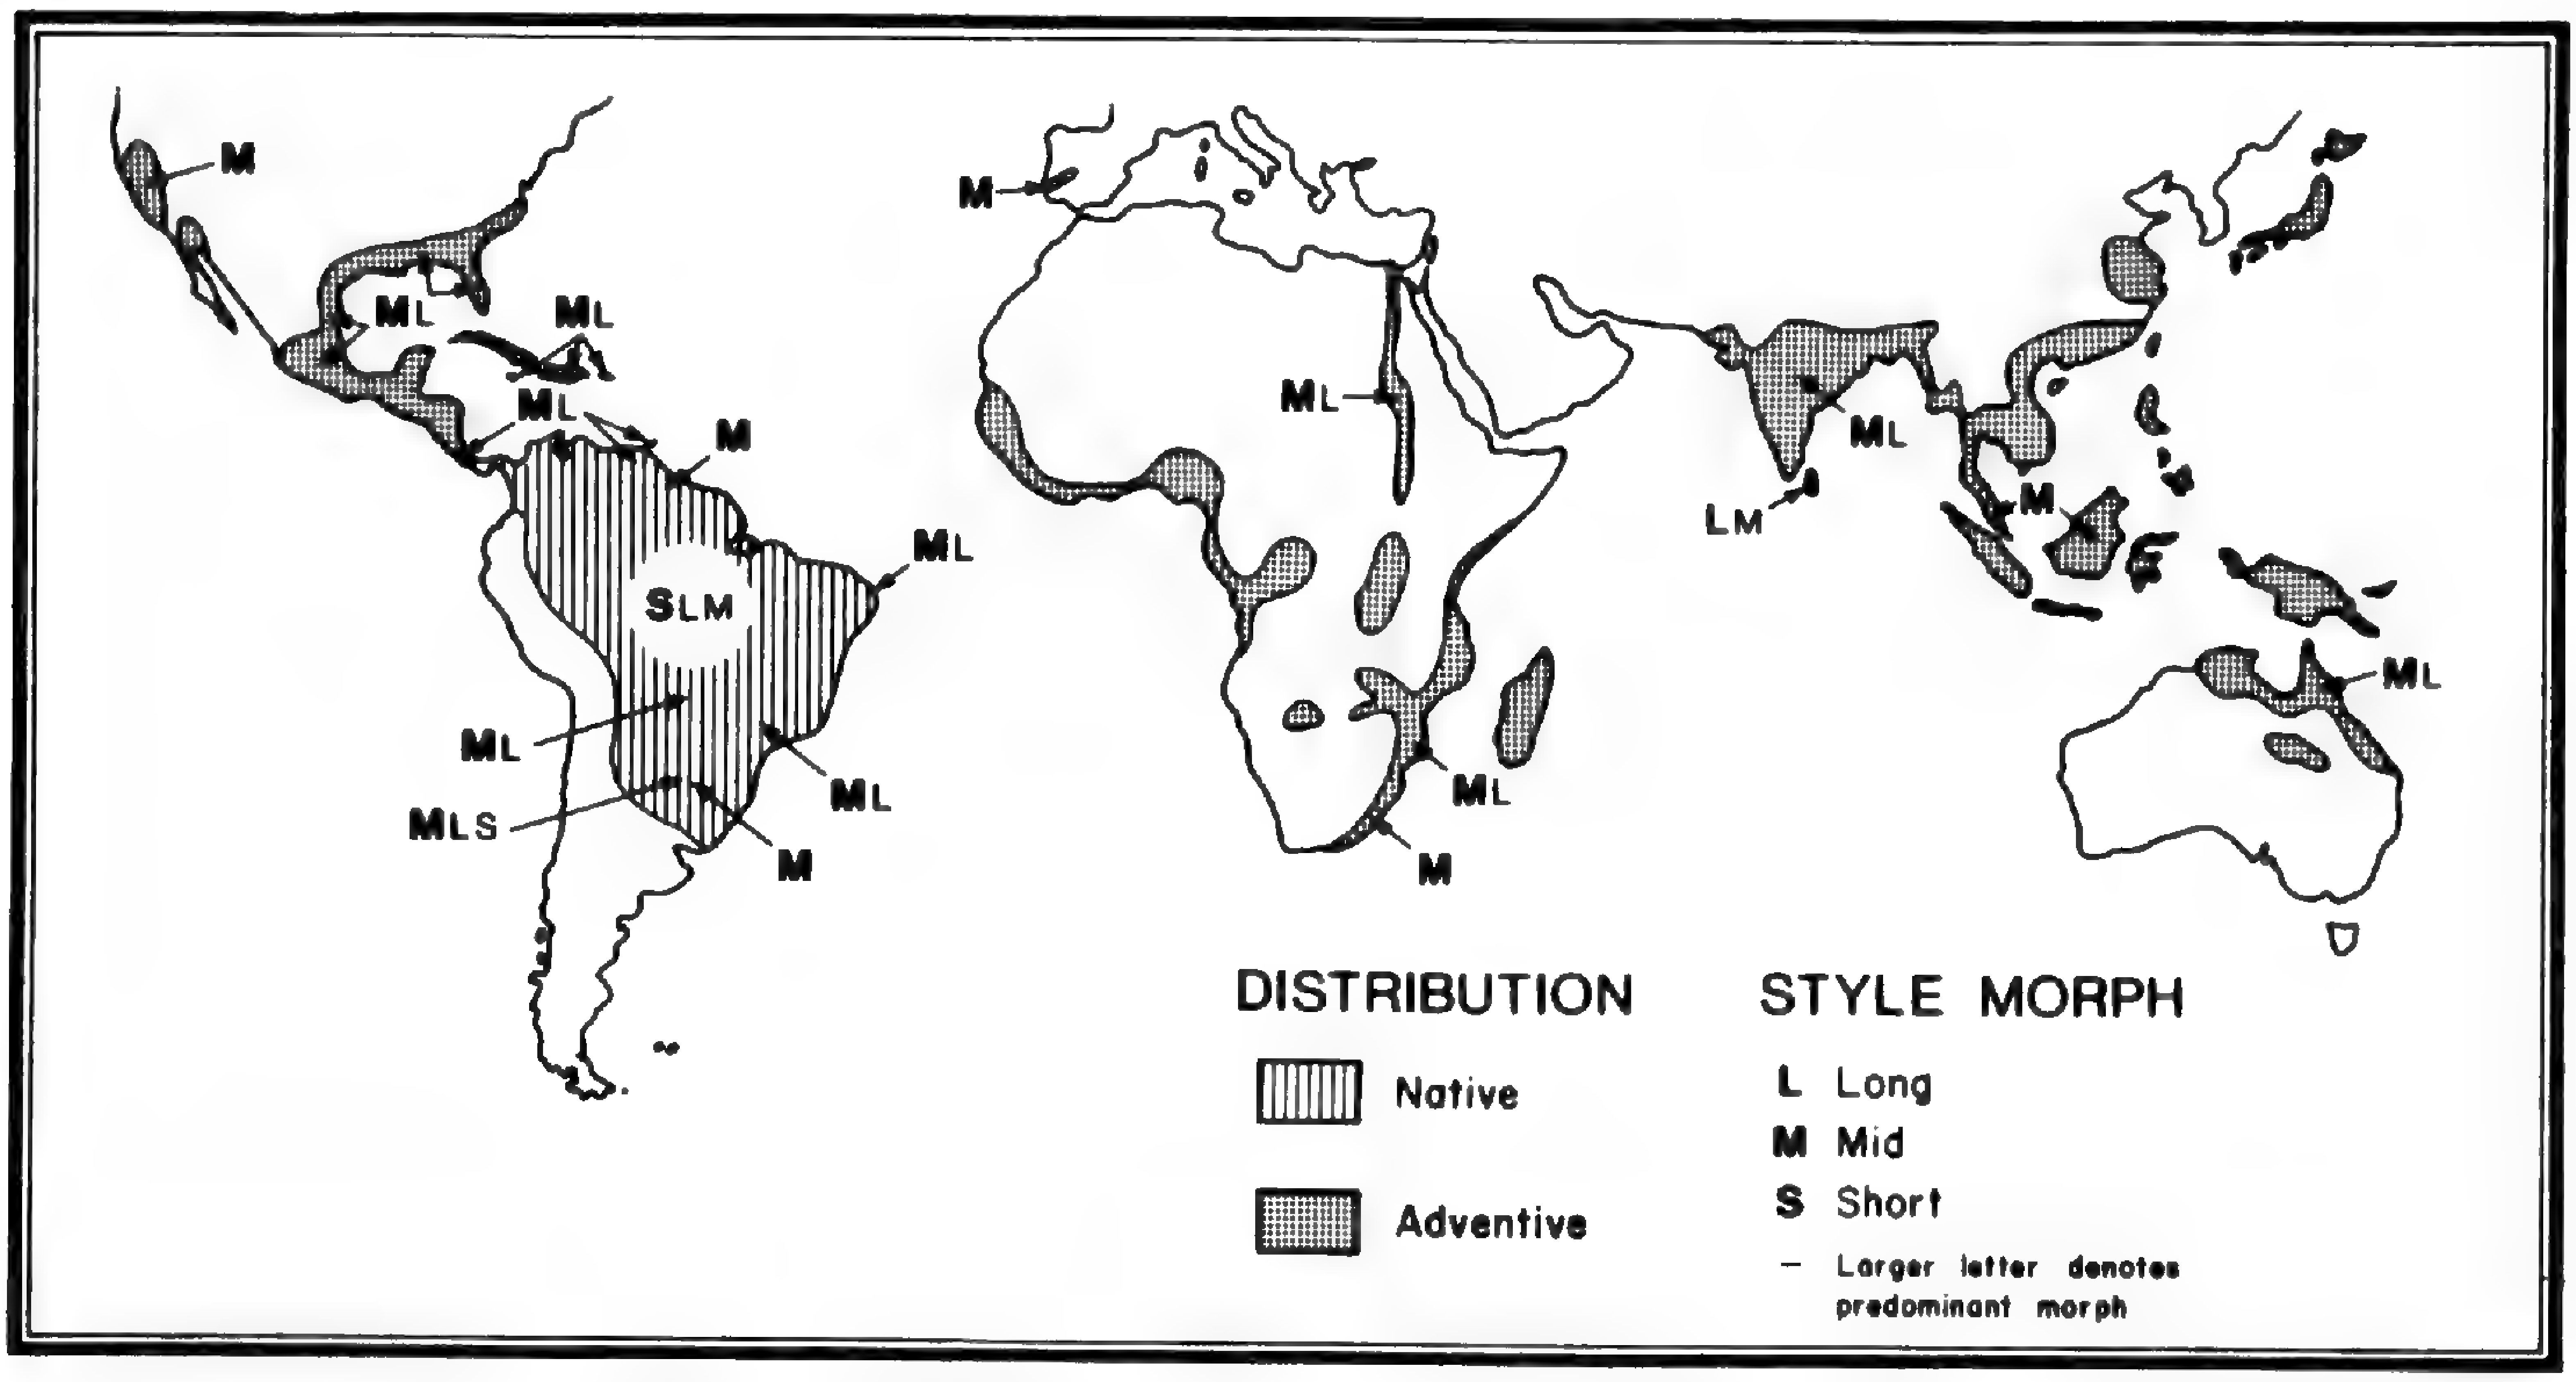

FIGURE 4. *The geographical distribution of style morphs in* Eichhornia crassipes. *Modified from Barrett (1977a) and Barrett & Forno (1982).*

cause of the close juxtaposition of stigmas and anthers.

In *E. azurea* and *E. paniculata*, semi-homostylous populations differ from their outcrossing progenitors in several floral traits. They often possess smaller, less showy flowers, reduced numbers of flowers per inflorescence, weak pollen heteromorphism, and lower pollen–ovule ratios. As described above, these differences parallel those that distinguish outcrossing and selfing species of *Eichhornia* (Table 2). This point is well illustrated by comparing the degree of pollen heteromorphism displayed by populations of *E. paniculata* with contrasting mating systems (Fig. 5). The difference in size of pollen produced by contrasting stamen levels is large in tristylous populations, whereas dimorphic and monomorphic populations show increasing pollen-size overlap. The weakening of pollen heteromorphism accompanying the evolution of semi-homostyly probably reflects relaxed selection pressures and the random accumulation of small mutations affecting pollen size. These patterns suggest that pollen size is a canalized trait in outcrossing populations and that heteromorphism is maintained by strong stabilizing selection. The functional significance of pollen-size heteromorphism to pollen–pistil interaction in heterostylous species is still a matter of some conjecture (see Ganders, 1979).

Semi-homostylous variants are most common in *E. paniculata*. They predominate in Jamaica and are frequently encountered in dimorphic and monomorphic populations in northeast Brazil. In tristylous populations, however, they occur rarely, suggesting some selective disadvantage. The development of semi-homostyly in *E. paniculata* occurs most commonly in the M morph (Fig. 6), with populations displaying various floral modifications in different parts of the range of the species (Barrett, 1985a). This suggests that the breakdown of tristyly is occurring repeatedly in the species. Semi-homostylous variants in *E. paniculata* are not exclusively derived from the M morph. Occasionally, modified L plants are encountered in populations from northeast Brazil, and material from

TABLE 4. *Average frequencies of the floral morphs in populations of* Eichhornia paniculata *from northeast Brazil and Jamaica. The majority of M plants in nontrimorphic populations exhibit modifications of the short-level stamens (see text).*

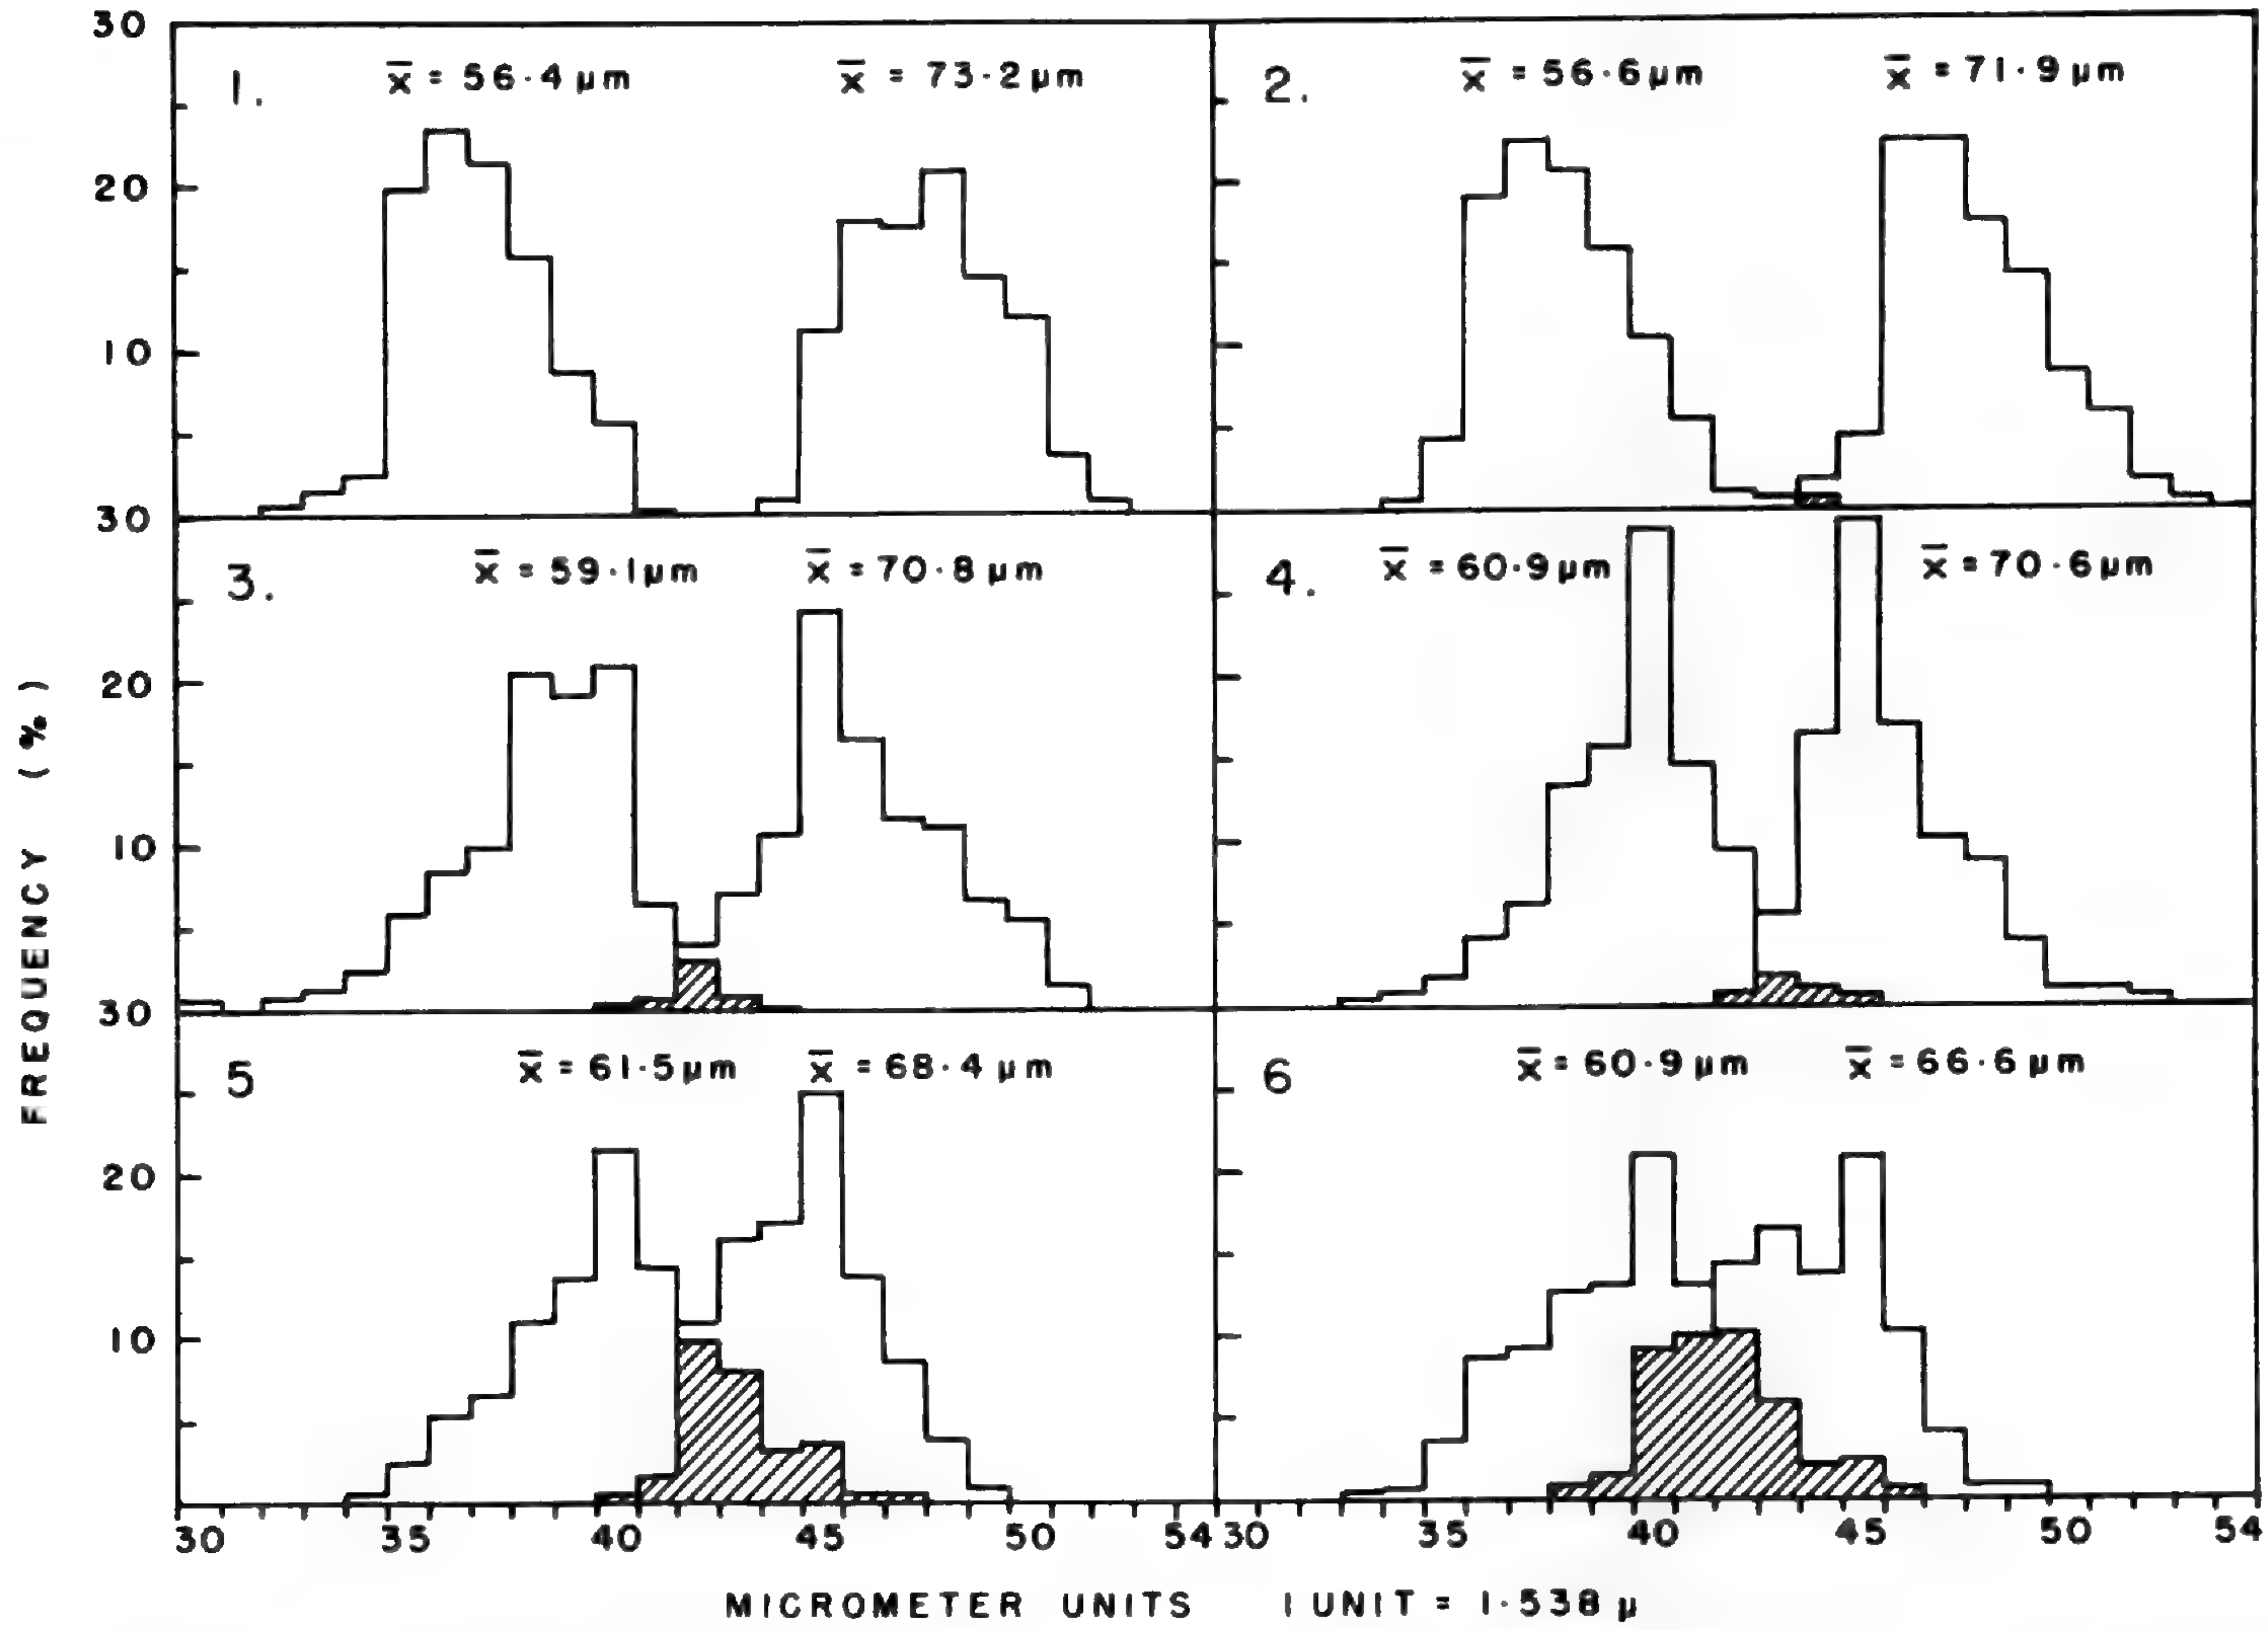

FIGURE 5. *Patterns of pollen-size heteromorphism in six populations of* Eichhornia paniculata *with contrasting breeding systems. The distributions for each population were obtained by measuring the equatorial axis of 200 dry pollen grains originating from the two stamen levels of a flower. To facilitate comparisons among populations, all measurements were conducted on six flowers from six plants of the M morph in each population. Plants of the M morph in nontristylous populations possessed varying degrees of genetic modification of the short stamen level (see text for details). Populations 1–4 are from northeast Brazil, populations 5 and 6 are from Jamaica. Populations 1 and 2 are trimorphic, 3 is dimorphic (L, M), and 4–6 are monomorphic (M).*

the only reported occurrence of the species in Central America (*Haynes 8442, 8603,* (ALU) Rio Las Lajas, Department of Rivas, Nicaragua) is composed exclusively of semi-homostylous long-styled plants. Ongoing genetic and developmental studies (Richards & Barrett, 1984 and unpubl. data) of the range of semi-homostylous variants in *E. paniculata* are aimed at determining the inheritance patterns and developmental pathways responsible for the breakdown of tristyly in the species.

In *E. crassipes* semi-homostyle formation is apparently rare. I have observed semi-homostyles in only two populations. Both were dimorphic (L, M), and in each case the modified phenotypes only differed from unmodified forms in the relative lengths of their reproductive parts (Barrett, 1979 and unpubl. data). If these phenotypes became reproductively isolated from their unmodified progenitors, it is likely that genetic modifications in other aspects of their reproductive biology would occur.

The reported semi-homostyles in a population of *E. crassipes* from Costa Rica are also modified forms of the M morph (Barrett, 1979). However, in contrast to *E. paniculata,* where alterations involve elongation of short-level stamens, the breakdown of herkogamy in this population of *E. crassipes* is primarily the result of shortening of long-level stamens. This indicates that a different developmental pathway is involved. In addition, the recent discovery in *E. crassipes* of a semi-homostylous L morph in northeast Brazil (S. C. H. Barrett, unpubl. data) indicates that, in common with *E. paniculata,* semi-homostyle formation can occur in both M and L morphs.

The arrangement of reproductive organs in semi-homostylous populations of *E. azurea* suggests that they are M variants with elongated short-level stamens (Barrett, 1978 and unpubl. data). Why the M morph of *Eichhornia* species appears to be more prone than other morphs to genetic modifications favoring increased levels of self-fertilization

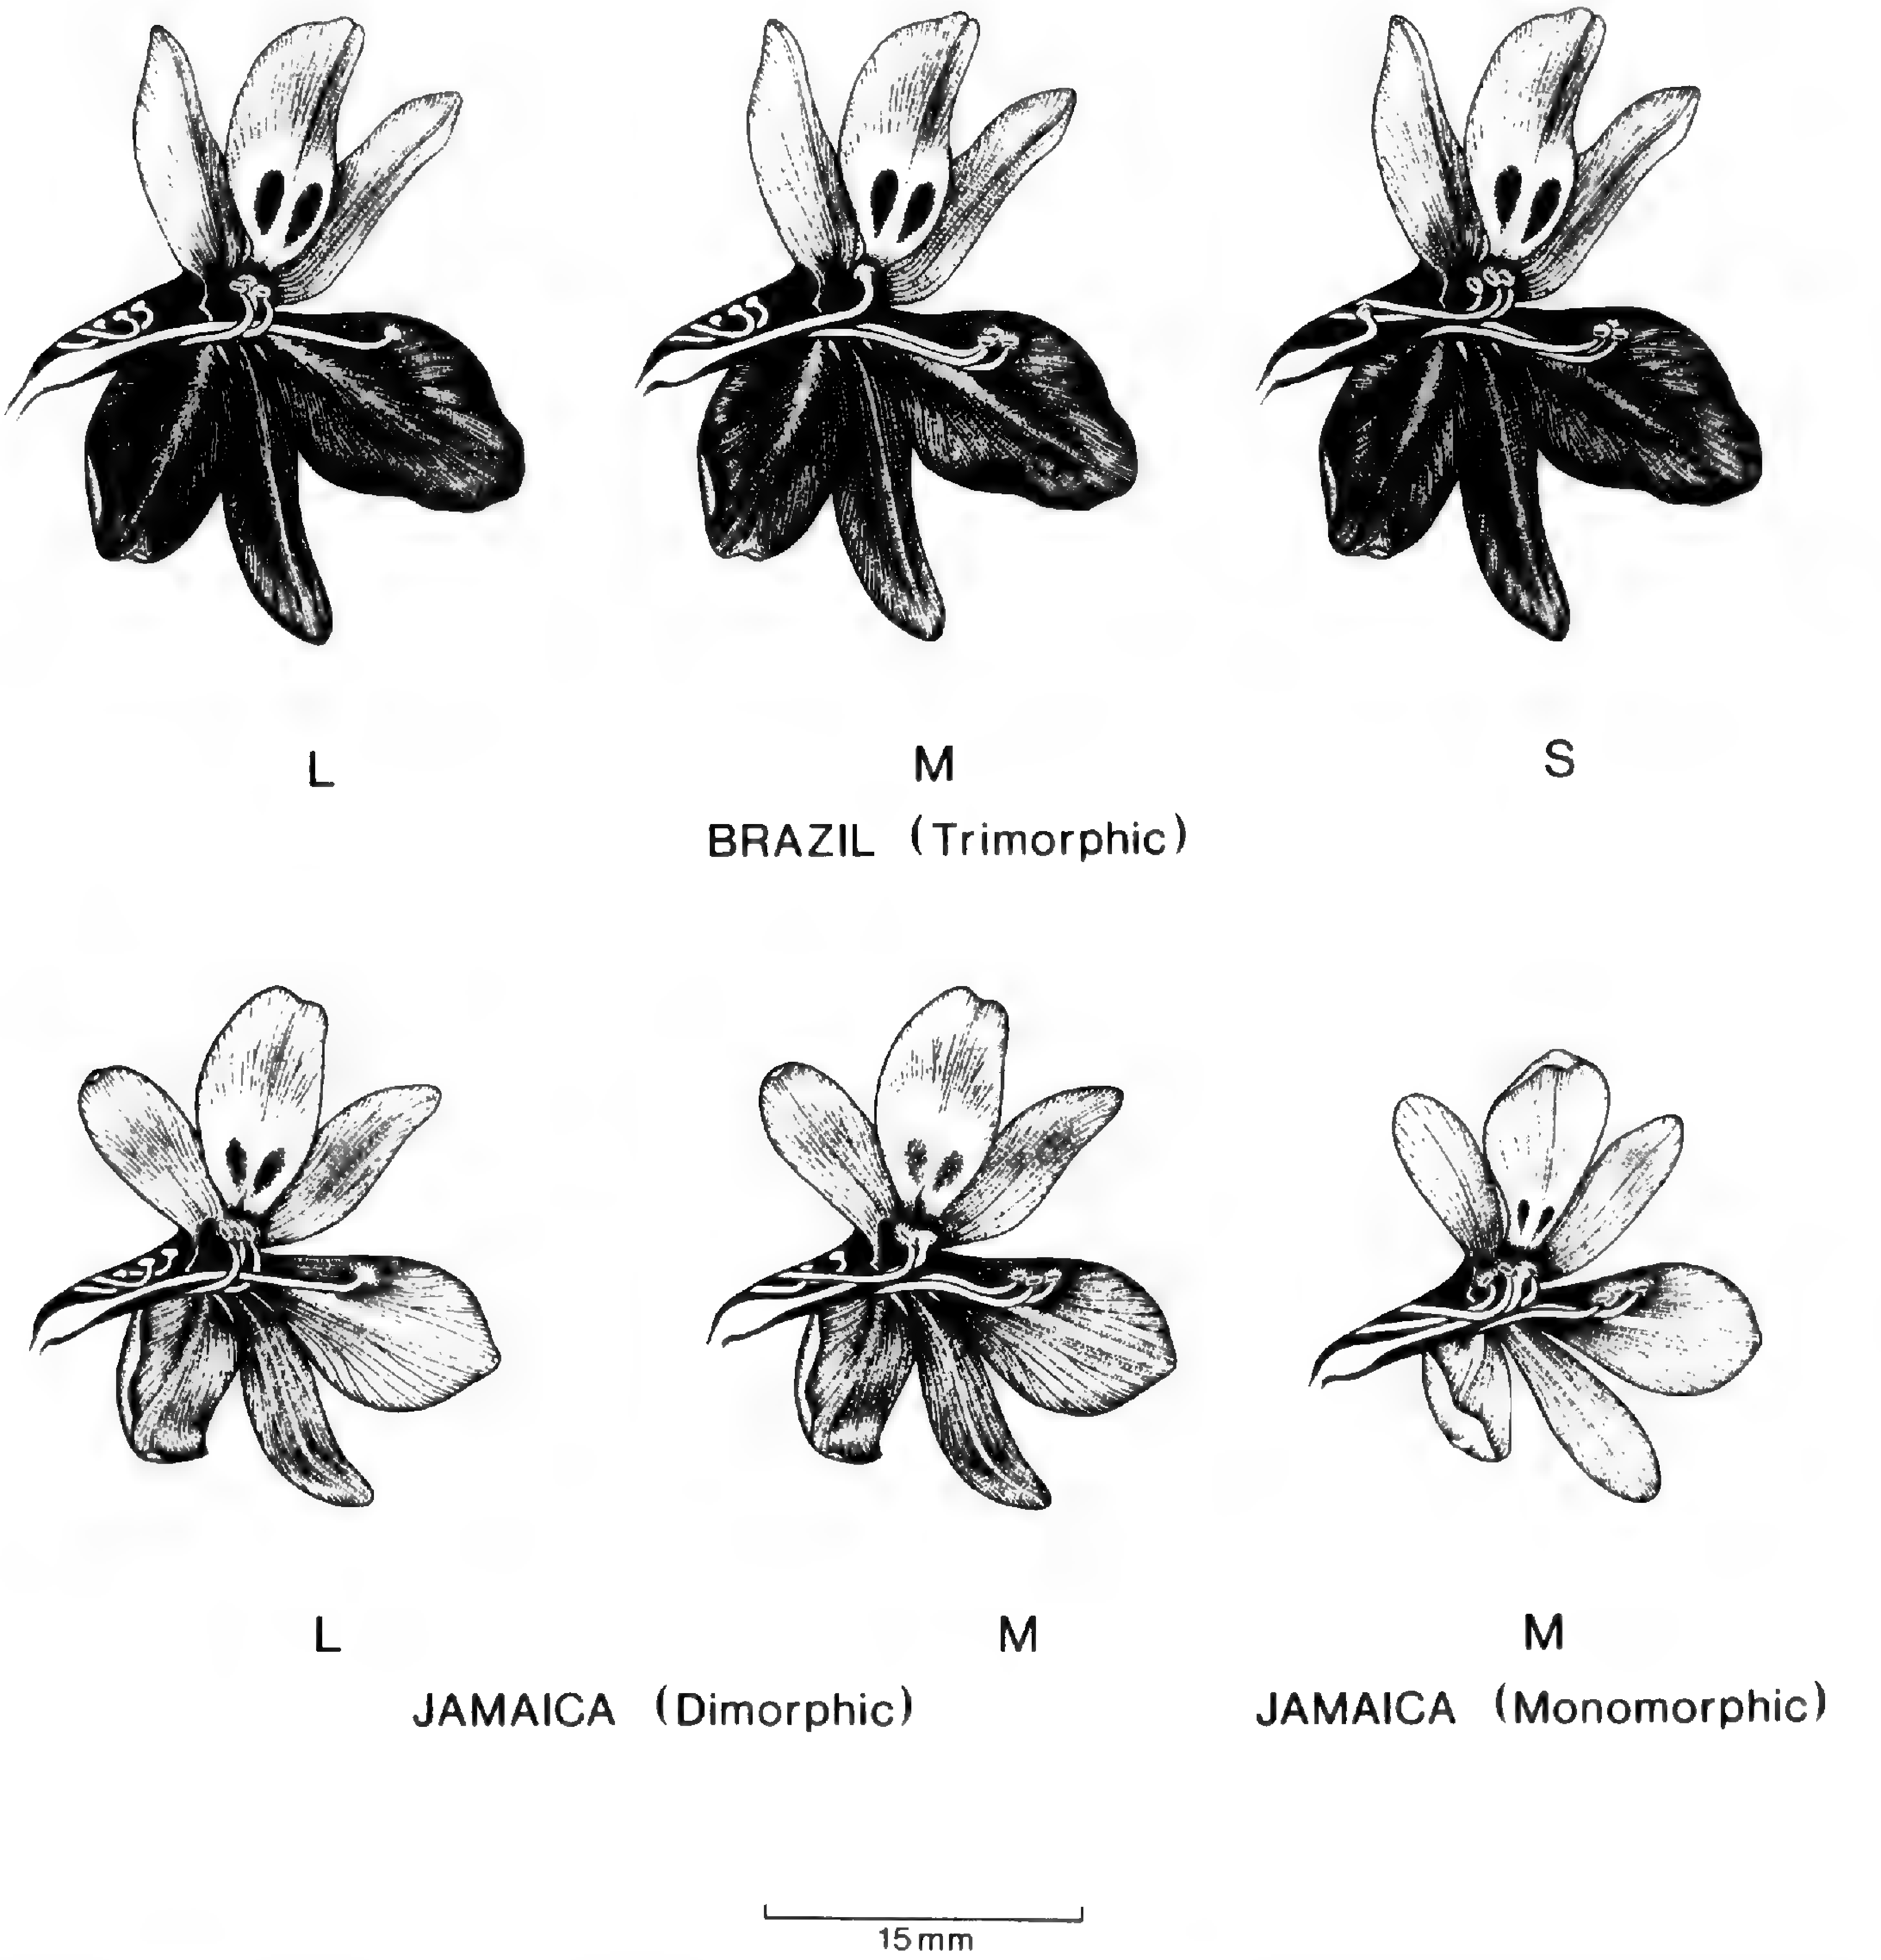

FIGURE 6. *The evolutionary breakdown of tristyly to semi-homostyly in* Eichhornia paniculata. *Flowers of the L, M, and S morphs from an outcrossing trimorphic population (B5) are contrasted with two semi-homostylous M variants from Jamaica (dimorphic J15, monomorphic J3). The semi-homostylous M variants differ from one another in the number of short-level stamens (1 versus 3) that are adjacent to the mid-level stigma. No stamen modifications of the L morph occur in dimorphic populations from Jamaica. For further details see Barrett (1985a) and Glover & Barrett (1986a).*

is not clear but may be associated with differences in the development and floral architecture of the morphs. In the Lythraceae and Oxalidaceae, semi-homostyly also appears to occur more commonly in the M morph (Stout, 1925; Ornduff, 1972).

The establishment of semi-homostyly in tristylous species of *Eichhornia* demonstrates that when selection pressures that maintain outcrossing are relaxed or changed in direction, the complex syndrome of traits that constitute the tristylous syndrome can rapidly break down towards increased self-fertilization. Furthermore, the wide range of semi-homostylous variants that occur in *E. paniculata* suggests that the processes responsible for the dissolution of floral polymorphism are still active in contemporary populations. This provides an opportunity to investigate directly the selection pressures acting on the mating system and to determine the ecological and genetic conditions that favor the evolution of self-fertilization. *Eichhornia paniculata* is particularly favorable for such studies because it possesses a short life

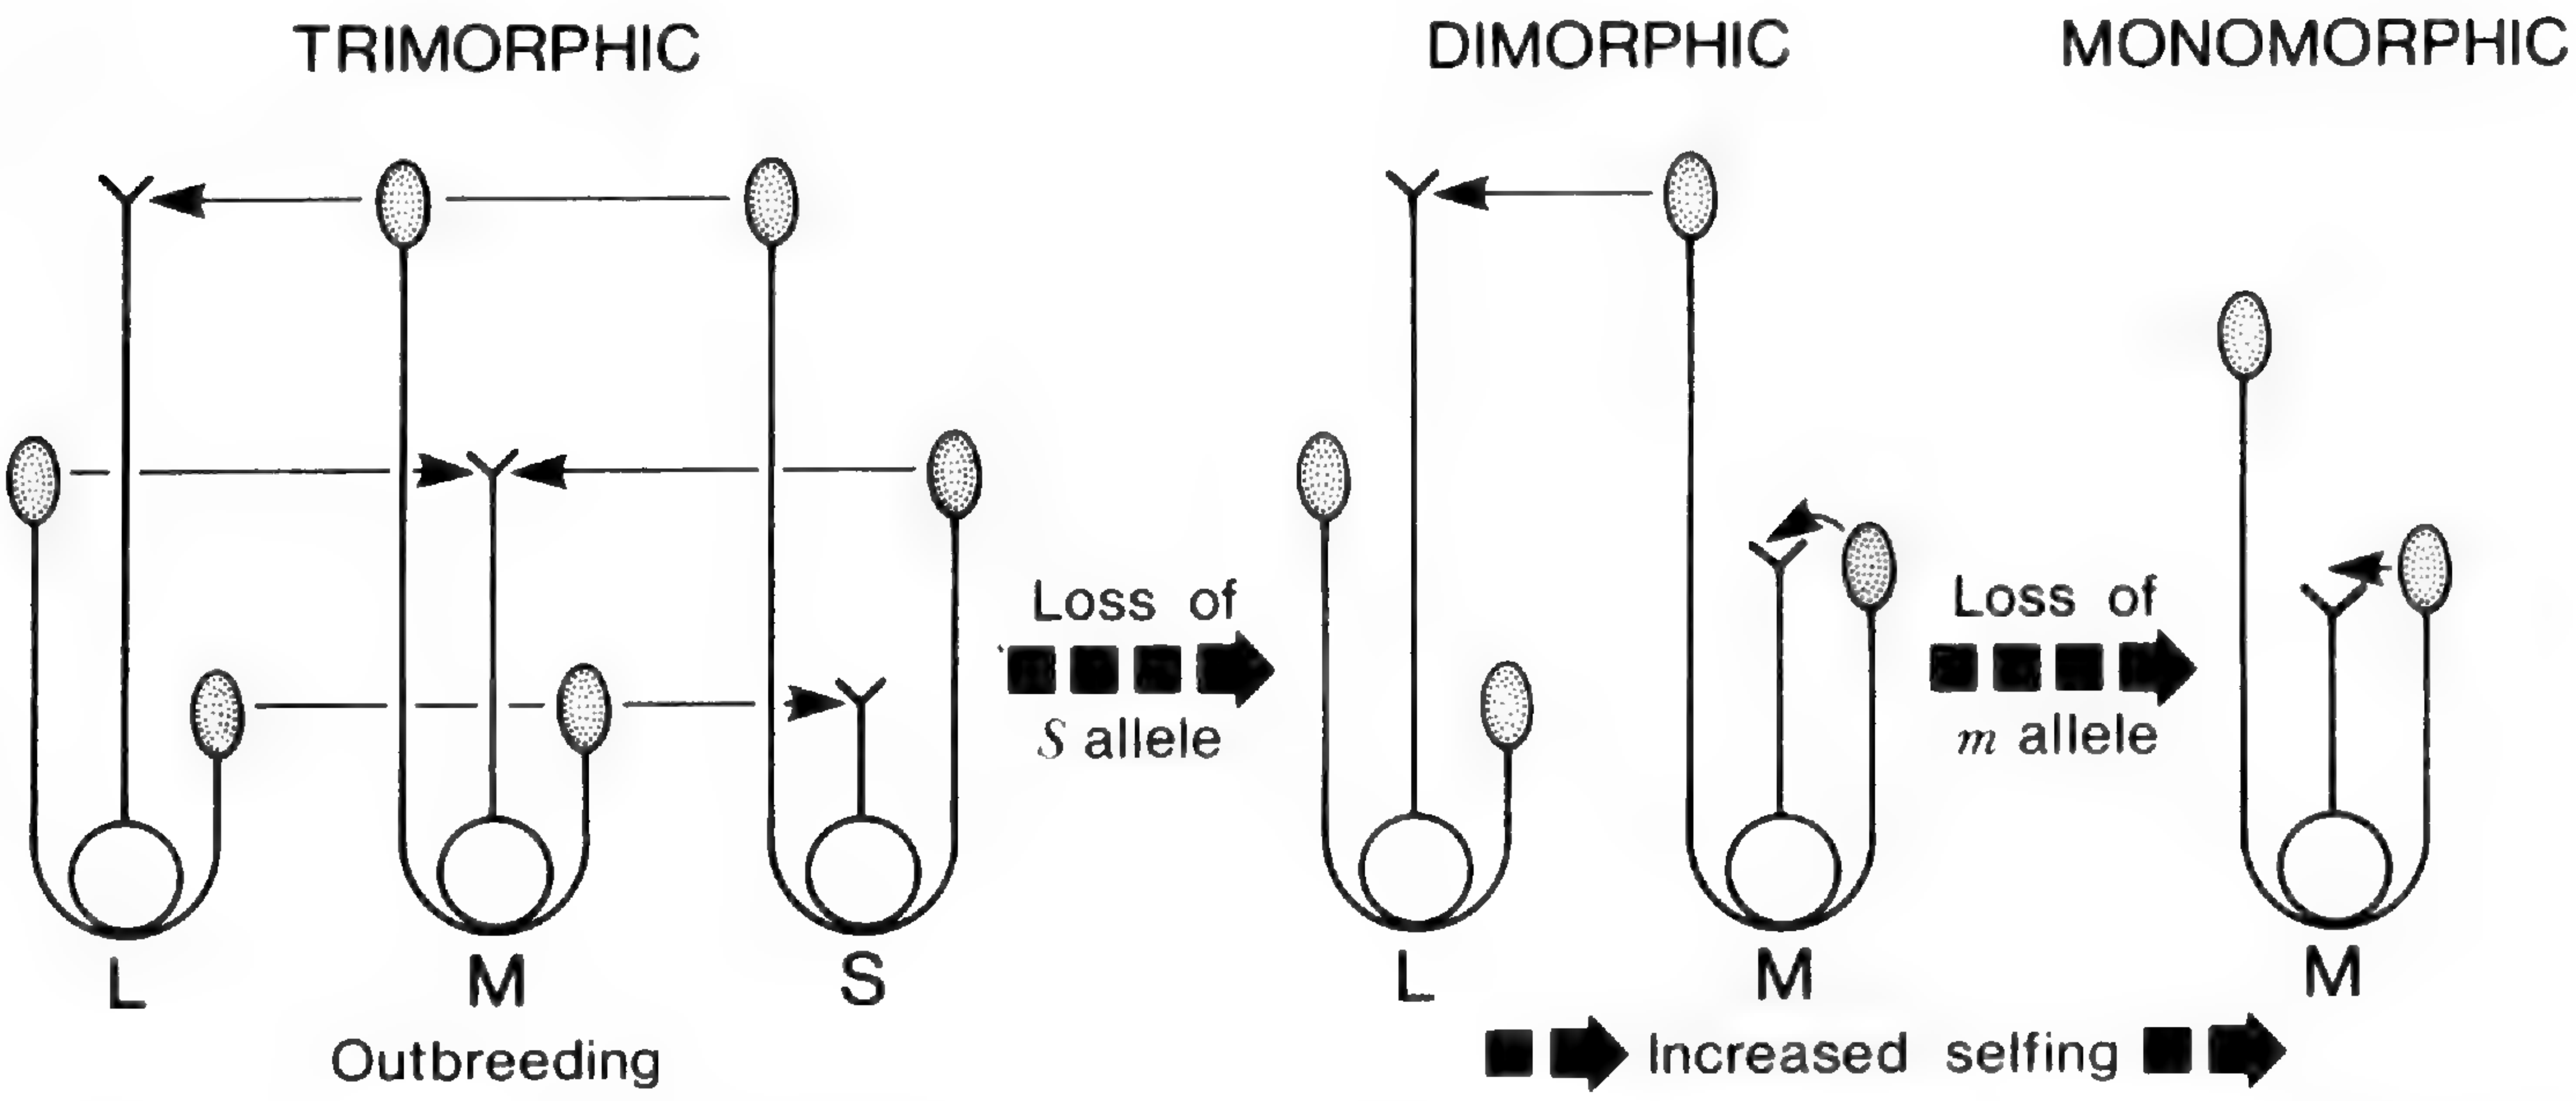

FIGURE 7. *Model of the breakdown of tristyly to semi-homostyly in* Eichhornia paniculata. *Arrows indicate predominant matings. Note the modifications in short-stamen position of the M morph in dimorphic and monomorphic populations. After Barrett (1985b).*

cycle, and population turnover is rapid due to the unpredictable nature of its habitats. These features increase the likelihood of detecting microevolutionary changes. This situation contrasts with that in *E. azurea* and *E. crassipes* where, because of heavy emphasis on clonal propagation, evolutionary changes in the breeding system of populations are more difficult to measure.

The breakdown process in Eichhornia paniculata. Surveys of the patterns of floral-morph frequency in populations of *E. paniculata* in conjunction with studies of their reproductive ecology and genetics have enabled the formulation of a model of the breakdown process (Barrett, 1985b; Glover & Barrett, 1986a, 1987). Figure 7 illustrates the major stages in the breakdown of tristyly to semi-homostyly in the M morph of *E. paniculata*. The model emphasizes two key stages: loss of the *S* allele and hence the S morph, and second, loss of the *m* allele and thus the L morph. Stochastic influences on population size, as discussed above, are thought to be largely responsible for the disappearance of the S morph from populations. However, because of its concealed stigma, a loss of specialized long-tongued pollinators in small populations may also reduce the maternal fitness of the S morph and hence its representation in founding populations. Comparisons of the fecundity of floral morphs in populations serviced by either long-tongued bees (*Florilegus festivus* and *Ancyloscelis* spp.) or generalist bees (*Trigona* spp. and *Apis mellifera*) provide evidence in support of this suggestion (S. C. H. Barrett, unpubl. data).

Loss of the L morph and fixation of the M morph in populations of *E. paniculata* are associated with the spread of mating system modifier genes and the evolution of semihomostyly. The genes that modify the short-level stamens of the M morph have no significant phenotypic effects when carried by the L and S morphs. As a result, in dimorphic populations, plants of the M morph frequently display altered stamen positions, whereas the L morph remains unmodified (e.g., fig. 3 in Glover & Barrett, 1986a, and Fig. 6). This pattern is also evident in *E. crassipes* (e.g., fig. 2 in Barrett, 1979). This phenotypic difference between the floral morphs of *E. paniculata* has a profound effect on their mating systems. Unlike tristylous populations where each morph is highly outcrossed, in dimorphic populations the M morph often experiences a high level of self-fertilization, whereas the L morph remains largely outcrossing (Glover & Barrett, 1986a; Barrett et al., 1987; Barrett, 1988a). With this mating asymmetry, and no major fitness differences between progeny arising from them, the M morph will likely replace the L morph. This is because the genes that cause an increased rate of self-fertilization have an "automatic advantage," since the maternal parent will transmit genes via both pollen and ovules to selfed progeny and thus evade the "cost of meiosis" (Maynard Smith, 1978).

An additional advantage that modified M plants possess over other floral morphs is their facility for automatic self-pollination in the absence of pollinating agents. Frequent colonizing episodes resulting in periods of low density are more likely to favor establishment of semi-homostylous variants, and this likely accounts for the predominance of populations monomorphic for the M morph in Ja-

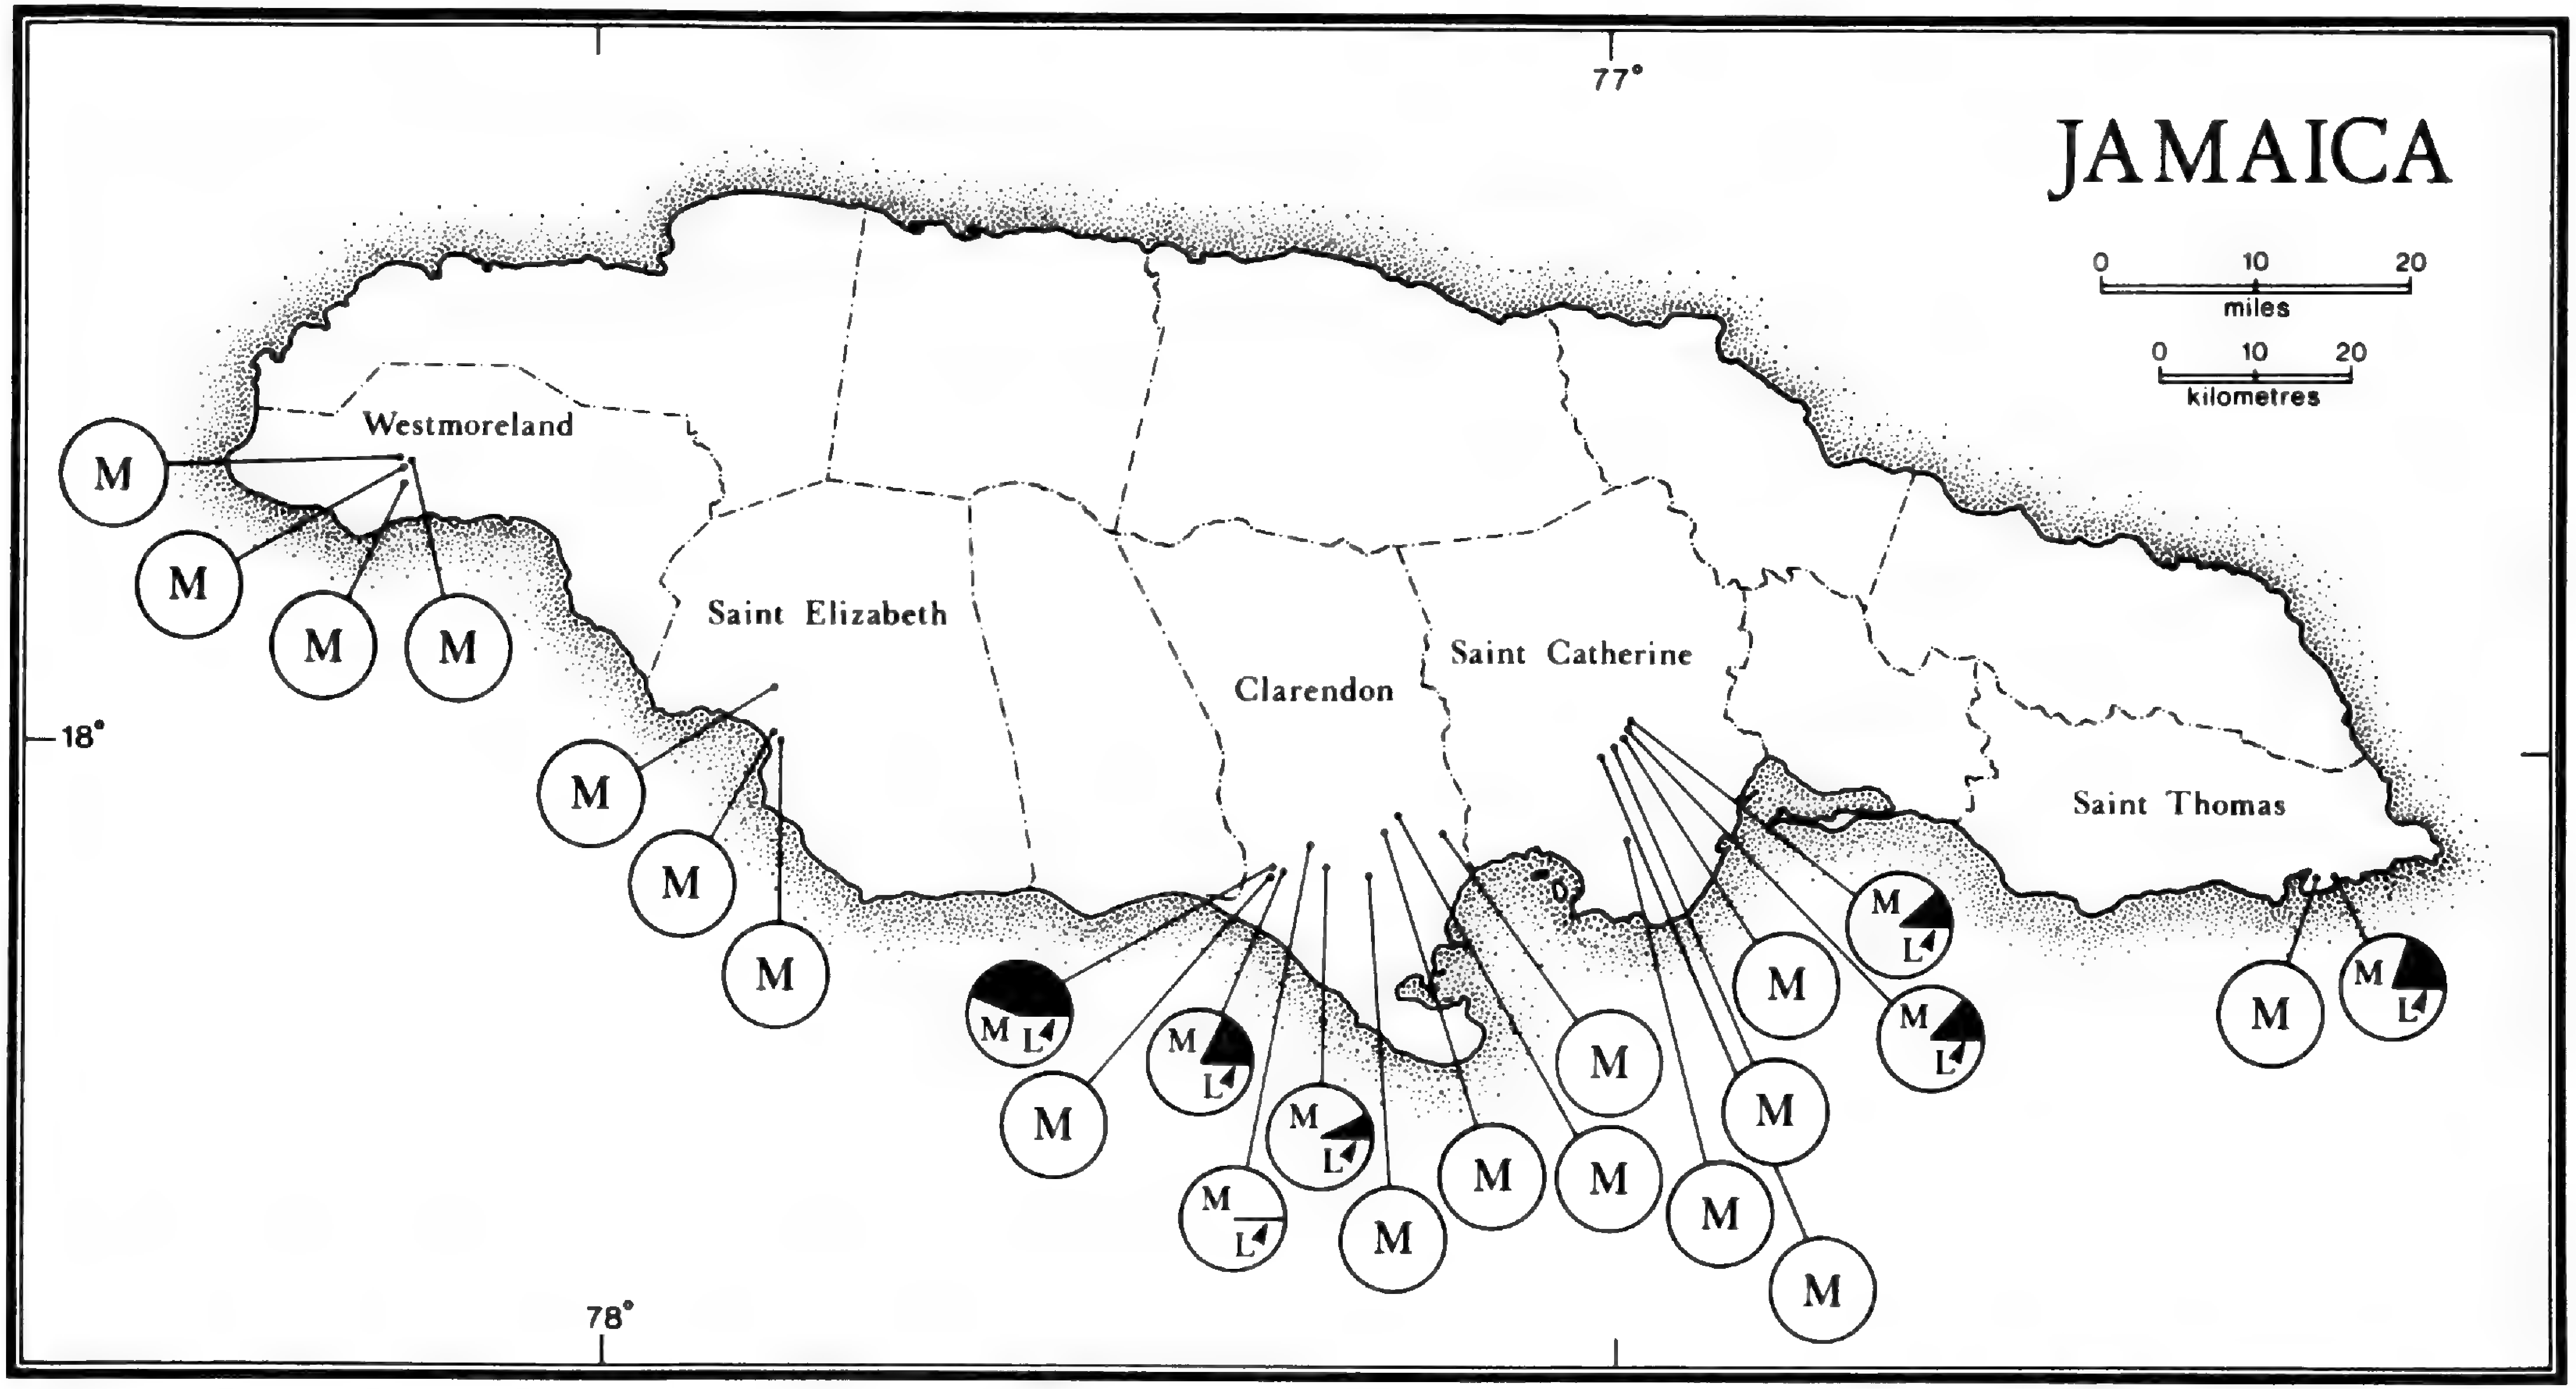

FIGURE 8. *Pattern of style-morph distribution in* Eichhornia paniculata *populations from Jamaica. Surveys were conducted in January 1979, 1984, and 1987. All plants of the M morph in Jamaica exhibit modified short-level stamens and are highly autogamous.*

maica (Fig. 8). The fecundity advantage of semi-homostylous variants of the M morph over the L morph has been demonstrated in Jamaican populations of *E. paniculata* (Barrett, 1988a) as well as in a dimorphic (L, M) population of *E. crassipes* (Barrett, 1979). The reproductive assurance of homostyly under conditions of low density and uncertain pollinator service has been used to explain the geographic patterns of floral variation in several other heterostylous groups (Baker, 1953, 1959; Ganders, 1975; Barrett & Shore, 1987).

FLORAL HETEROMORPHISMS IN SELFING TAXA

A second source of evidence in support of the derived nature of selfing in *Eichhornia* comes from investigation of the patterns of variation in floral traits within and among populations of predominantly autogamous taxa. As we have seen, in monomorphic and dimorphic populations of *E. paniculata*, residual floral heteromorphisms that were originally components of the ancestral tristylous syndrome remain in populations despite their largely selfed mating systems. Although the expression of these traits may be considerably modified from their original form, their occurrence in selfing species of *Eichhornia* is direct evidence that these taxa are descended from tristylous ancestors via evolutionary breakdown of tristyly.

Intrapopulation variation. Over most of the range of *E. heterosperma* and *E. diversifolia*, populations are composed of a single floral phenotype with a mid-length style and one set of anthers positioned just above the stigma and another below (Figs. 9 and 10, respectively). Because flower size is reduced in both species, the distance separating the reproductive organ levels is often small. In some populations this makes it difficult to determine the homologous positions of an ancestral tristylous condition and thereby infer the morphs from which the phenotypes descended. In most populations the phenotypes are best interpreted as semi-homostylous M plants in which elongation of the short stamen level into the mid position has occurred. Although this origin seems most plausible, based on analogy with semi-homostyle formation in outcrossing *Eichhornia* species, the possibility that some phenotypes are modified S plants with elongated styles cannot be ruled out.

Field studies of *E. heterosperma* in Venezuela and *E. diversifolia* in northeast Brazil have revealed a different pattern of floral variation. In both species a second floral phenotype can be found in populations in addition to the phenotype described above. The two phenotypes differ in style length, style coloration, pollen size, and the relative positions of their reproductive parts (Table 5). The expression of traits in the second phenotype indicates that it is a semi-homostyle derived from the L morph. The two semi-homostyles in *E. diversifolia* are illustrated in Figure 10. A trait of particular value in determining the origin of these floral phenotypes is style coloration. In tristylous *Eichhornia* species the three floral morphs differ in the degree of pigmentation of their styles. For example, in *E. crassipes* the L morph has a purple style, the M morph a lavender style, and the S morph a white style (Barrett, 1977a). In *E. diversifolia* and *E. heterosperma* the styles of the two semi-homostyles are pigmented to different degrees with the semi-homostylous L phenotype being either purple (*E. diversifolia*) or pink (*E. heterosperma*) and the semi-homostylous M phenotype light pink or white. In *E. heterosperma*, the two morphs can also differ in perianth color, with the semi-homostylous L phenotype possessing dark blue tepals and the M phenotype pale blue tepals. Differences in perianth color among the floral morphs of *Eichhornia crassipes* have also been reported, although this is not a universal feature of the species throughout its range (Müller, 1883; Haigh, 1936; Barrett, 1977a).

Populations of *E. diversifolia* and *E. heterosperma* that contain the two semi-homostylous phenotypes are largely self-pollinating, and it seems unlikely that the residual polymorphisms have any functional significance. If this is true, we might expect that mutation pressure will eventually break down the discontinuities that currently exist between the forms. Further field studies are required, however, to establish the overall distribution patterns of the morphs and to determine whether fitness differences that relate to floral phenotype exist. A recent survey of *E. diversifolia* populations in Ceará, northeast Brazil, provided no evidence that the two semi-homostylous phenotypes exhibit nonrandom distributions (S. C. H. Barrett, unpubl. data).

The rarity of *E. paradoxa* has restricted our investigations of its floral biology to surveys of herbarium specimens and to experimental studies of two natural populations from Paraiba and Sergipe, northeast Brazil. Even in this small sample several distinct patterns have emerged. The two field populations were each composed of a uniform but different self-pollinating semi-homostylous phenotype. One of these is illustrated in Figure 1B. The arrangement of reproductive parts and style coloration in the phenotypes is similar to the two semi-homostylous forms described above. It there-

Trait	*E. diversifolia* Semi-homostylous L		*E. diversifolia* Semi-homostylous M	*E. heterosperma* Semi-homostylous L		*E. heterosperma* Semi-homostylous M
Mean style length	26.3 ± 0.8	***	21.1 ± 0.9	23.7 ± 0.7	**	22.8 ± 0.6
Mean height of upper stamens	24.1 ± 0.9	***	25.8 ± 1.2	22.4 ± 0.7	***	24.1 ± 0.7
Mean height of lower stamens	18.4 ± 0.8	ns	18.8 ± 1.2	17.7 ± 0.8	***	20.0 ± 0.8

*** $P < 0.001$, ** $P < 0.01$, ns = not significant following Student's *t*-tests.

fore seems reasonable to assume that they are semi-homostylous L and M morphs. This can be confirmed by controlled crosses between the phenotypes, followed by genetic analysis of F_1 and F_2 variation.

Herbarium collections of *E. paradoxa* from a population in Bahia (*Harley 21401* (K), Bahia, Brazil) appear to contain three floral phenotypes that correspond to the L, M, and S morphs of a tristylous system. These plants possess inflorescences that contain many large flowers, and it is possible that the population retains a functionally tristylous breeding system. If this is true, *E. paradoxa* would resemble *E. azurea* and *E. paniculata* in displaying both outcrossing and selfing population systems. Because of its rarity and markedly disjunct distribution, it is probable that the species possesses considerable interpopulation differentiation, with individual populations displaying different stages in the breakdown of tristyly. Further studies of this interesting taxon are planned.

Floral monomorphism. Studies of the remaining two *Eichhornia* species (*E. natans* and *E. meyeri*) have as yet provided no evidence of polymorphisms in floral traits associated with the heterostylous syndrome. Both species exhibit mid-length styles and two stamen levels positioned very close to the stigma, one above and one below (Fig. 9B for *E. meyeri*). *Eichhornia natans* has highly reduced uniform blue flowers, and it is possible that the species is "quasi-homostylous" rather than semi-homostylous (see Ornduff, 1972). In quasi-homostyly the close juxtaposition of anthers and stigmas results from the reduced size of flowers rather than from genetic modifications in the relative positions of reproductive parts. Glasshouse studies of *E. meyeri* material collected from Paraguay (*Billiet & Jadin 3211* (BR), Nueva Asunción, Paraguay) indicate that the species is self-compatible, highly autogamous, and without residual pollen-size heteromorphism. The flowers of this collection are illustrated in Figure 9. Further work on both species is required to establish firmly the relationships of their breeding systems to an ancestral tristylous condition. This may be difficult if both species have lost all of the polymorphic variation associated with the tristylous syndrome. In *E. natans* this could have occurred through a genetic bottleneck during dispersal and establishment on the African continent. In *E. meyeri* progressive extinctions leading to its current rarity may have had a similar effect.

CONCLUSIONS

Studies of intraspecific and interspecific patterns of variation in the breeding systems of *Eichhornia* species indicate that tristyly has broken down repeatedly in the genus to give rise to predominantly selfing population systems. This conclusion rests on two lines of evidence: 1) the evolution of semi-homostylous forms within each of the three primarily tristylous species (*E. azurea*, *E. crassipes*, *E. paniculata*), and 2) the occurrence of residual floral heteromorphisms in several of the largely autogamous semi-homostylous species (*E. diversifolia*, *E. heterosperma*, *E. paradoxa*). The pathway of evolution from outcrossing to selfing in *Eichhornia* appears to be the only major shift in breeding system in the genus. This contrasts with the Lythraceae and Oxalidaceae, where, in addition to semi-homostyle formation, stable distylous breeding systems have evolved from tristyly (Mulcahy, 1964; Ornduff, 1972; Lewis & Rao, 1971; Weller, 1976; Charlesworth, 1979).

The selective pressures responsible for the change from outbreeding to inbreeding are always difficult to identify (Jain, 1976); however, ecological and genetic studies of *Eichhornia* populations have provided some insights into the conditions that foster the breakdown of tristyly. Genetic bottlenecks resulting from long-distance dispersal, as well as colonization of unpredictable habitats with uncertain moisture regimes play major roles in disrupting the maintenance of tristyly. Two features of *Eichhornia* species make them particularly prone to these effects: 1) their small-seeded habit favoring bird dispersal, and 2) their occurrence in tropical aquatic habitats that are susceptible to frequent droughts. These aspects of *Eichhornia* ecology result in frequent colonizing episodes and periodic fluctuations in population size. Under these influences, ecological and genetic conditions are likely to favor the establishment and spread of selfing genotypes. In small newly founded populations, serviced by unreliable generalist pollinators, semi-homostylous variants are likely to be at a selective advantage because of the reproductive assurance that autonomous self-pollination provides. In addition, the genetic load of populations may be sufficiently low, owing to frequent bottlenecks (see Lande & Schemske, 1985), that inbreeding depression may not be a serious obstacle to the spread of semi-homostylous variants.

Our discussion of the breakdown of tristyly in *Eichhornia* has focused primarily on details of the ecology and genetics of natural populations. However, for a comprehensive model of the breakdown process to be obtained, information from morphology and development needs to be integrated with studies from population biology. This is of particular importance in heterostylous groups, because the floral morphs can respond differently to selection and drift as a result of their particular floral morphologies and inheritance patterns. While in *Eichhornia* mutations affecting floral structure and mating system can arise in each morph, the available evidence indicates that the M morph is more susceptible to evolutionary modification. This may be because developmental constraints restrict the range of floral modifications that can occur in the L and S morphs. In addition, the S morph is frequently lost from populations through stochastic processes and may rarely encounter the selection pressures operating in small populations that favor the evolution of self-fertilization. Thus loss of the S morph may simply reflect a genetic constraint imposed by the two-locus system of inheritance of tristyly. While frequent colonizing episodes and ecological radiations into temporary aquatic habitats appear to be the major driving forces responsible for the evolution of breeding systems in *Eichhornia*, constraints imposed by the morphology and genetics of the polymorphism have guided the nature of the floral modifications that have occurred.

DISTYLY AND MONOMORPHISM IN *VILLARSIA* (MENYANTHACEAE): SOME EVOLUTIONARY CONSIDERATIONS[1]

Robert Ornduff[2]

ABSTRACT

Distyly occurs in four of the five genera of the Menyanthaceae, as do breeding systems such as dioecy, gynodioecy, and homostyly that are believed to be derived from distyly. Most species of the largely Australian genus Villarsia *are distylous, but the Western Australian* V. albiflora *has monomorphic (nonheterostylous) flowers and appears to be homostylous. Despite this, individuals of this species are self-incompatible, although most members of the four populations studied are intercompatible. The incompatibility system of* V. albiflora *appears to be controlled by multiple alleles. Another Western Australian species,* V. parnassiifolia, *has distylous flowers and strong self-incompatibility. Long × Long crosses of this species fail to produce seeds, but Short × Short crosses commonly produce a full complement of seeds. Thus, this species possesses a self-incompatibility system, but Shorts have an unexpectedly high degree of intramorph intercompatibility, suggesting that the incompatibility system of this morph likewise is controlled by multiple alleles. Five of eight natural populations sampled of* V. parnassiifolia *showed Short-dominated morph ratios, suggesting that offspring of Short × Short pollinations may constitute a portion of these Short-dominated natural populations.* Villarsia albiflora *may represent a recombinant homostyle, a true-breeding Short morph derived from a distylous ancestor with a breeding system similar to that of* V. parnassiifolia, *or a species possessing a floral morphology and breeding system ancestral to the distyly that occurs widely in the Menyanthaceae. A scheme for the origin of distyly in* Villarsia *is presented.*

The Menyanthaceae consist of five genera of wetland or aquatic herbs. *Menyanthes* and *Fauria* (*Nephrophyllidium*) are monotypic north-temperate genera, both of which bear distylous flowers. *Nymphoides* is widely distributed in tropical and temperate regions of both hemispheres; distyly is common in this large genus, as are derivative breeding systems such as dioecy, gynodioecy, and autogamy associated with homostyly (Ornduff, 1966, 1970b, 1973; Vasudevan Nair, 1975). *Liparophyllum* is a monotypic genus restricted to New Zealand and Tasmania; its flowers are monomorphic and the species is self-compatible (Ornduff, 1973). *Villarsia* occurs in southeastern Asia, South Africa, and Australia, with the largest concentration of species in southwestern Western Australia. Several Australian *Villarsia* species have distylous flowers and an associated self- and intramorph incompatibility system (Ornduff, 1974, 1982, 1986, 1988; Fig. 1). My recent work has revealed that some species of *Villarsia* with distylous flowers have various altered incompatibility systems; one of these species, the Western Australian *V. parnassiifolia* (Labill.) R. Brown, is discussed in this paper. Another species, *V. albiflora* F. Muell., is a Western Australian species which has nonheterostylous flowers (Fig. 1), a self-incompatibility system, and essentially full intercompatibility among members of a population. This species is thus not the self-compatible homostyle of the type that commonly occurs in various other predominantly distylous genera (Richards, 1986). This paper documents the nature of the incompatibility systems of *V. parnassiifolia* and *V. albiflora* and discusses the possible relationships between the unique breeding system of *V. albiflora* and those that occur in other species of *Villarsia*. Since work on these two species, as well as others of the genus, is still in progress, this report is preliminary.

MATERIALS AND METHODS

Seeds were collected in 1983 from four populations of *Villarsia albiflora* in Western Australia:

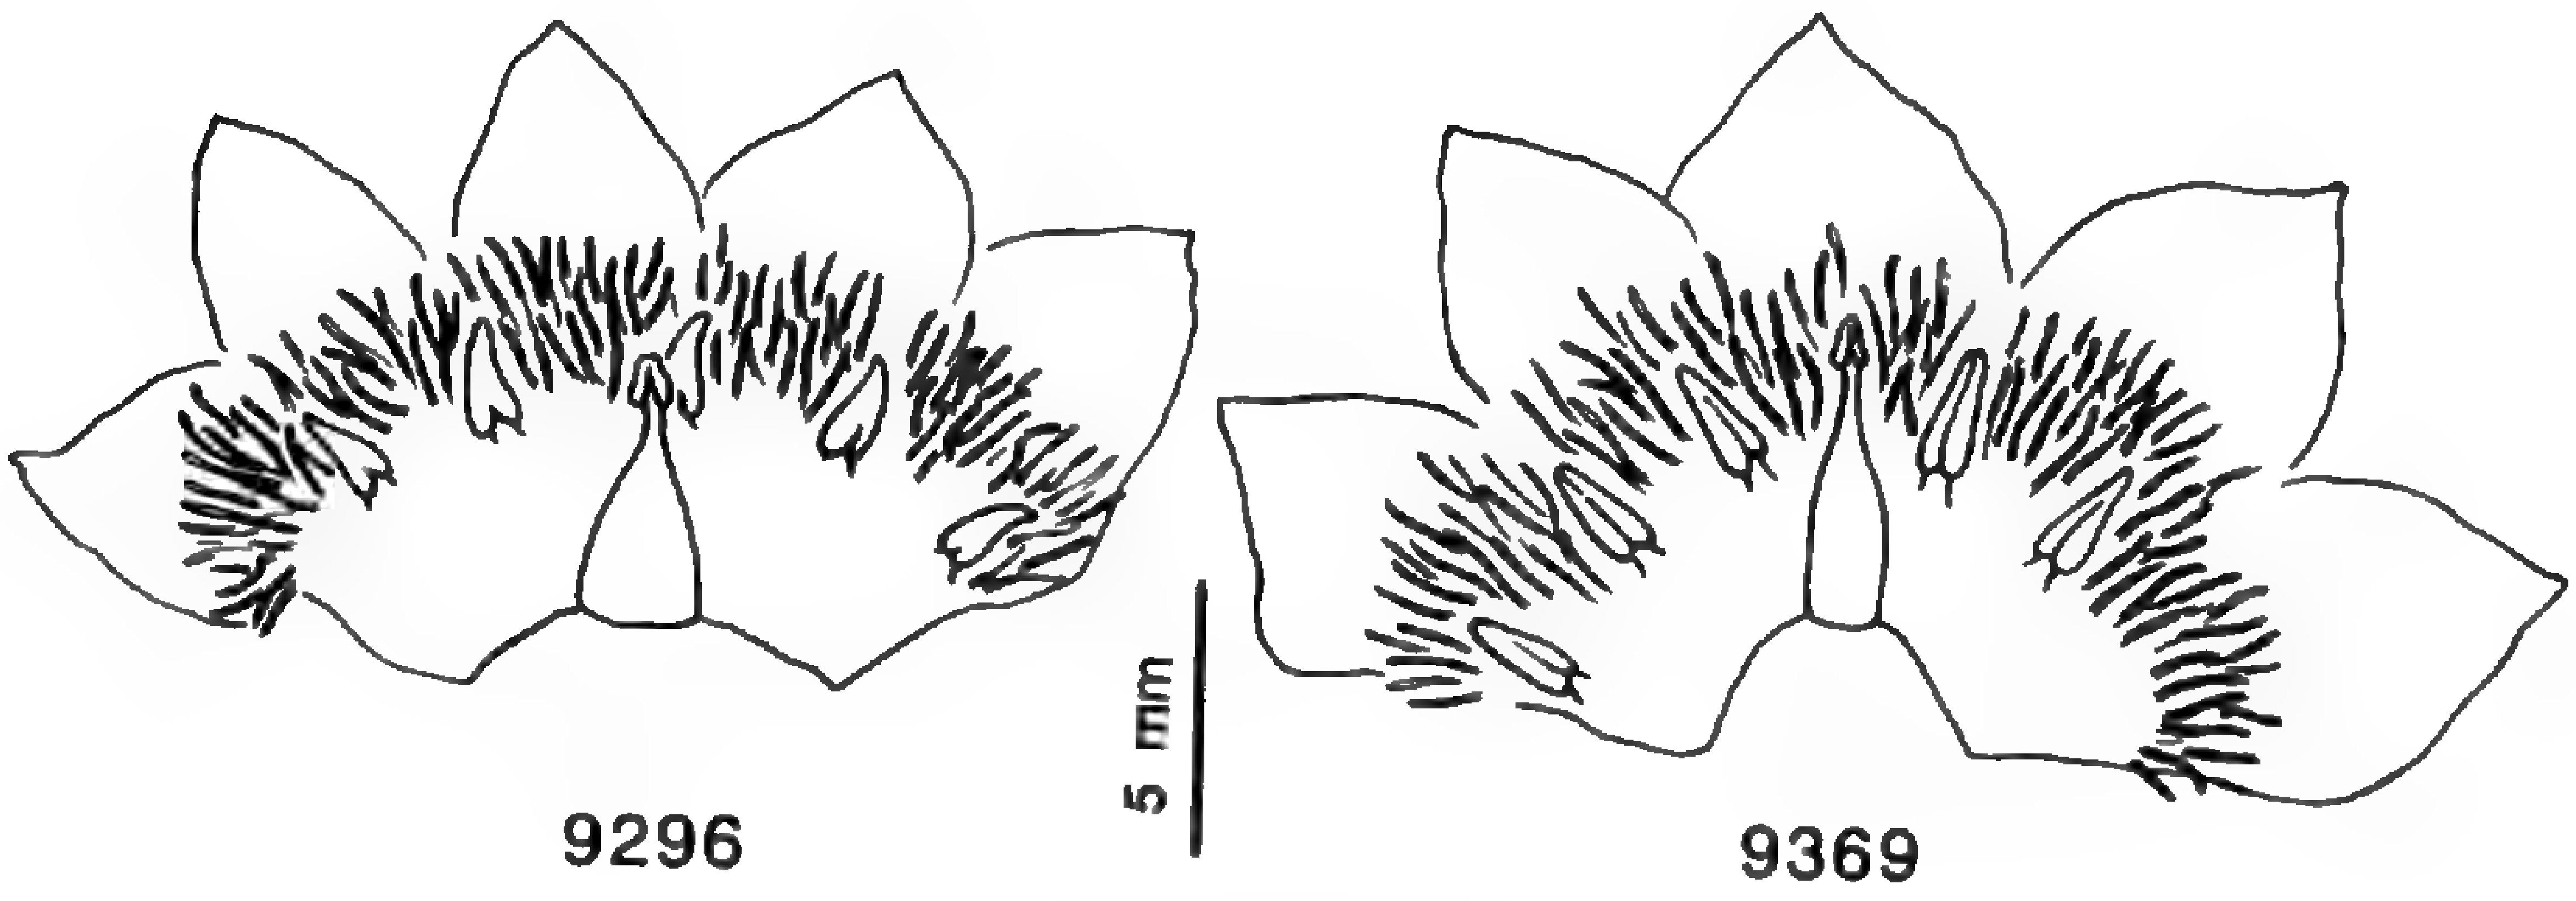
Villarsia parnassiifolia (9404)



Villarsia albiflora

FIGURE 1. *Dissections of distylous flowers of* Villarsia parnassiifolia *and of monomorphic flowers of* V. albiflora.

9296, Gnangara Lake, near Perth; 9365, Medina, near Perth; 9369, the Capel-Boyanup area; and 9397, near Mount Chudalup. This sampling encompasses most of the geographical range of this species, which is diploid (Ornduff & Chuang, in press). At the same time, seeds were also collected from two populations of *V. parnassiifolia*: 9404, a diploid population near Walpole, and 9413, a tetraploid population at Parry Beach, near Denmark (Ornduff & Chuang, in press), both occupying central positions in the range of this species along the southern coast of Western Australia. Plants were grown from these seeds in the greenhouses at the University of California, Berkeley. Thirty-eight individuals of *V. albiflora* and 10 long-styled plants (Longs) and 13 short-styled individuals (Shorts) of *V. parnassiifolia* were used in the crossing program. Each individual in a progeny was assigned a plant number for reference purposes. Each plant was self-pollinated and crossed with as many other individuals in the population as possible during the spring and summer of 1986 and 1987. At least six pollinations for each type of cross were performed. Nearly mature capsules were collected individually in seed envelopes, and the number of seeds counted. Flowers of self- and cross-pollinated plants of both species were collected 24 hours after pollination, the gynoecium excised, mounted, stained, and observed under ultraviolet light to observe the behavior of pollen and pollen tubes following various types of pollinations (using the method of Martin, 1959). Seeds of intra- and intermorph crosses of *V. parnassiifolia* (population 9413) were sown in a greenhouse, the seedlings grown to flowering, and the style lengths of each individual recorded.

RESULTS

All seed-set figures were assigned arbitrarily to one of three categories (Figs. 2, 3). "High" seed production refers to crosses in which all pollinations produced capsules with large numbers of seeds; "intermediate or variable" seed production includes crosses in which seed production was markedly lower than the "high" category of that seed parent, or in which some crosses failed to produce seed; and "low" seed production refers to crosses producing few or no seeds. These categories will not be quantified in this paper because of high variances in the first two categories and the small number of pollinations (a minimum of six) con-

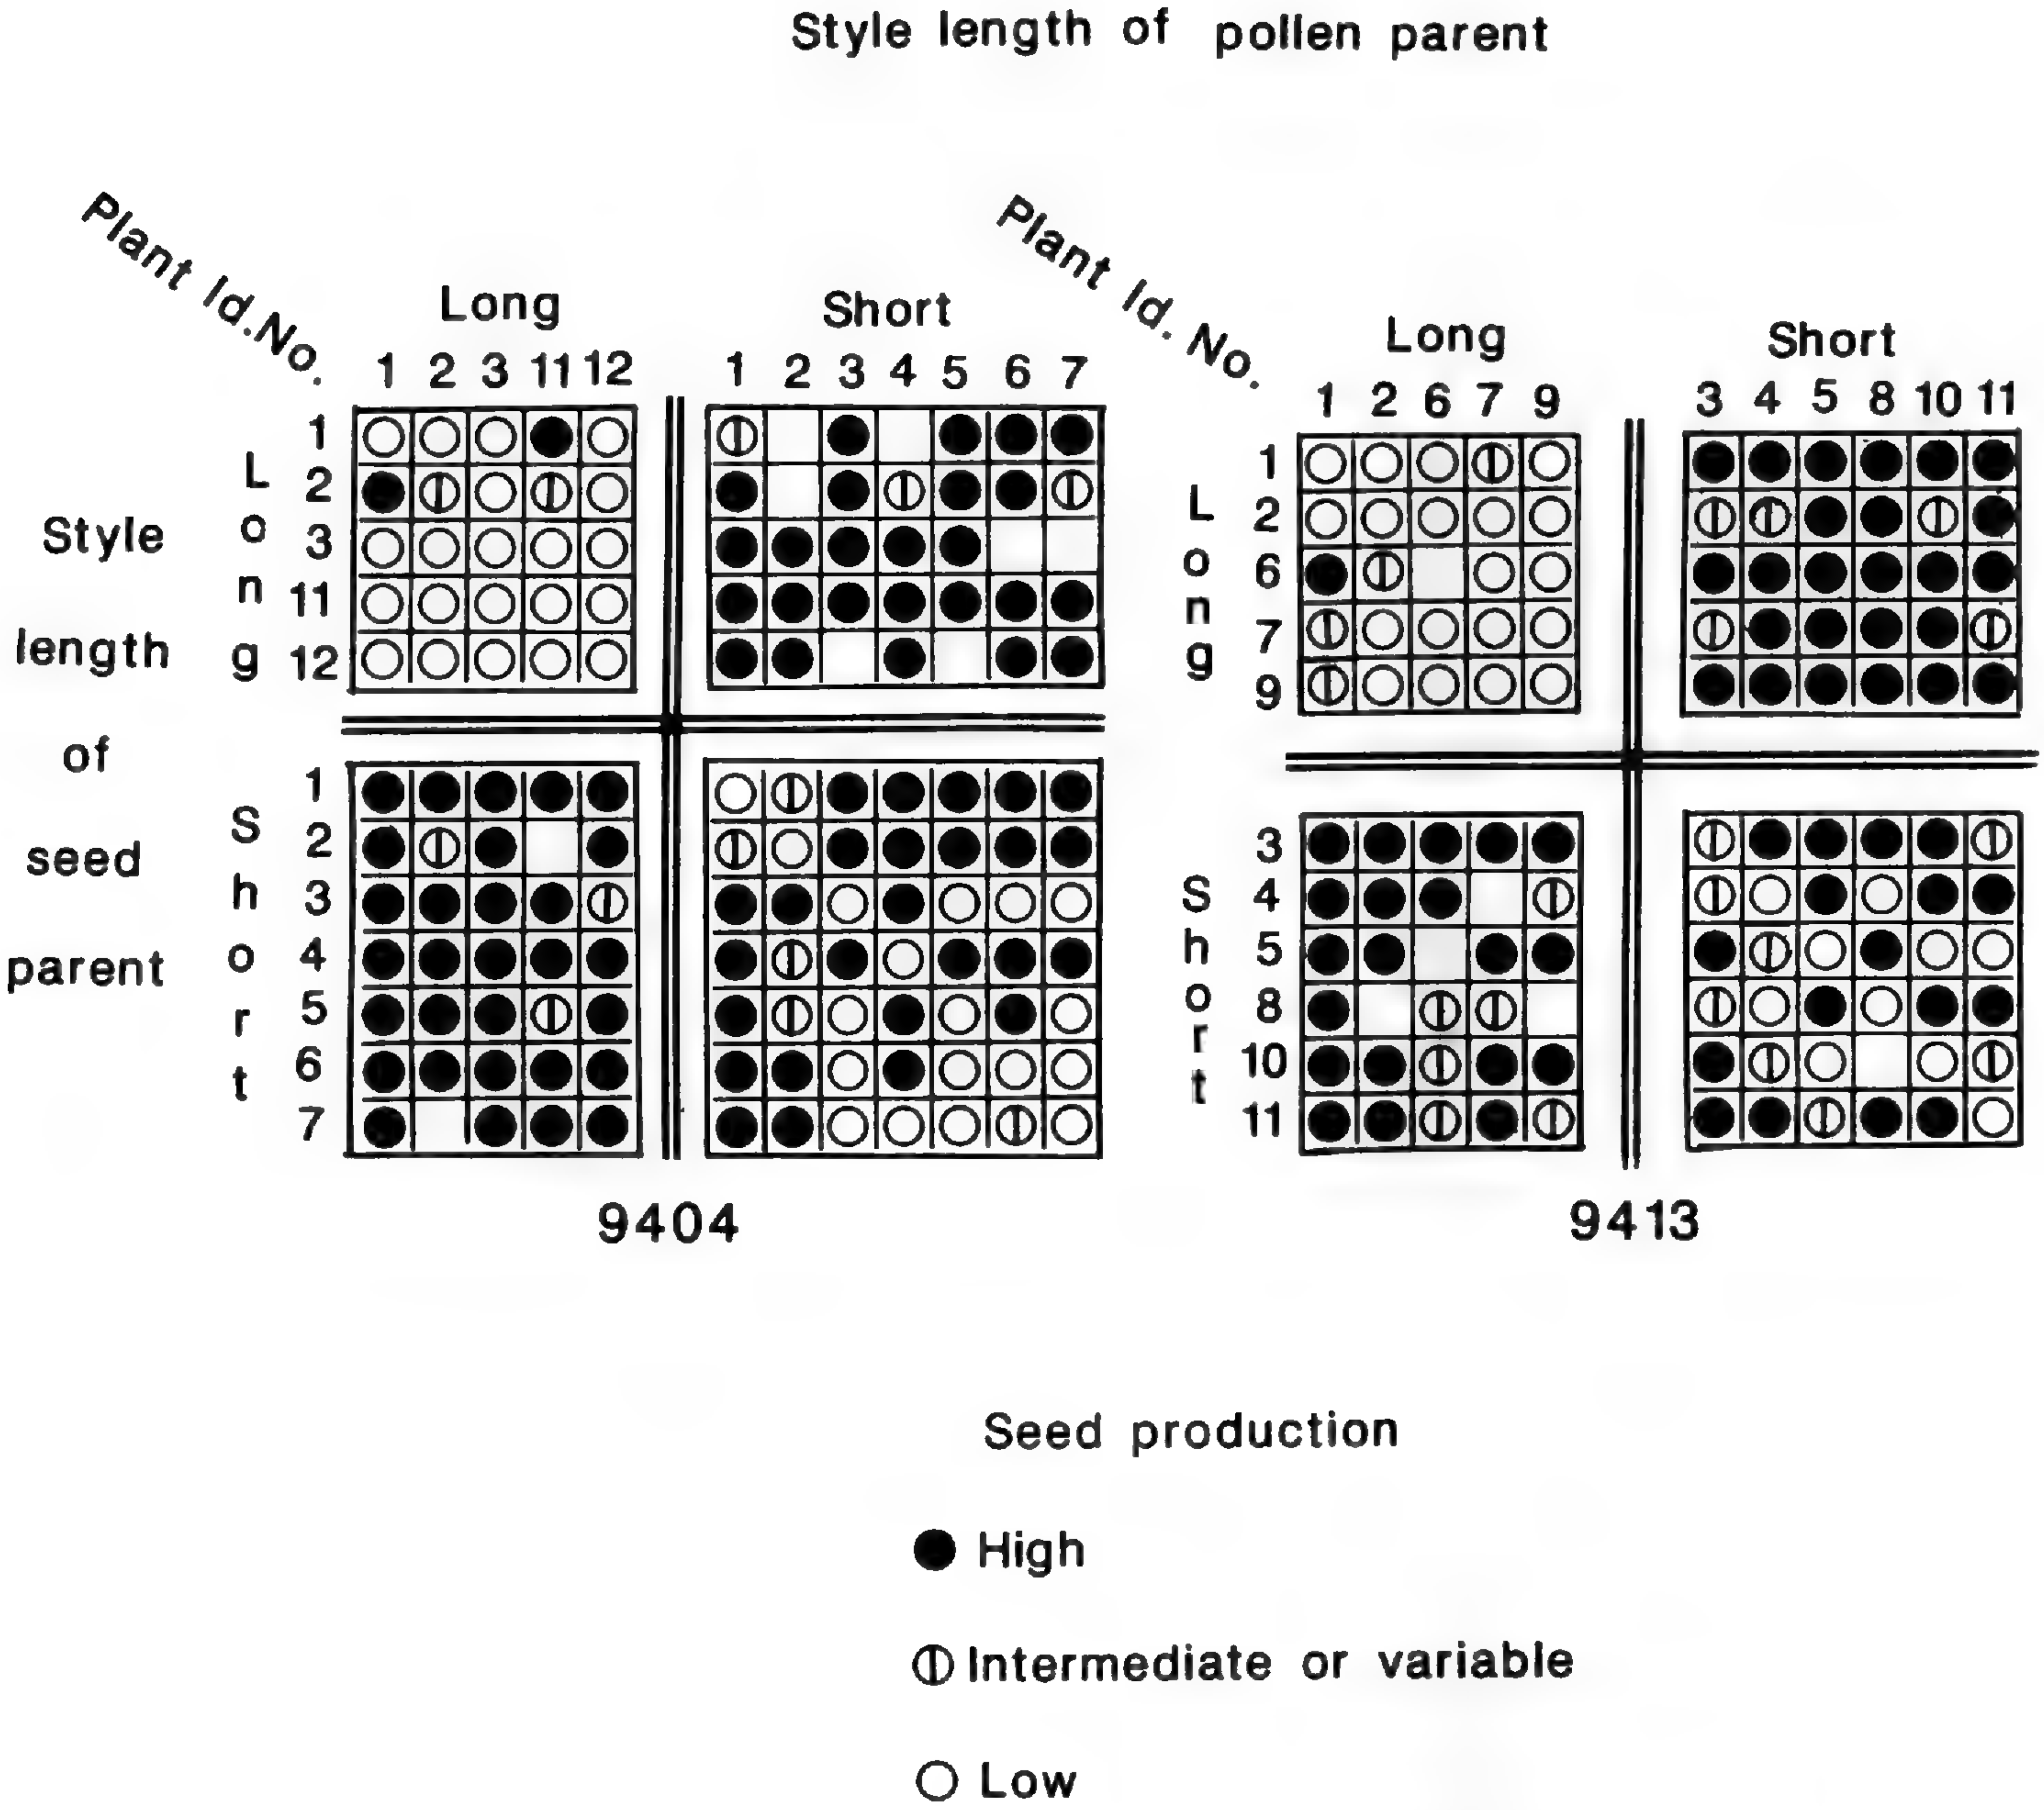


FIGURE 2. *Seed production following artificial self- and cross-pollinations of the two morphs of the distylous* Villarsia parnassiifolia, *using two greenhouse-grown populations. The vertical and horizontal series of numbers refer to individual plants in each population. Seed production figures are described in text.*

ducted for each cross. Additional work is planned to increase the sample sizes. However, I am confident that the "high" and "low" categories represent two distinct types of results and provide a meaningful and relatively consistent basis on which to discuss the nature of the breeding systems in the two *Villarsia* species discussed in this paper. Whether the "intermediate or variable" category represents something other than a procedural artifact awaits additional data.

Villarsia parnassiifolia. Longs and Shorts of this species are strongly self-incompatible; only one of the nine selfed Longs and one of the 13 selfed Shorts produced any seeds following selfing (Fig. 2). Intermorph pollinations produced generally high seed-sets: 50 of the 58 Long × Short pollinations and 51 of the 60 Short × Long pollinations produced high seed-sets. Only three of the 40 Long × Long crosses produced a high seed-set, and an additional six of these crosses produced some seeds, indicating a high level of intramorph incompatibility of Longs. In contrast, 43 of the 71 Short × Short crosses produced high seed-sets, and an additional 13 of the crosses produced some seed, indicating a high level of intramorph compatibility of Shorts. Each Short in the two populations was fully compatible with at least one other Short in that population, and a few Shorts were compatible with most other Shorts in the same population. Most successful Short × Short crosses were successful in both directions, and most that failed did so in both directions. No differences were noted in behavior between the diploid and the tetraploid populations of *V. parnassiifolia*.

Crosses between four Longs and four Shorts of tetraploid population 9413 all produced both Longs

Seed production

● High

⦶ Intermediate or variable

○ Low

FIGURE 3. *Seed production following artificial self- and cross-pollinations of the monomorphic* Villarsia albiflora, *using four greenhouse-grown populations. The vertical and horizontal series of numbers refer to individual plants in each population.*

and Shorts in each progeny. Five Shorts of this population used in five Short × Short crosses produced Longs only in one progeny, Shorts only in two progenies, and Longs and Shorts in two progenies. Two 9413 Shorts selfed produced Longs and Shorts in each progeny. Two Long × Long crosses produced only Longs in their progenies. Although the progeny sizes are small, these results make it likely that the Shorts carry a dominant allele and Longs are homozygous recessive.

Villarsia albiflora. Results of pollinations using 38 individuals in four populations of *V. albiflora* provided relatively consistent results. All individuals proved to be self-incompatible, producing few or no seeds upon self-pollination (Fig. 3). Pollen grains on selfed stigmas either failed to germinate or germinated with growth of the pollen tube into stigmatic tissue but not further. Most individuals produced high seed-sets when crossed with other individuals in the population. Most crosses that failed in one direction were successful in the other direction, or provided seed-sets in the "intermediate or variable" category in that direction. Only one instance was found of apparent bilateral incompatibility (between plants 4 and 16 of population 9369). Thus, the nonheterostylous *Villarsia albiflora* has a pronounced self-incompatibility system, but most members of each population are intercompatible.

DISCUSSION

Villarsia parnassiifolia has morphologically distylous flowers and a strong self-incompatibility system. Although Long × Long crosses generally failed to produce seeds, most Short × Short crosses were fully compatible, producing high seed-sets. No differences were observed in the behavior of diploids and tetraploids. Self- and intramorph incompatibility are commonly associated with distyly, and in most examples where intramorph compatibility exists, as in some species of *Hedyotis* (Rubiaceae), *Melochia* (Sterculiaceae), and *Amsinckia* (Boraginaceae), it is associated with self-compatibility as well (Ganders, 1979).

The occurrence of self-incompatibility but intramorph compatibility in distylous species is rare. It has been reported in the borages *Anchusa hybrida* Ten. (Dulberger, 1970) and *A. officinalis* L. (Philipp & Schou, 1981). I am reluctant to consider the examples of *Narcissus tazetta* L. and *Mirabilis froebelii* (Behr) Greene cited by these authors to represent heterostyly. In *Anchusa officinalis*, Schou & Philipp (1984) demonstrated that the morphological features of distyly are controlled by a single diallelic locus, with Longs homozygous recessive and Shorts with one or two dominant alleles, which is the common genetic basis of distyly (Ganders, 1979). However, as Dulberger (1970) suggested is the case for *Anchusa hybrida*, the incompatibility system of *A. officinalis* is controlled by at least two alleles, and these segregate independently from those controlling the morphological features of distyly (Schou & Philipp, 1984).

The condition described in *Villarsia parnassiifolia* resembles that of the two *Anchusa* species but differs in that the Long but not the Short morph of *V. parnassiifolia* possesses intramorph- as well as self-incompatibility. It would appear that in the Long morph of this species the incompatibility alleles are linked to the "morphological" locus, but in the Short morph they are not. How this is accomplished (if it is) is unclear.

Style lengths of the few small progenies obtained by self- and intramorph pollinations of the tetraploid population of *Villarsia parnassiifolia* are consistent with the notion that the Short morph of this species carries a dominant allele with Longs thus homozygous recessive, but exact interpretation of the scant data may be obscured by tetrasomic inheritance. Short-dominated morph ratios occur in five of the eight field populations sampled of this species (Ornduff, 1986; $P = <0.05$ with the Wilcoxon's signed-ranks test), suggesting that under field conditions Short × Short crosses commonly participate in contributing to the composition of natural populations.

The floral morphology of *Villarsia albiflora* suggests that it is a homostyle, but this tentative conclusion requires examination. In genera or families with both distyly and homostyly, the homostylous condition is usually viewed as the result of genetic recombination in the S "supergene," leading to production of flowers combining carpel characters of one morph with stamen characters of the other morph. Commonly, such homostyles are Long-homostyles, although Short-homostyles are also known. Homostyly has been recorded in diverse genera such as *Armeria* (Plumbaginaceae; Baker, 1966), *Gelsemium* (Loganiaceae; Ornduff, 1970c), *Limonium* (Plumbaginaceae; Baker, 1953), *Nymphoides* (Menyanthaceae; Ornduff, 1970a), *Oldenlandia* (Rubiaceae; Bir Bahadur, 1970), *Piriqueta* (Turneraceae; Ornduff, 1970a), *Primula* (Primulaceae; Darwin, 1877; Ernst, 1955), *Turnera* (Turneraceae; Urban, 1883; Barrett & Shore, 1987), *Villarsia* (Menyanthaceae; Ornduff, 1974), and *Waltheria* (Sterculiaceae, Bir Bahadur, 1977). Because a single homostyle flower usually bears a combination of pollen of one morph with carpels of the other morph, such homostyles are generally self-compatible and sometimes largely autogamous. Other types of homostyles occur in *Amsinckia* (Boraginaceae; Ray & Chisaki, 1957), *Hedyotis caerulea* (Rubiaceae; Ornduff, 1977), *Mitchella repens* (Rubiaceae; Ganders, 1975), and *Primula* (Primulaceae; Ernst, 1955). The nature and placement of anthers and stigmas of these homostyles vary, but cannot be attributed to genetic recombination alone and must involve the additional action of modifier genes. Such homostyles may be self-compatible (as in *Amsinckia* and some species of *Primula*) or self-incompatible (as in *Mitchella repens*, *Hedyotis caerulea*, and some species of *Primula*). In the latter examples, self-incompatible homostyles appear to be very rare or known only from cultivated material (Ganders, 1975). Once homostyly has developed, even as a result of simple genetic recombination, carpel, stamen, and other floral traits may subsequently be altered by modifier genes to accommodate the homostyly in the direction of greater autogamy (as apparently is the case in *Piriqueta cistoides*, Ornduff, 1970a) or in the direction of greater xenogamy (as apparently is the case for some races of *Turnera ulmifolia*; Barrett, 1988).

The nature and origin of the floral monomorphism of *Villarsia albiflora* are not clear. If we assume for purposes of discussion that this species represents a recombinant homostyle, its self-incompatibility and essentially full intercompatibility are consistent with the idea that style-length and incompatibility reactions are not uniformly controlled by sets of linked alleles in distylous *Villarsia* species. However, since incompatibility of Short pollen but not Long pollen appears to be unlinked to style length, this may require that the putative homostyly of *V. albiflora* is Long-homostyly (i.e., the style of Longs combined with anther position and incompatibility behavior of Shorts in one flower) rather than Short-homostyly. Whether this supposition will survive the scrutiny of further study remains to be seen.

A second, perhaps more attractive (or at least potentially less flawed) hypothesis is that the monomorphism of *V. albiflora* represents a situation in which the flowers of this species are fundamentally Shorts, and in which the Longs of a presumed distylous ancestor have been lost. The anther position and stylar morphology of *V. albiflora* resemble those of Shorts of *V. parnassiifolia* more closely than they do those of Longs of that species (Fig. 1). Short × Short pollinations of *V. parnassiifolia* are mostly compatible ones that produce vigorous offspring under artificial and, apparently, natural conditions. It is possible that in the evolution of *V. albiflora*, a postulated distylous ancestor lost the *s* allele and thus the Long morph, leading ultimately to a condition where populations consist of true-breeding homozygous Shorts carrying only the dominant *S* allele. If this postulated ancestor possessed the breeding system and Short-dominated morph ratios characteristic of *V. parnassiifolia* today, periodic severe reductions in population size as a consequence of the cyclic fluctuations in annual rainfall that have characterized southwestern Western Australia since mid or late Tertiary times (Hopper, 1979) might have resulted in the loss of the *s* allele and thus the loss of Longs. This would result in true-breeding homozygous Shorts as the exclusive components of surviving populations. Since *Villarsia* typically occurs in mesic to aquatic circumstances, recurrent xerothermic periods could have had strong effects on population sizes and distribution of species in this genus.

Because of the occurrence of distyly in four of the five genera of Menyanthaceae, it is natural to assume that the floral condition and incompatibility system of *V. albiflora* are derivative ones from a distylous antecedent. A third evolutionary scenario contrary to this directionality in evolution is that the floral monomorphism of *V. albiflora* is primary in the genus and that distyly elsewhere in *Villarsia* has been derived from this type of monomorphism. Starting with a self-incompatible nonheterostylous species similar to *Villarsia albiflora* (which today shows some interpopulation variability in position of stigmas relative to anthers, Fig. 1; Ornduff, 1986), selection might operate to favor increased distance between stigmas and anthers as a means of reducing pollen wastage by selfing. One means of achieving this could be via style-length dimorphism associated with a slight shifting of anther position (the positions of anthers in the two morphs of the distylous *V. parnassiifolia* are not very different; Fig. 1). Initially, the alleles controlling floral dimorphism would be unlinked to those multiple alleles controlling the incompatibility reaction (as in *Anchusa*). Gradually, linkage between these two sets of alleles would develop with a concomitant decrease in the number of incompatibility alleles; in *Villarsia parnassiifolia* such a linkage appears to occur in Longs but not in Shorts. Ultimately, the alleles controlling floral dimorphism would be tightly linked to those controlling incompatibility, the latter having been reduced to a pair of alleles at a single locus. At this point, distyly of the conventional type that occurs in a variety of unrelated genera would have been achieved. In *Villarsia*, such "conventional" distyly and incompatibility occur in *V. capitata* Nees (Ornduff, 1982) and *V. congestiflora* F. Muell. (Ornduff, 1988).

Assuming this latter scheme represents an approximation of the sequence of events in the evolutionary history of *Villarsia*, it would explain an apparent anomaly that I commented on many years ago, namely that *V. capitata* and *V. congestiflora* "possess an unusual combination of highly advanced characters" with the "primitive" one of distyly (Ornduff, 1982). If distyly is indeed a condition that has developed from monomorphism within *Villarsia*, this anomaly is resolved, since distyly is thus viewed as advanced and not primitive.

This last suggested series of events is highly speculative. When more information becomes available on the breeding systems of other species of *Villarsia*, this third scenario should be evaluated in the context of different suggestions concerning the mode of origin of distyly proposed or discussed by Charlesworth & Charlesworth (1979), Ganders (1979), Muenchow (1982), and Gibbs (1986).

Clearly, breeding systems in the Menyanthaceae merit further experimental work and theoretical consideration.

WIND POLLINATION IN AQUATIC ANGIOSPERMS

Christopher D. K. Cook[1]

ABSTRACT

Aquatic angiosperms have evolved from terrestrial ancestors several times. About 79 angiosperm families and 380 genera contain aquatic species; 119 genera (31.3%) are wind pollinated. Among these wind-pollinated aquatics, 100 genera have obvious terrestrial relatives that are also wind pollinated. Sixteen genera (4.2%) have no obvious terrestrial relatives but belong to exclusively anemophilous families; the anemophily, however, could be associated with life in water. In only two genera (0.5%), Brasenia *(Cabombaceae) and* Limnobium *(Hydrocharitaceae), is it likely that the evolution from entomophily to anemophily has taken place in the aquatic environment. In* Hydrilla *(Hydrocharitaceae) the pollen grains are heavy and are propelled through air from the male to the female; although this mechanism almost certainly evolved in water, it is not considered to be true anemophily where buoyant grains are carried by air movements. Wind pollination is not considered an important feature especially associated with life in the aquatic environment.*

Crane (1986) suggested that the seeming simplicity of wind pollination has deflected interest in a process that is, in fact, far from straightforward. However, combining the detailed pioneer work on pollen dimensions and pollen production by Pohl (1937a, b) with the physical approaches by Whitehead (1969) and Niklas (1985) and with the renewed morphological approach of Crane (1986), a better view of wind pollination in gymnosperms and terrestrial angiosperms is emerging. Wind pollination and associated characteristics have rarely been studied in aquatic angiosperms.

The main purpose of this review is to collect information bearing on the question of which aquatic plants are pollinated by wind. By comparing these with their terrestrial ancestors it should be possible to find out which of them have modified their pollination mechanisms. In turn, this should give insight into the question: is wind pollination especially associated with the aquatic environment? Perhaps the highest development of aquatic angiosperms is the use of water for the transfer of pollen (hydrogamy). It is also an aim of this review to see if wind pollination is a prerequisite to hydrogamy.

The term aquatic is used in the sense described by Cook et al. (1974); it includes plants whose photosynthetically active parts are submerged in water or floating on the water surface permanently or, at least, for several months each year. Within the angiosperms the aquatics have evolved from terrestrial ancestors several times, as Sculthorpe (1967) pointed out. It is important to appreciate that most aquatic angiosperms resemble terrestrial flowering plants, not only in gross features of floral morphology, but also in exhibiting similar trends of floral specialization. The aquatic members of predominantly anemophilous families Centrolepidaceae, Cyperaceae, Hydatellaceae, Juncaceae, and Poaceae from the point of view of their pollination biology resemble the terrestrial members and are thus not described in detail here.

The first angiosperms were almost certainly insect pollinated, so anemophily is a derived state (for example, see Crane, 1986). It is also clear that wind pollination has originated several times from diverse stocks. Anemophily has evolved at different times from different morphological backgrounds with differing degrees of efficiency. It is not surprising that it is sometimes difficult to make a clear-cut distinction between wind-pollinated plants and those pollinated by other means. Many predominantly wind-pollinated species may be regularly visited by pollen-eating insects (particularly syrphid flies) and may occasionally be pollinated by insects. For such plants Stelleman (1984) used the term ambophily.

Quantitative data on the efficiency of wind pollination or even direct observations are lacking among aquatics. The decision of whether a species is wind pollinated or not is often based on morphological criteria. This is justifiable since there is a whole complex of characters associated with anemophily. The following list attempts to summarize the most important features of this wind pollination syndrome.

ANN. MISSOURI BOT. GARD. 75: 768–777. 1988.

1. The characteristics of wind-borne pollen grains are well summarized by Crane (1986): size 20–40(–60) μm diam., Reynolds number around 0.1 at a terminal velocity of 5 cm sec.$^{-1}$, spread singly, powdery and nonsticky (lipids absent, chemically altered or hidden within the wall), surface relatively smooth, resistant to changes in temperature and to desiccation (size and/or number of apertures reduced).
2. The flowers are usually unisexual: the male must dispense pollen, and the female must catch pollen.
3. The amount of pollen is increased: this is usually achieved by an increase in anther size and is often associated with a decrease in number of anthers in each flower and an increase in number of male flowers.
4. The flowers are usually separated from the leaves (temporally or spatially) and held above the water on specialized structures.
5. The perianth and bracts are reduced (to increase aerodynamic efficiency).
6. There are sometimes special arresting or explosive mechanisms to ensure that pollen gets into the airstream.
7. The number of ovules in each flower is usually reduced; the reason for this is not clear.
8. The stigmas are often specialized to increase "capture" efficiency.

I. Aquatics Previously Considered Anemophilous but Probably Entomophilous

Details of the pollination mechanisms of many aquatic angiosperms are unknown. Many with small and insignificant flowers have been considered to be wind or even water pollinated. The following, which have been thought to be wind pollinated, are probably pollinated by other means; all are illustrated in Cook et al. (1974).

ALISMATACEAE

Ten of the eleven genera have large showy petals; some are scented and have septal nectaries and are clearly insect pollinated. *Wiesneria*, a genus with two African and one Asian species, recently redescribed by Sivadasan (1986), has whorled, subsessile, unisexual flowers with small and reflexed perianths. The male flowers, which are borne above the females, have three stamens, the lowest number in the family. The carpels are reduced to three or four in each female flower. These characters may suggest anemophily, but the inflorescences are shorter than and partly hidden by the leaves; the petals, though small, are cream-colored and relatively conspicuous; the anthers are small (ca. 1 mm long); the filaments are short (ca. 0.5 mm long); the pollen grains are echinate, have numerous apertures (Fig. 6), and are somewhat sticky. These characters strongly suggest insect pollination. It is not known if *Wiesneria* is scented or if it produces nectar.

APONOGETONACEAE

Aponogeton, the only genus, sometimes has catkinlike inflorescences. A few species have unisexual flowers, and sometimes the perianth is reduced. These features suggest wind pollination. However, the pollen has supratectal spines in all species (see Bruggen, 1985) and most species investigated to date have septal nectaries and are strongly scented. *Aponogeton* is insect pollinated, but in some species some pollen may be transferred by wind. This is unlikely, however, as the pollen grains stick together in clumps.

ARACEAE

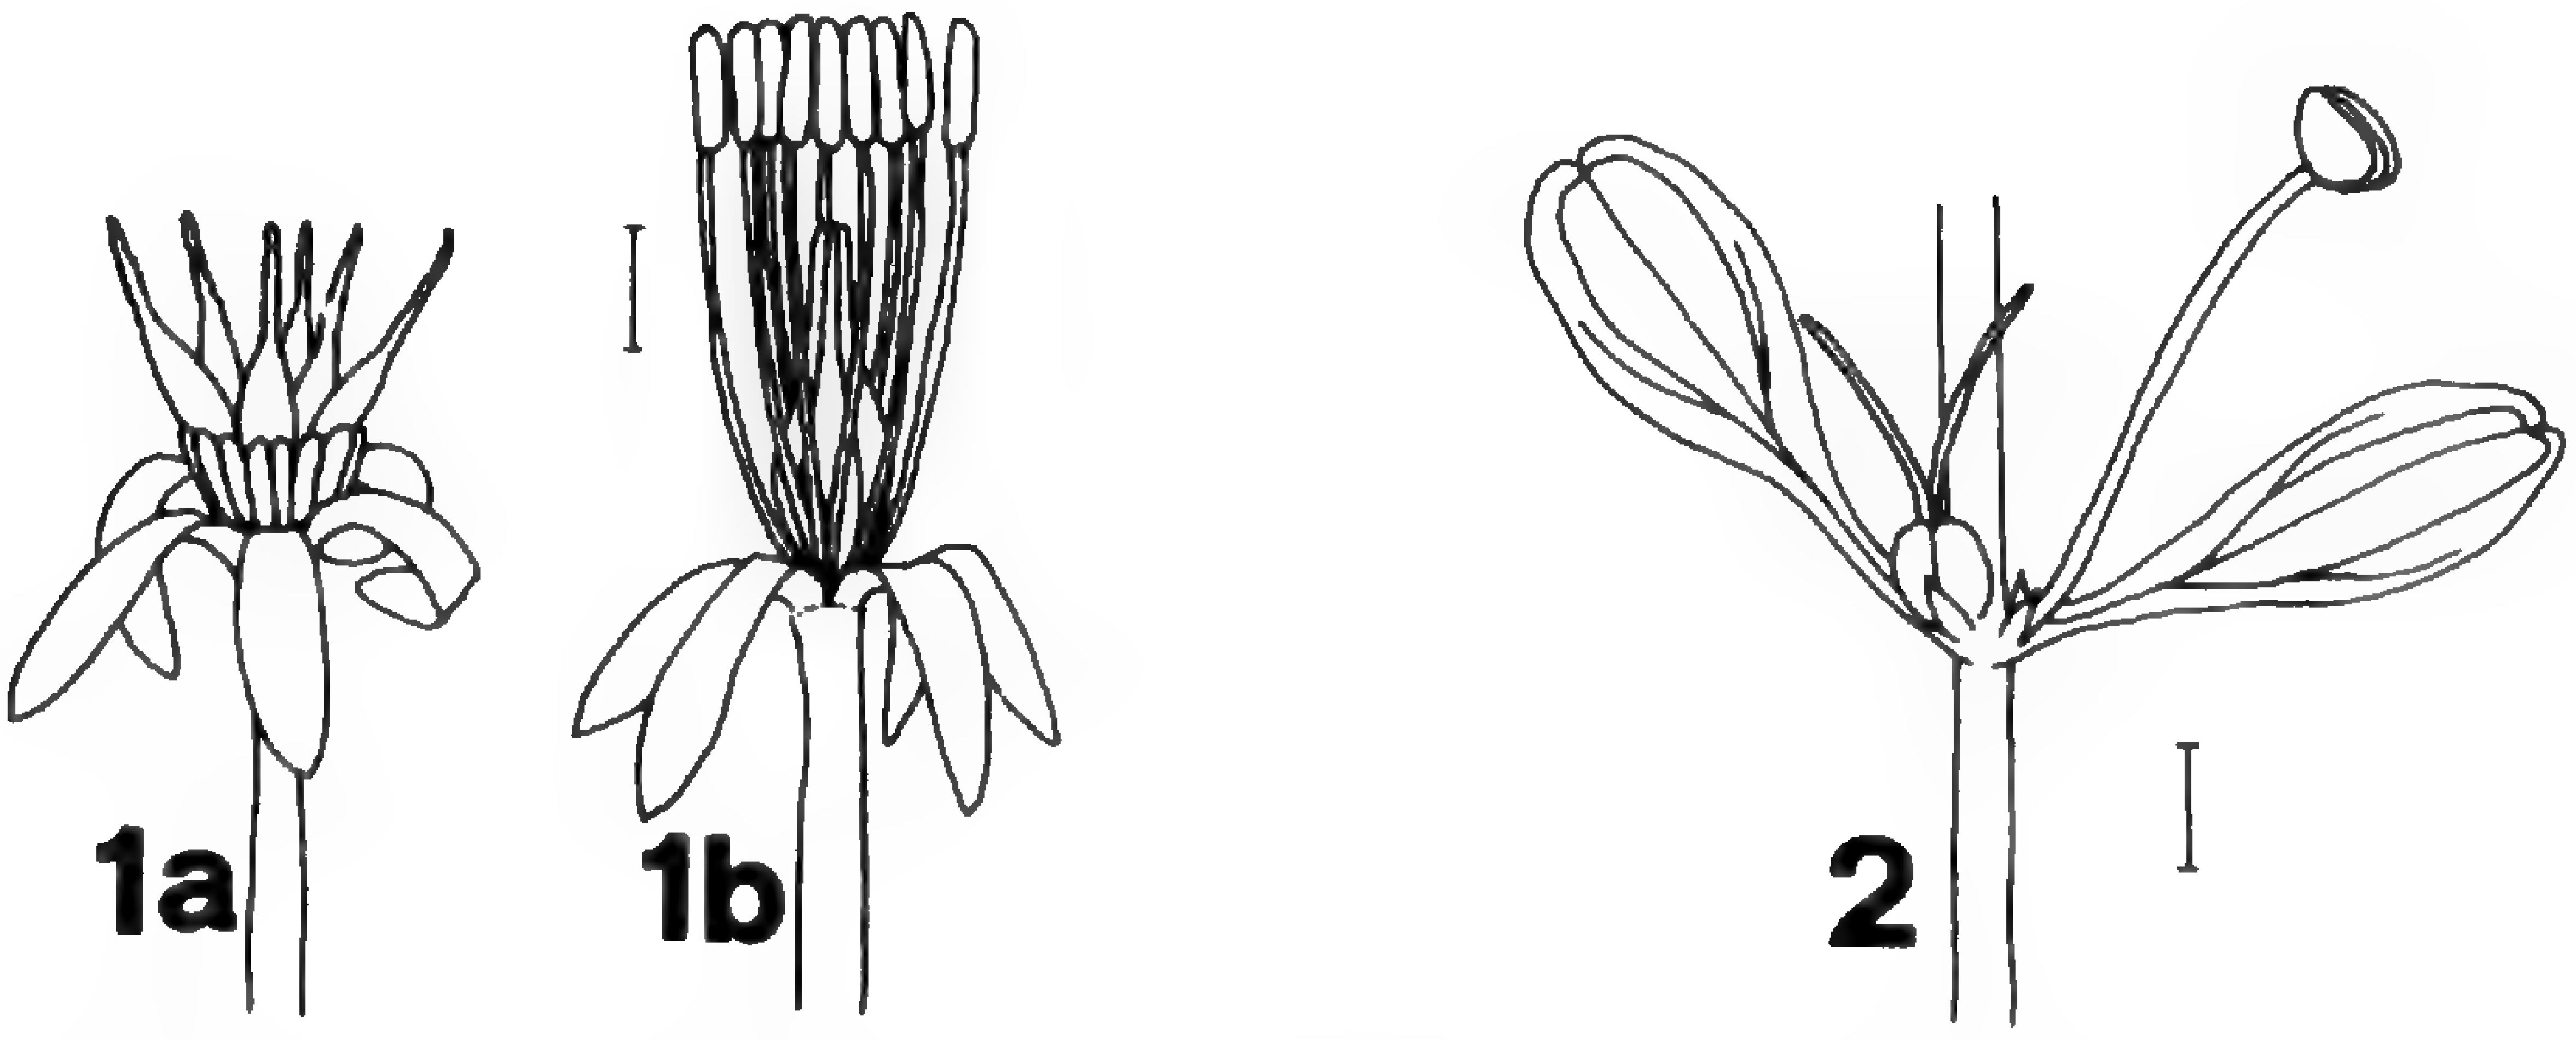
It has been suggested that *Acorus* and *Orontium* are wind pollinated. A considerable amount of work has been published on both genera, cited by Cook et al. (1974), but I have found no observational data on pollination. From their morphology (mostly bisexual flowers, relatively large perianth segments, small anthers, sticky pollen) they are probably entomophilous.

ERIOCAULACEAE

Because the flowers are small, rather insignificant, often unisexual, and apparently dry, they have been considered to be wind pollinated. However, the flowers are structurally complex and elaborate. In the few species examined, they secrete nectar, have sticky pollen, and are thus most likely insect pollinated or autogamous (see Stützel, 1981, 1984).

HANGUANACEAE

The flowers are small and unisexual with long slender filaments, which suggests anemophily (see Dahlgren et al., 1985). However, the pollen grains are spinulose, the male flowers have conspicuous fleshy bodies, and the stigmas are not exposed beyond the perianth, all of which suggests zoogamy. No direct observations on pollination have yet been reported.



FIGURES 1, 2. *1. Diagram of flowers of* Brasenia schreberi. *(a) Female phase. (b) Male phase. Scale bar = 6 mm.—2. Diagram of flowers of* Callitriche obtusangula. *Left, female flower. Right, male flower. Scale bar = 1 mm.*

LEMNACEAE

The flowers are unisexual, very small (stamens ca. 1 mm long, stigma ca. 0.5 mm above the carpel) and not obviously showy. Wind and water have been suggested as pollen vectors, but as Landolt (1986) pointed out, this is unlikely, as the pollen grains are spiny, sticky, often less than 20 μm in diameter, and sometimes only 20 grains develop in each locule; these characters all suggest zoogamy. Although water movements may bring flowers on different fronds in contact, the pollen is probably mostly transferred on the legs of different kinds of arthropods (flies, aphids, mites, small spiders). At least some races of *Lemna minor* and *Wolffiella oblonga* are self-incompatible, while many other species are self-compatible, although some of these are not autogamous and require a pollinator (for details see Landolt, 1986).

PODOSTEMACEAE

This family has about 45 genera, of which some, such as *Mourera* and *Tulasneantha*, are clearly insect pollinated. The majority, however, have very small, almost naked flowers (see Cook et al., 1974). Of these, some are probably autogamous, while others may well be wind pollinated (see Philbrick, 1984b). It is a shame that so little is known about the floral biology of this rather extraordinary family.

II. FAMILIES WITH WIND-POLLINATED SPECIES

CABOMBACEAE (sometimes included within the NYMPHAEACEAE)

Cabomba is insect pollinated, and *Brasenia* is wind pollinated (Fig. 1; see Osborn & Schneider, this volume: 778–794). *Brasenia* has most likely evolved to anemophily from entomophily in the aquatic milieu.

CALLITRICHACEAE

This monotypic family is wind pollinated (Fig. 2) or shows an extreme kind of autogamy above or below the water surface, described by Schotsman (1982, 1985) and Philbrick (1984a). It is doubtful that true hypohydrogamy (transfer of wet pollen through water to wet stigmas) takes place. It is also unlikely that epihydrogamy, with floating pollen, is an effective means of pollen transfer since the stigmas are usually either submerged or aerial.

HALORAGACEAE

Haloragis, *Laurembergia*, *Myriophyllum*, *Proserpinaca*, and *Vinkia* have aquatic species, all of which are well adapted to wind pollination. All have flowers with reduced and often caducous perianths (Fig. 3) and dry, powdery pollen liberated from long-filamented anthers. There is a trend from bisexual to unisexual flowers culminating in dioecy. Patten (1956) suggested without quantitative data that significant quantities of pollen may be transferred by insects in *Myriophyllum spicatum*.

HIPPURIDACEAE

This monotypic family has highly reduced bisexual or sometimes unisexual flowers. The stamens are reduced to one with a relatively massive anther, and the ovary is reduced to a virtually naked, one-seeded carpel (Fig. 4). The pollen is anemophilous-like. No published data on pollination have been found, but from personal observations it is strongly protogynous (Fig. 4), and seed-set is usually good. I can only assume it is wind pollinated.

Scale bar = 1 cm. (b) Female flower. Scale bar = 1 mm. (c) Male inflorescence. Scale bar = 1 cm. (d) Male flower. Scale bar = 1 mm.*

HYDROCHARITACEAE

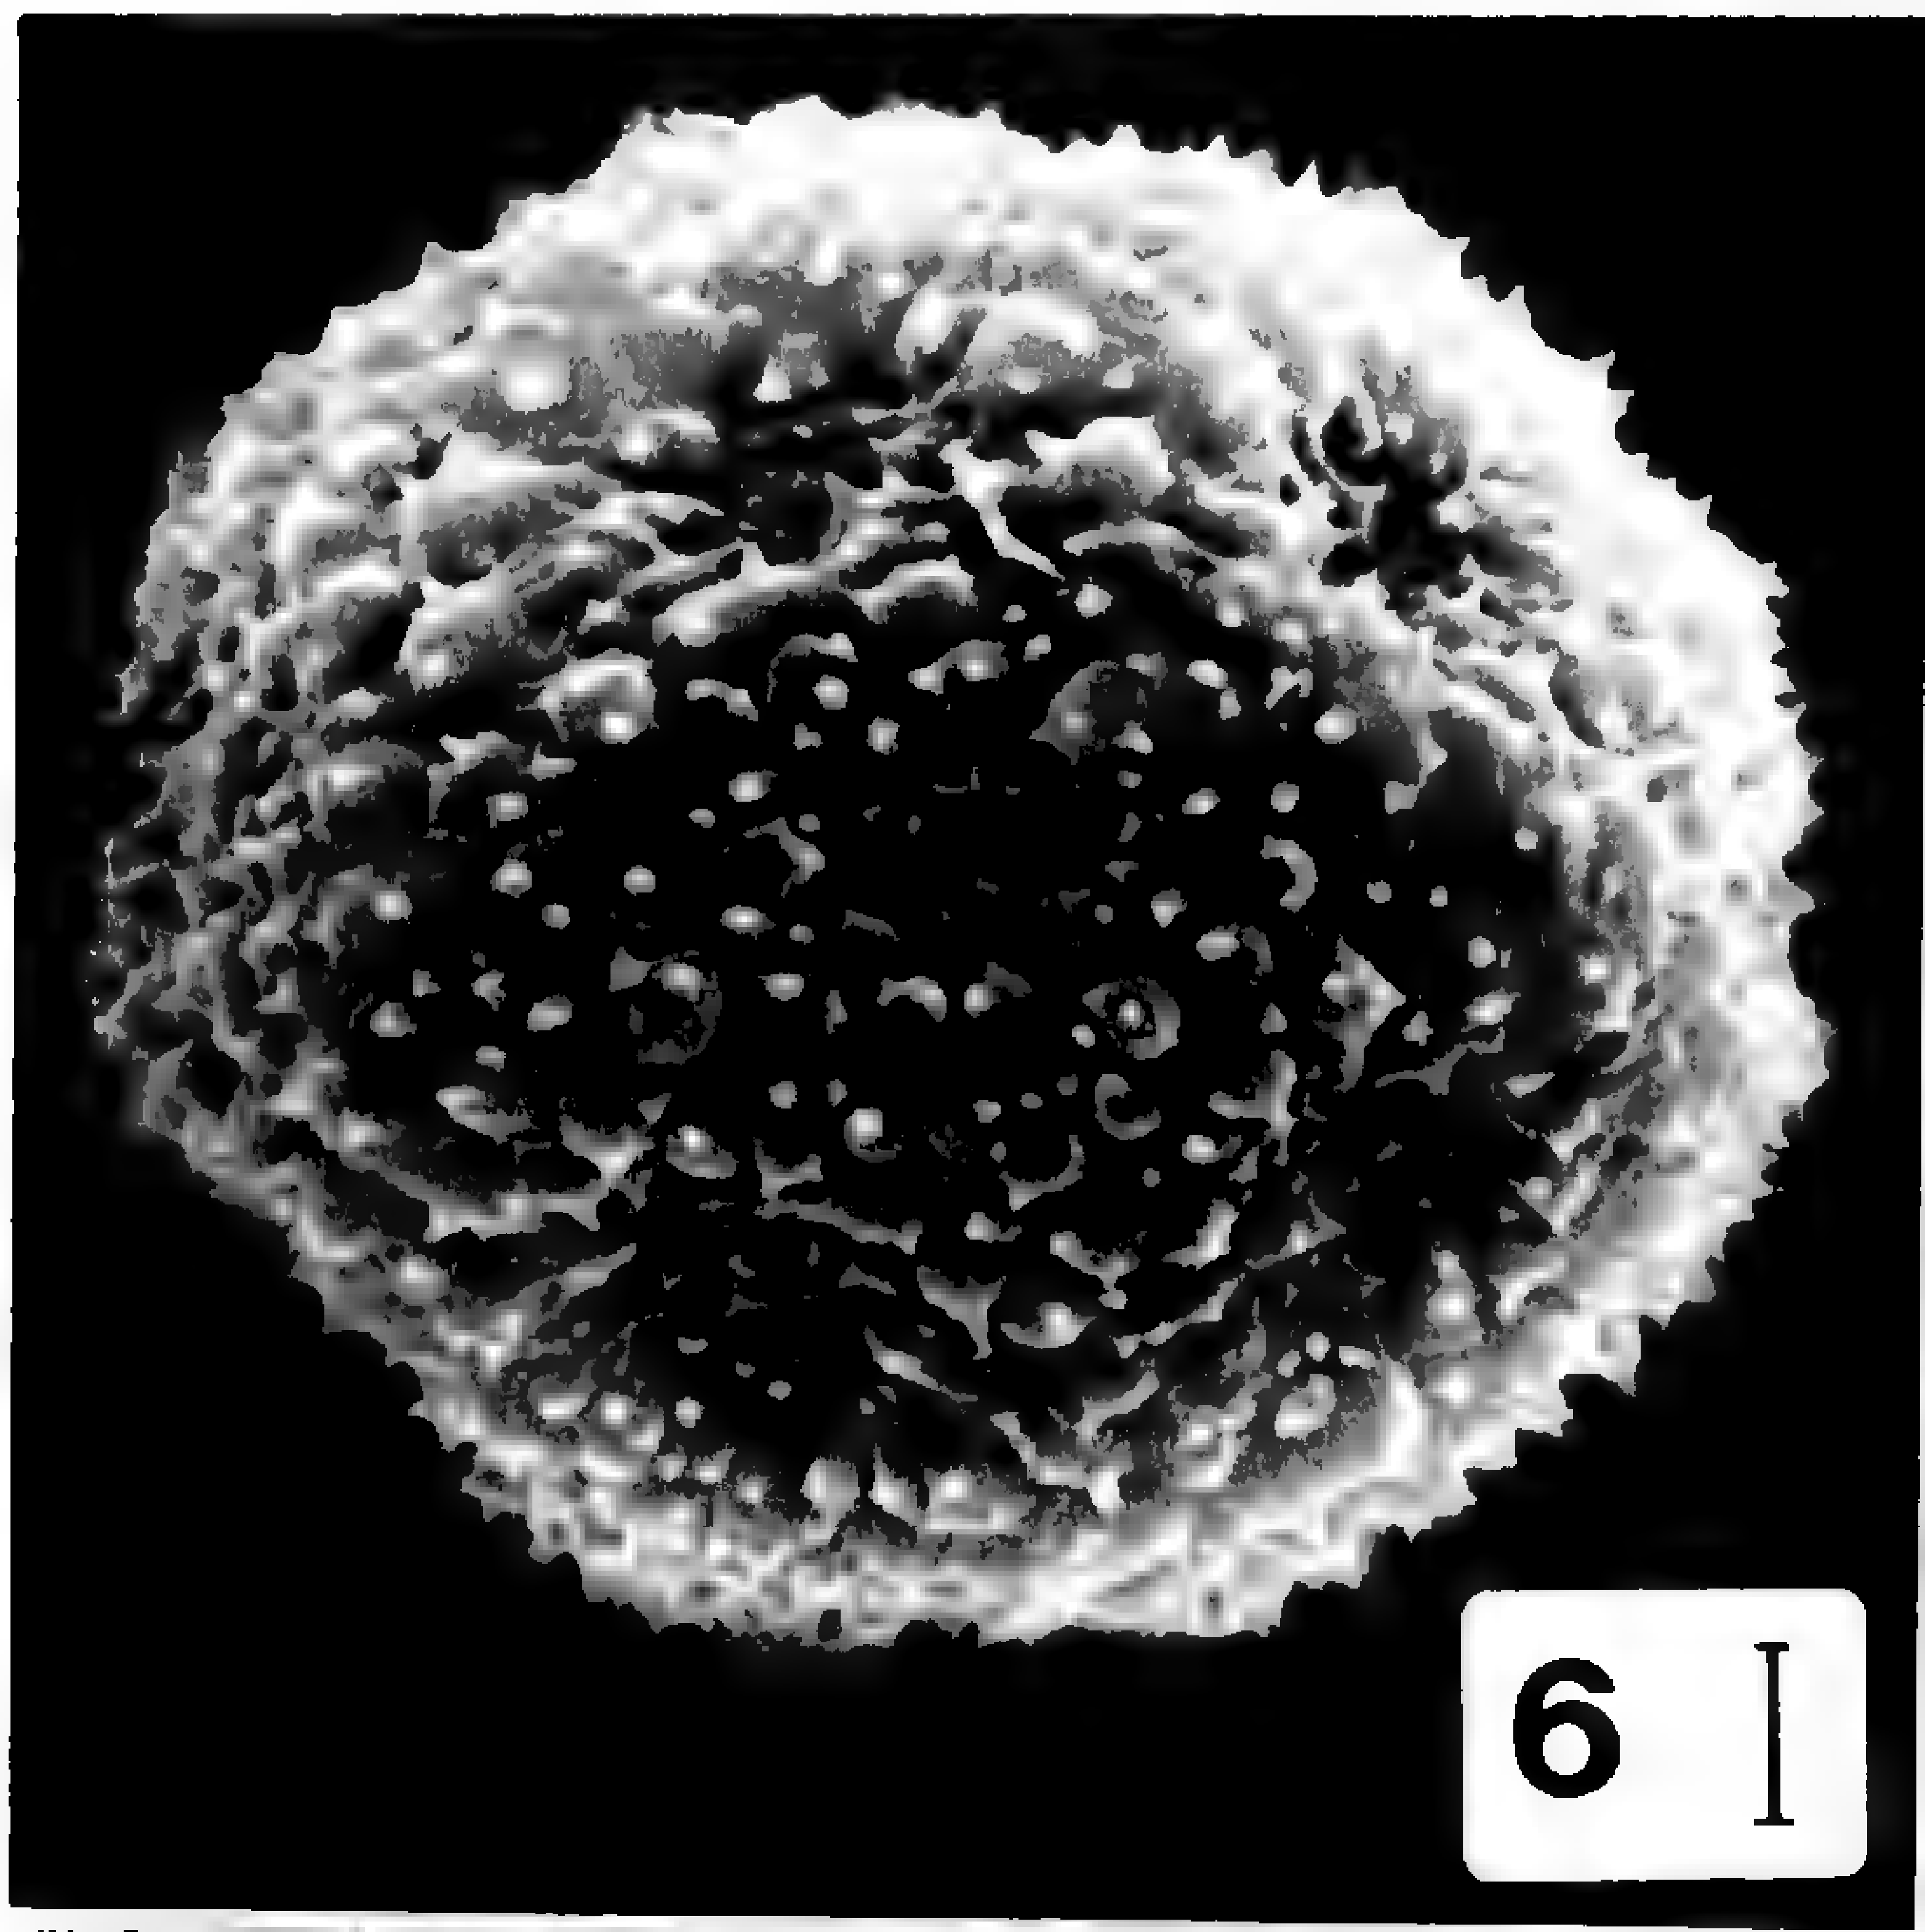
This exclusively aquatic family with 16 genera is extraordinary in its spectrum of floral structures, showing entomophily, anemophily, epi- and hypohydrophily (see Cook, 1982, for a general review). In *Appertiella, Enhalus, Lagarosiphon* (Figs. 7, 11), *Maidenia, Nechamandra,* and *Vallisneria* (Fig. 8) the male flowers become detached from the mother plant and are dispersed by wind or water currents; in these genera the pollen is sticky and transferred directly from anther to stigma. In *Elodea* the pollen is liberated on the surface of the water (Fig. 12) and is dispersed by wind or water currents to the stigma (Cook & Urmi-König, 1985). Although wind plays an important role in pollination, this kind of pollination is usually classified as epihydrophilous, since part of the pollen is in contact with water; however, it must be stressed that the pollen and stigma remain dry.

In pollination biology *Hydrilla* is remarkable, as shown by Cook & Lüönd (1982). The male flowers are liberated from the mother plant as buds, which then open explosively, shooting pollen grains through the air. The pollen of *Hydrilla* is inaperturate (the furrow illustrated by Yeo et al., 1984, is an artifact), spherical, 93 ± 5.7 μm in diameter, and densely covered with baculae 2 μm long, each bearing a small flamelike process (Fig. 9a, b). This pollen is too large and rough to "fit" in the wind pollination syndrome. The stigmas are rather small and borne at the base of a wineglasslike perianth (Fig. 10) exposed to the air but below the surface of the water. For effective pollination the pollen should not get into the airstream, as in other anemophilous plants, but must drop almost vertically to reach the stigmas, and it must stick and not bounce out again. The pollen is propelled through the air, but wind, as such, plays an unimportant role; I hope it is not necessary to create a new term for this unique pollination mechanism.

Described in detail by Cook & Urmi-König (1983), pollination in *Limnobium* is "normal" when compared with other genera of the Hydrocharitaceae. The sepals of the male flowers act as pollen-arresting organs (Fig. 13). The pollen is then "picked up" off the petals by the wind. The arched petals were suggested by Cook & Urmi-König (1983) to have an aerodynamic function, but after observations in the field it seems clear that their function is to keep the pollen dry when waves come or when it rains; when the flowers are immersed in water the sepals come to rest on the petals, thus enclosing an air bubble.

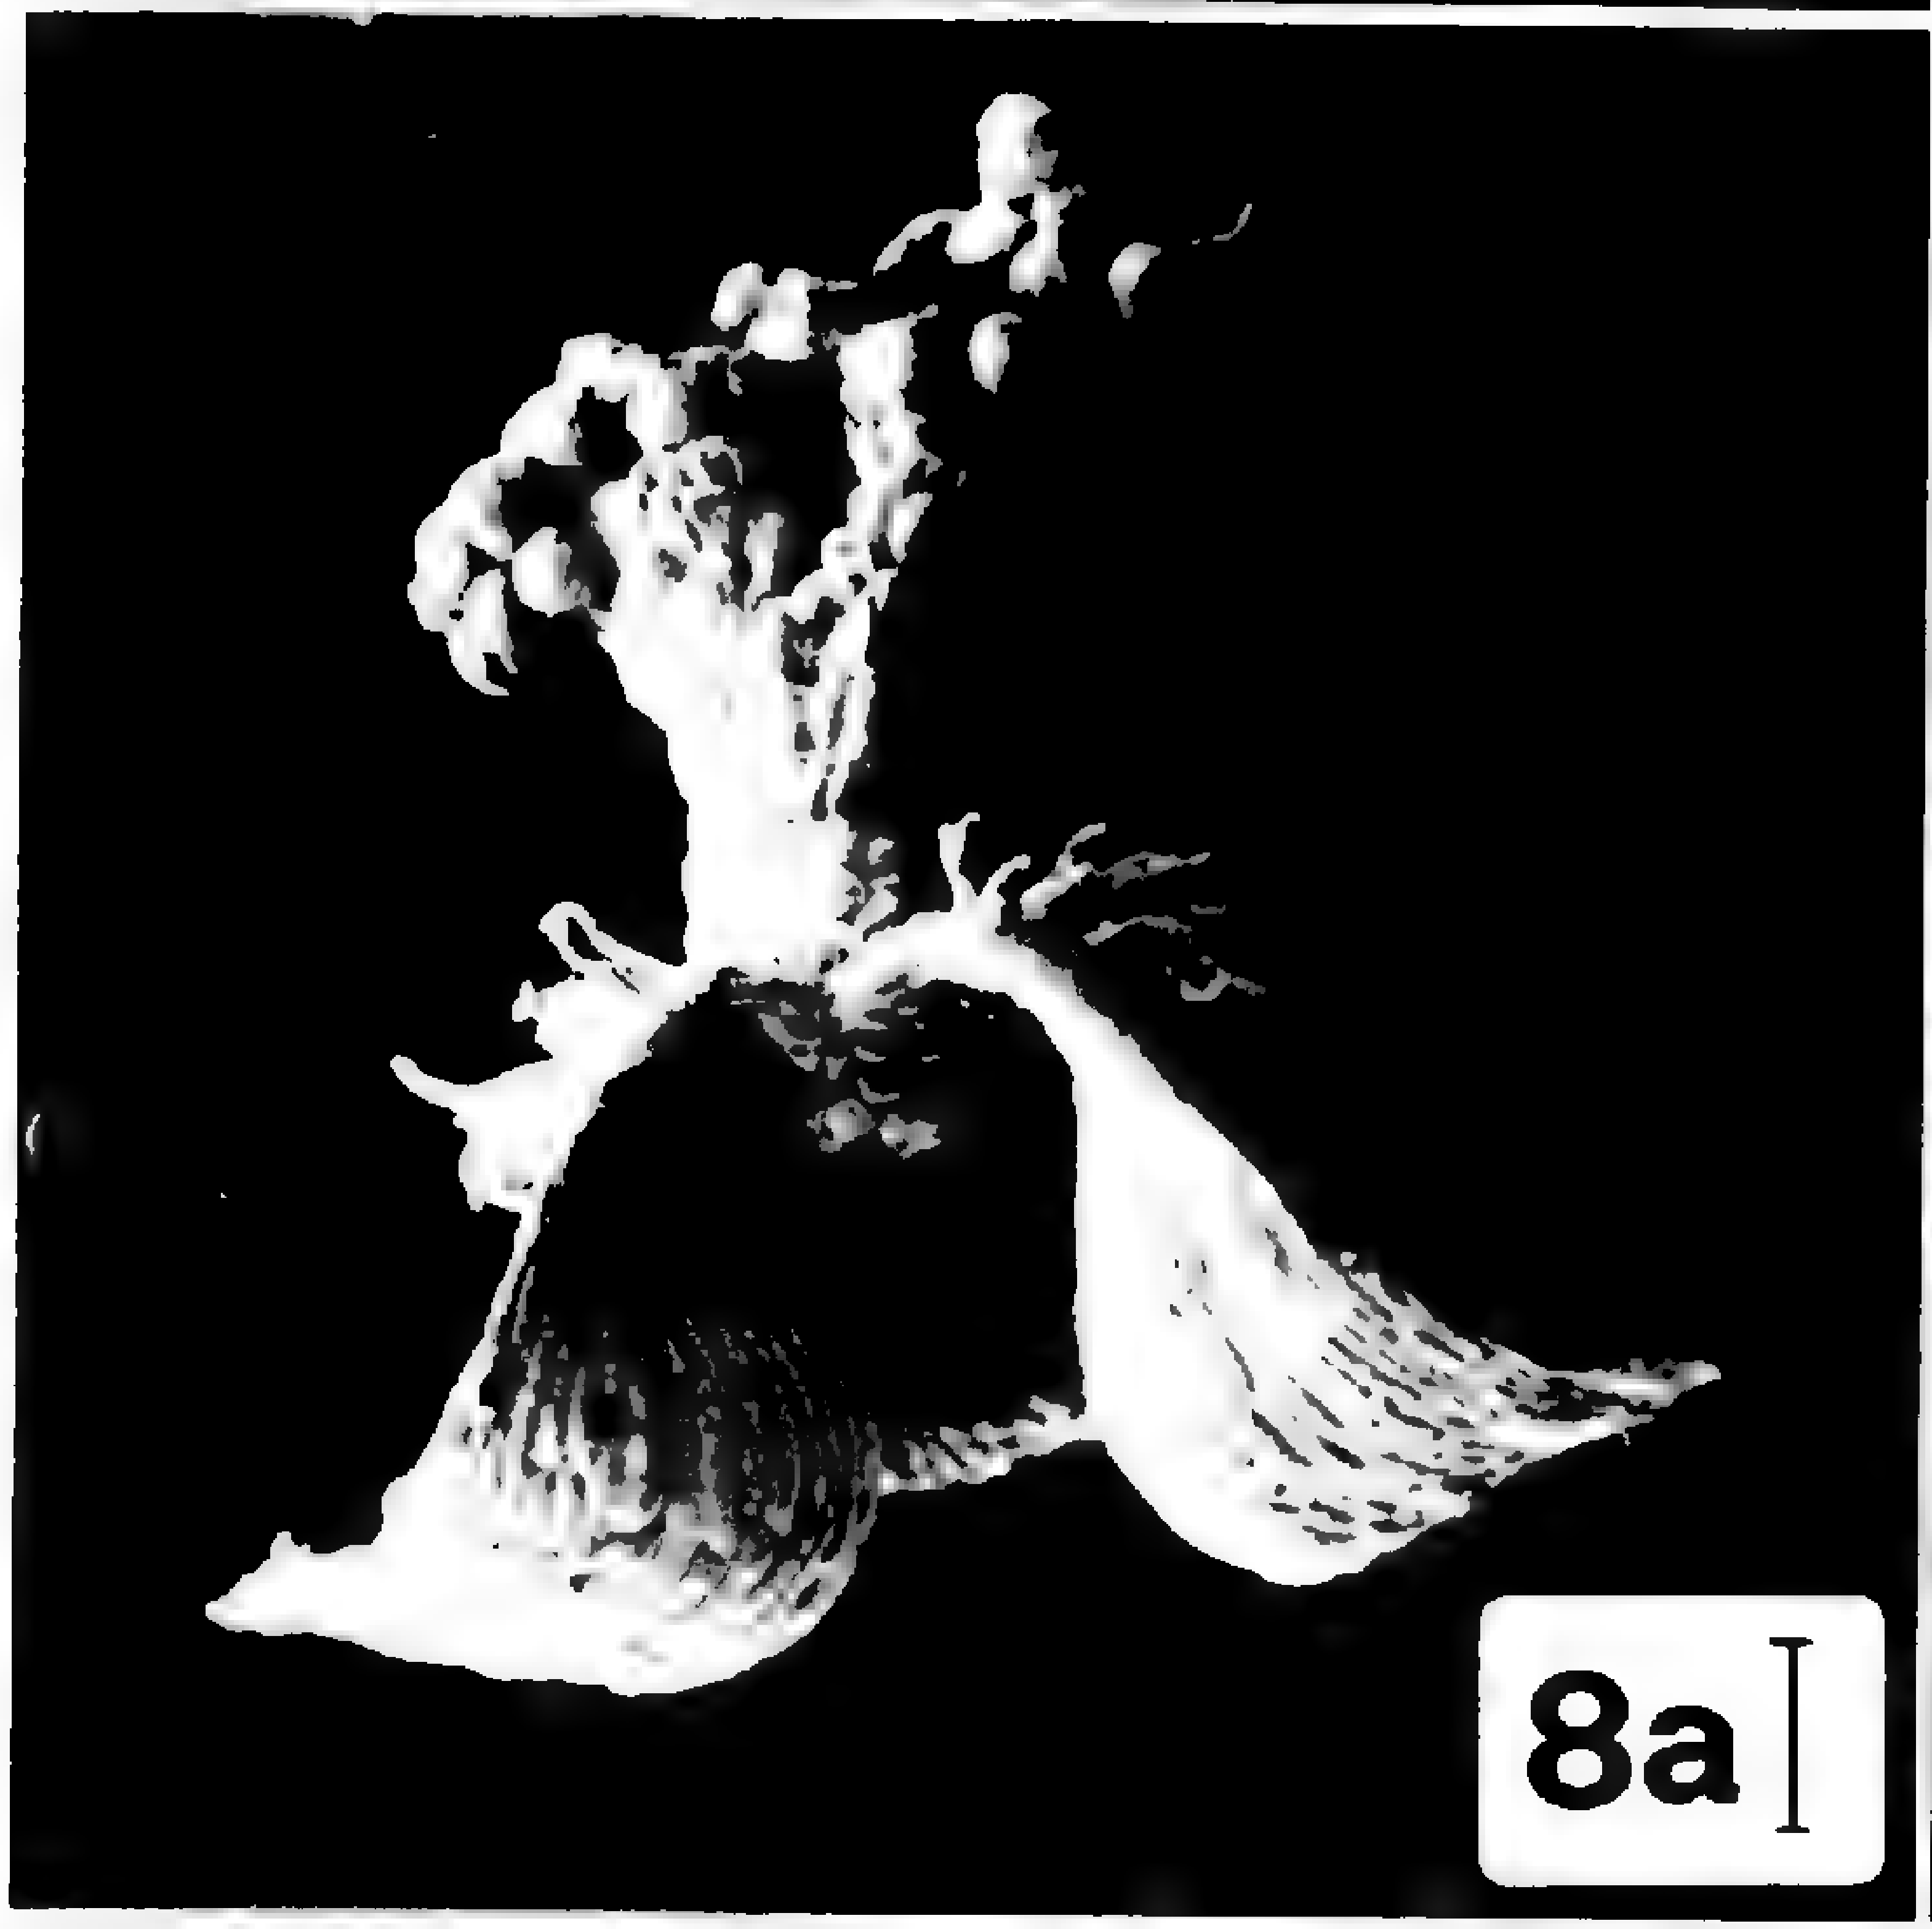
The marine genera *Halophila* and *Thalassia* have wettable pollen and stigmas and are pollinated underwater (hypohydrogamous).

Within the Hydrocharitaceae, *Limnobium* is the only genus with dry, powdery, and buoyant pollen that is transported to the stigmas by movements

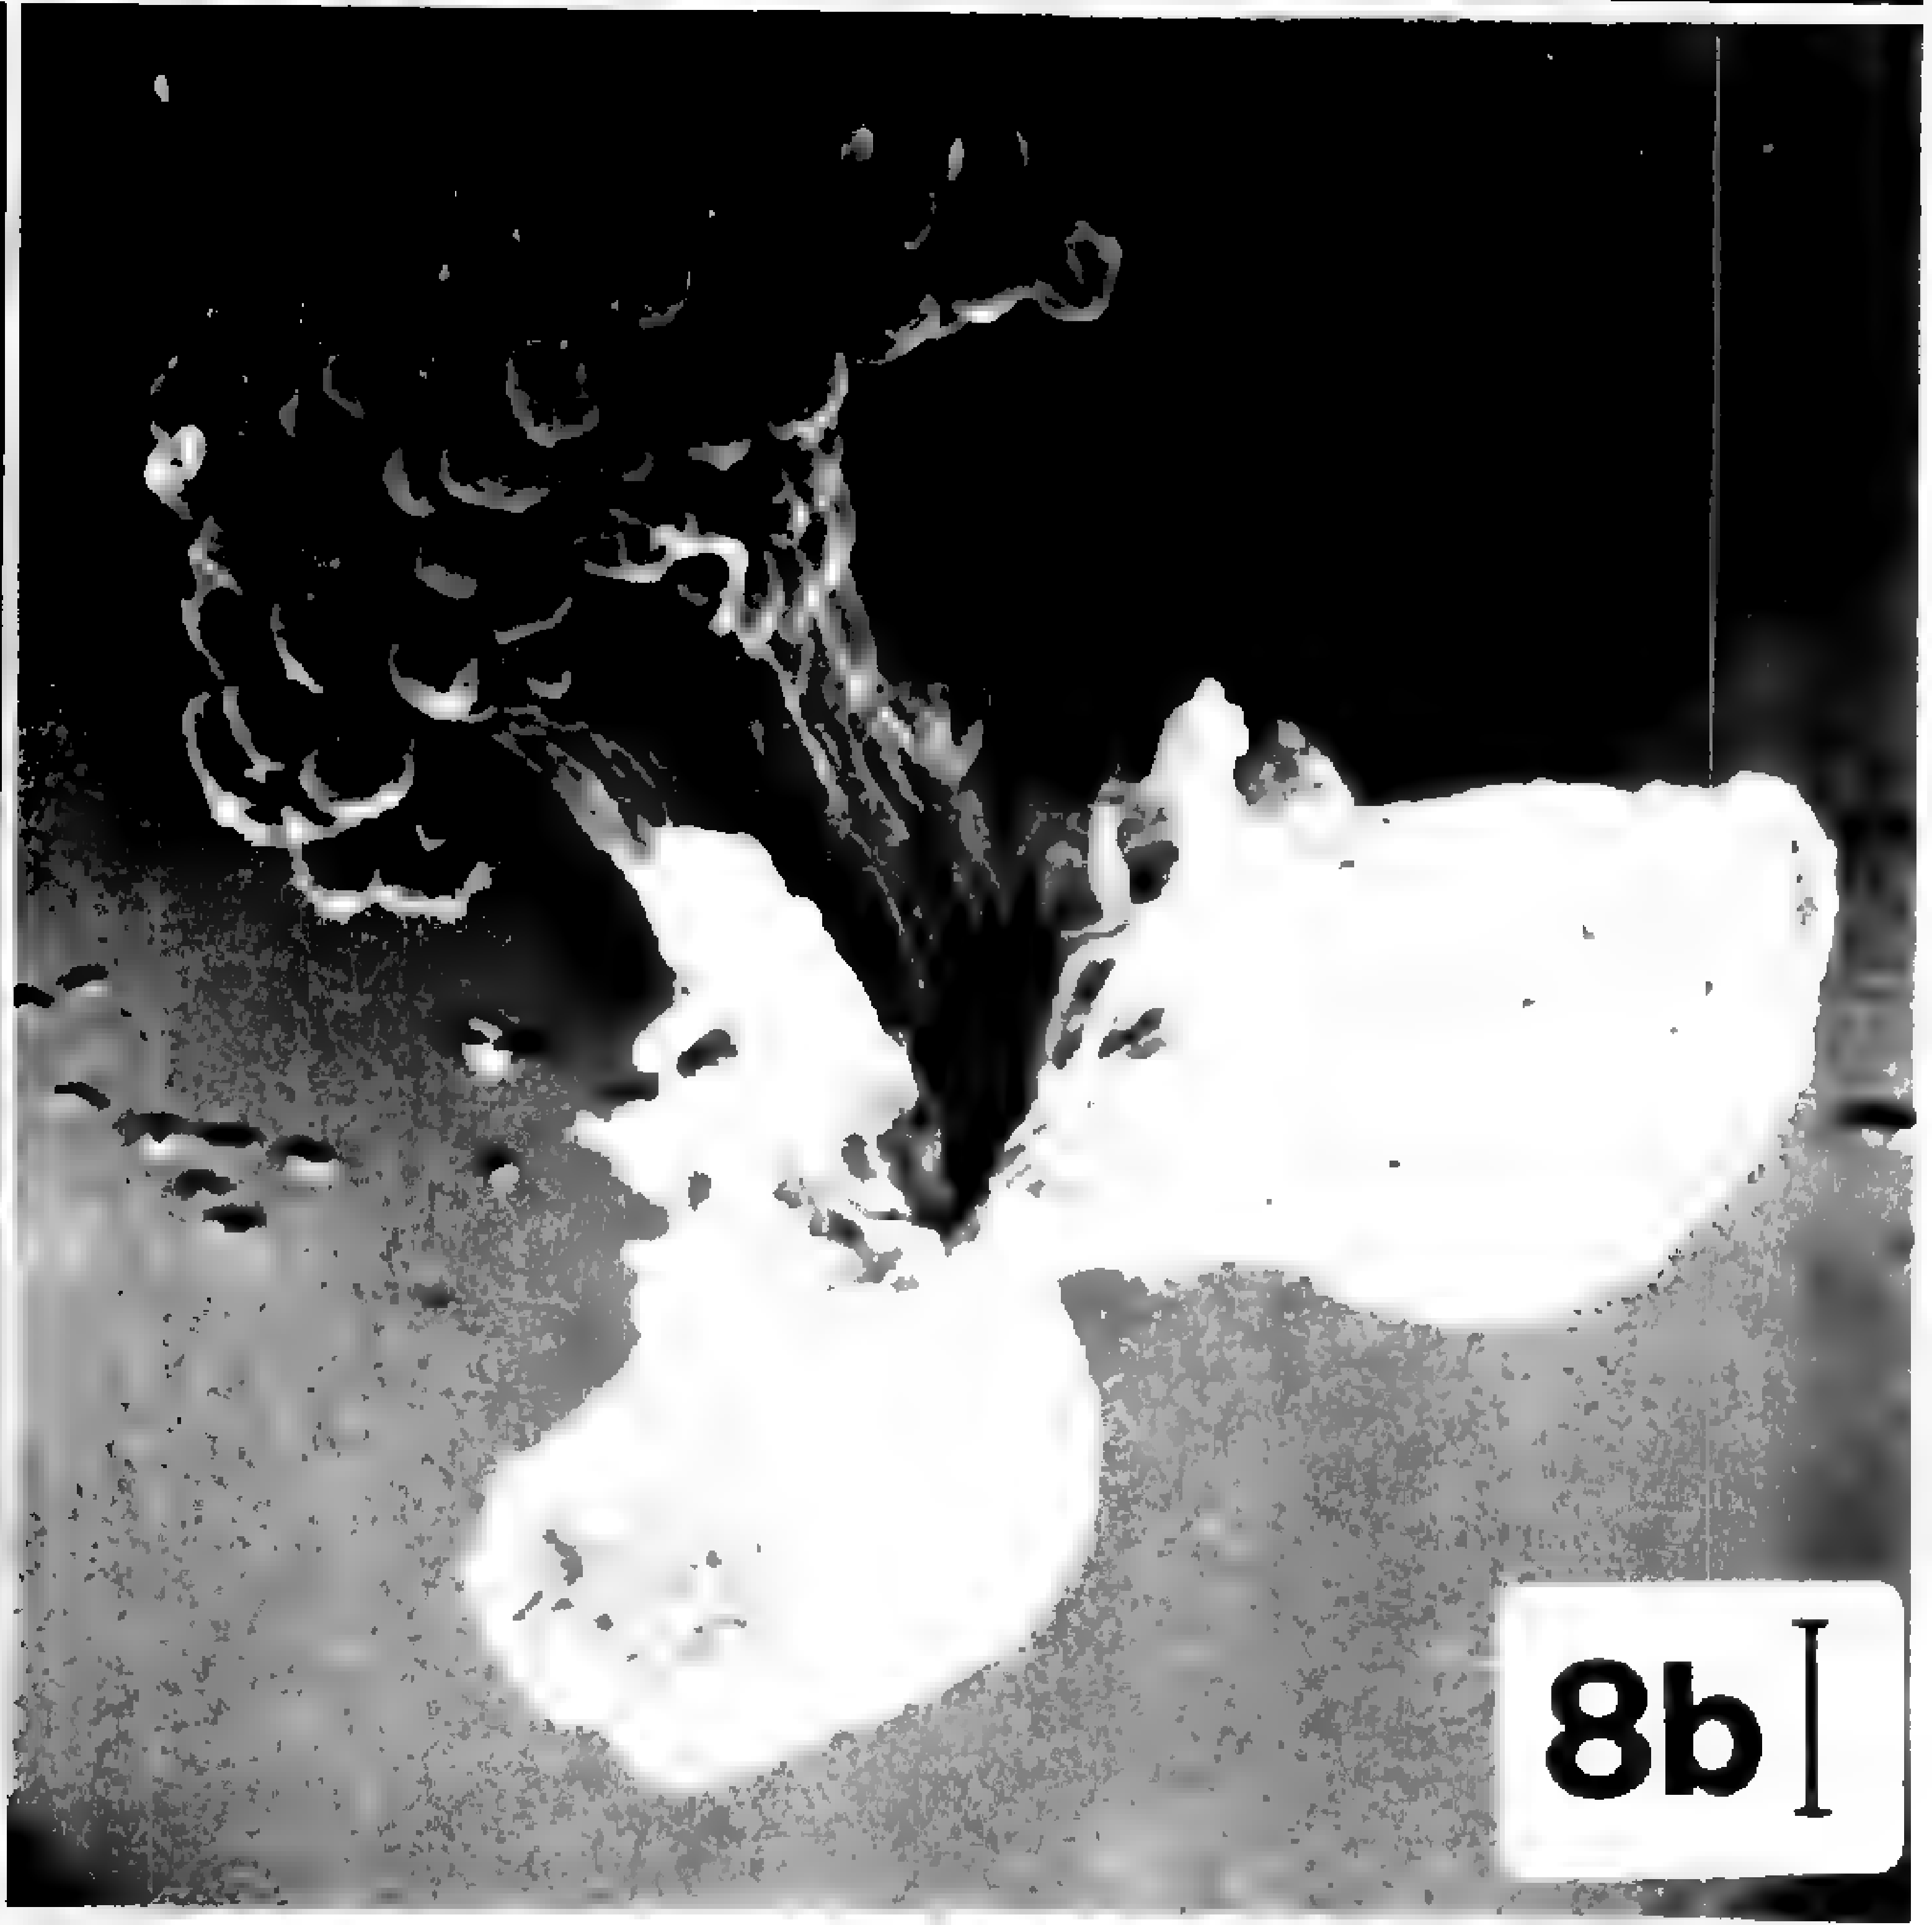


6

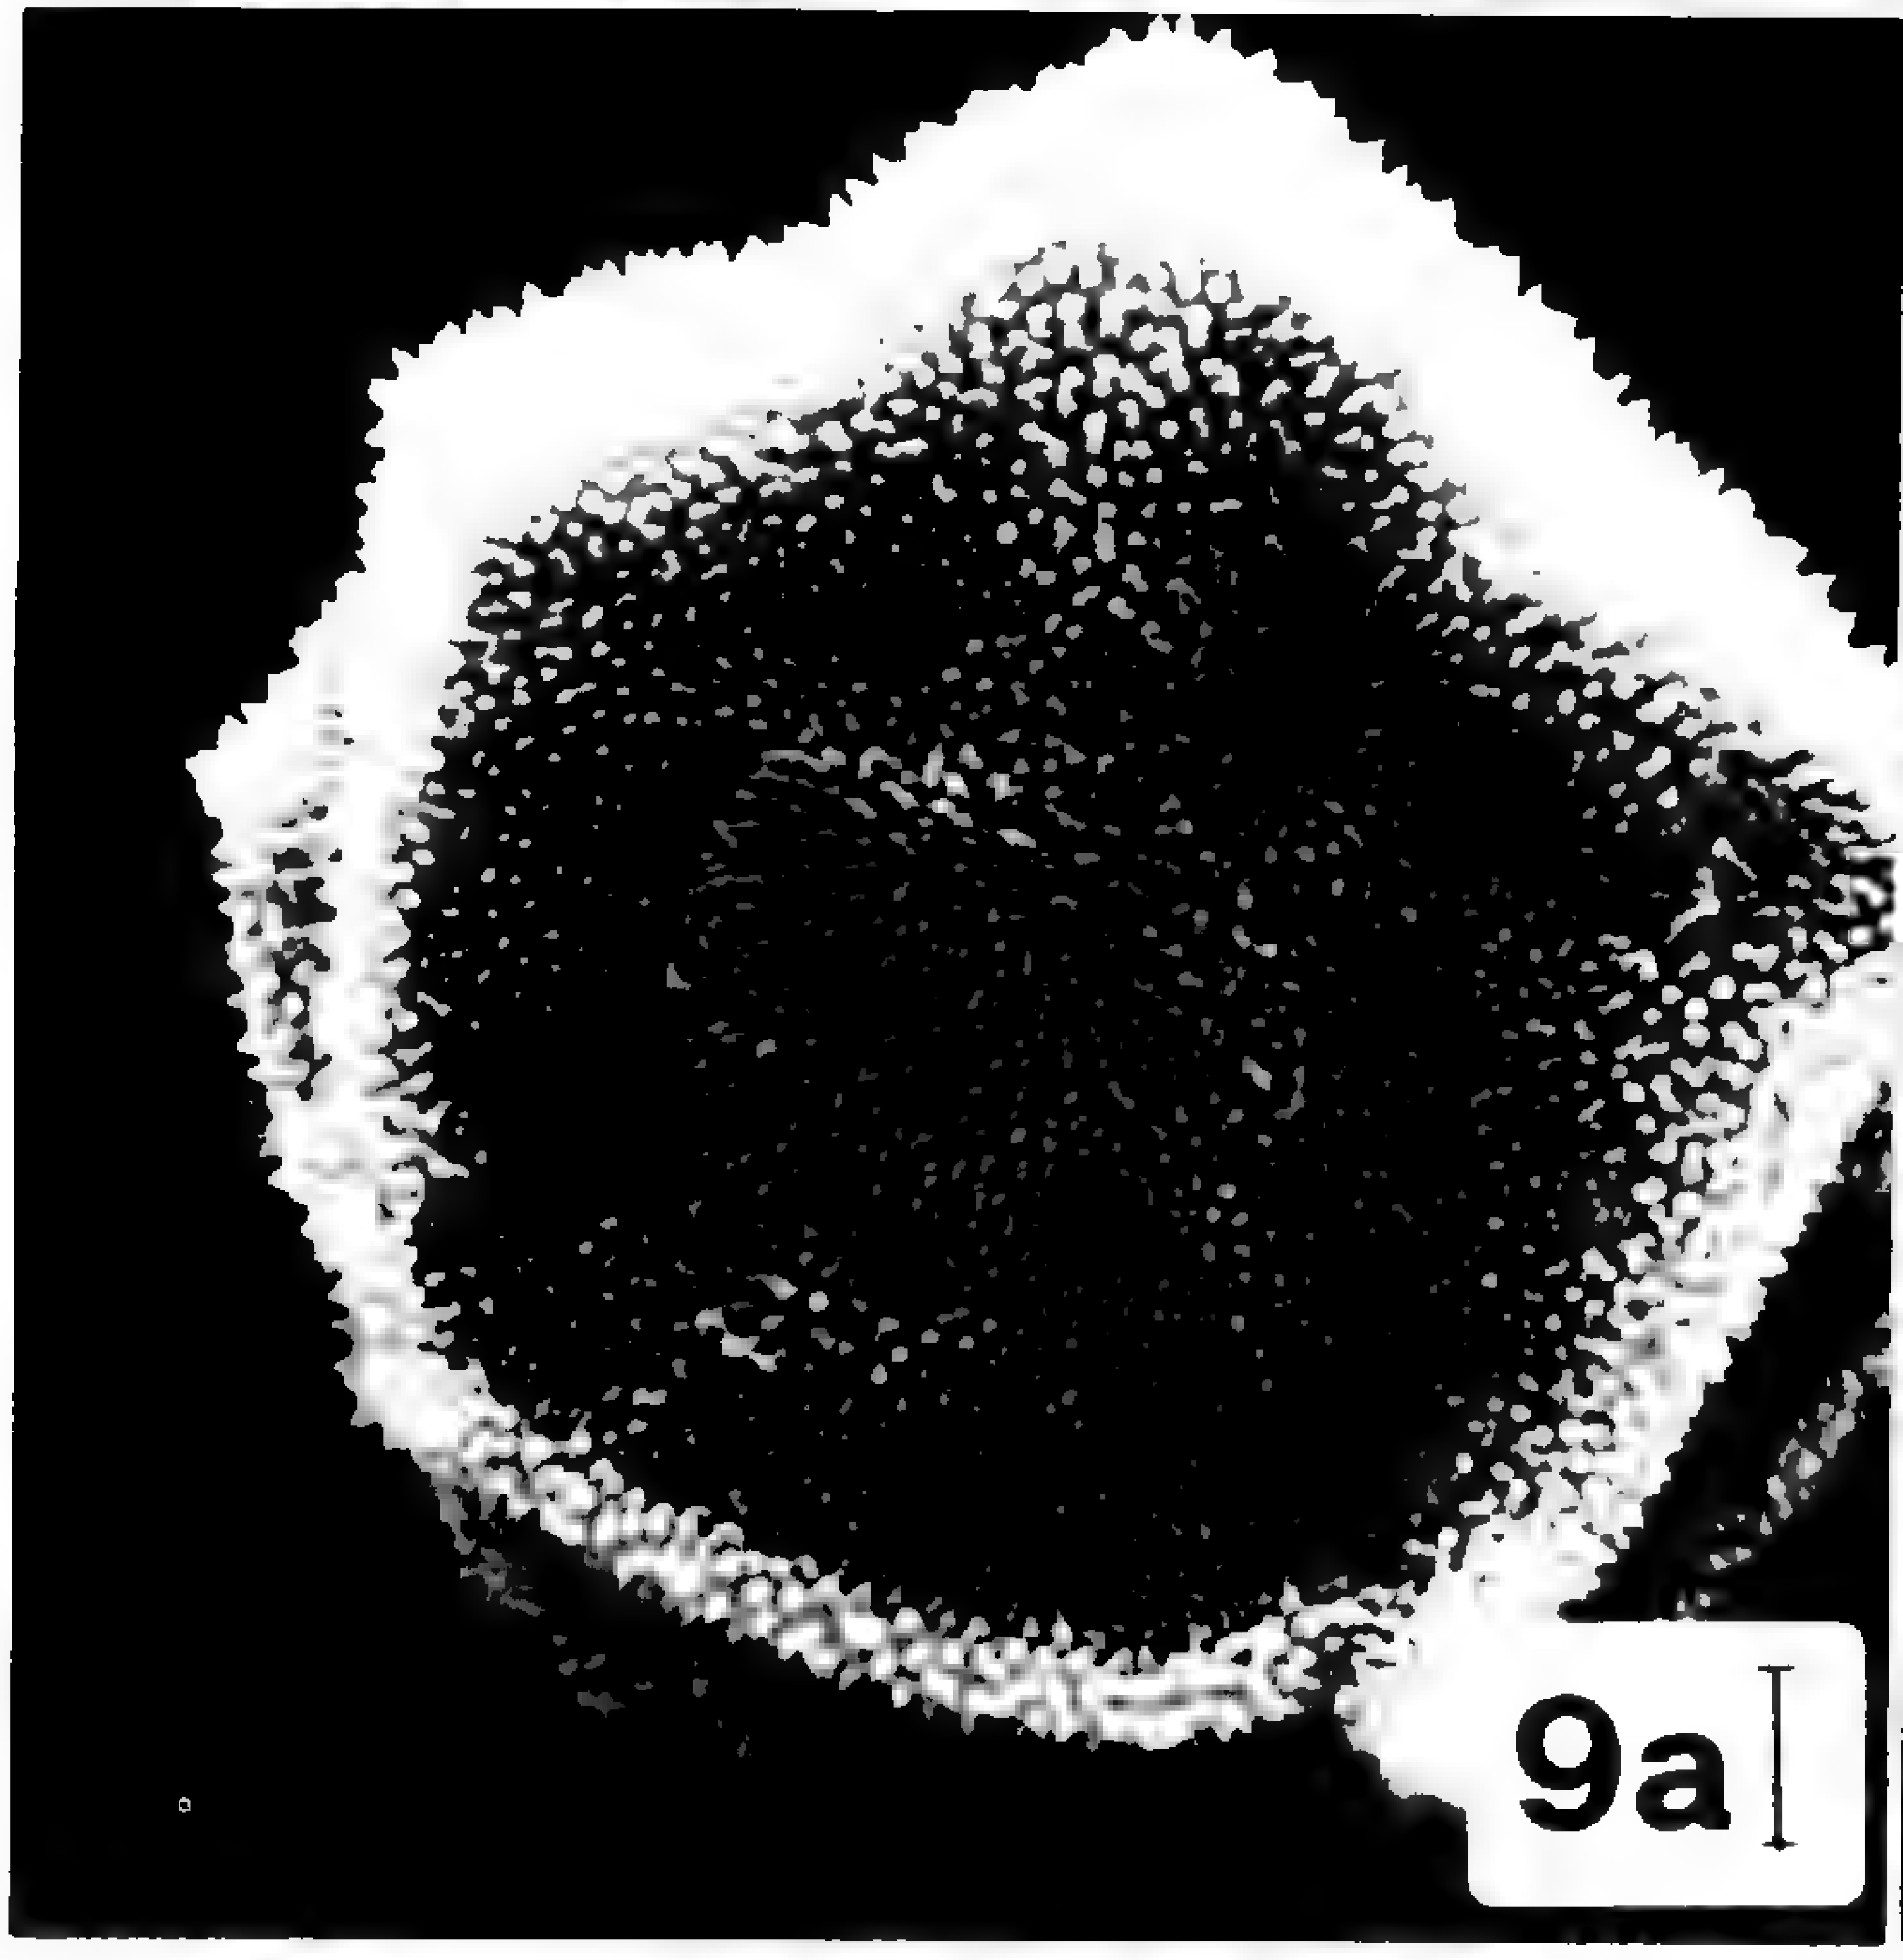
7



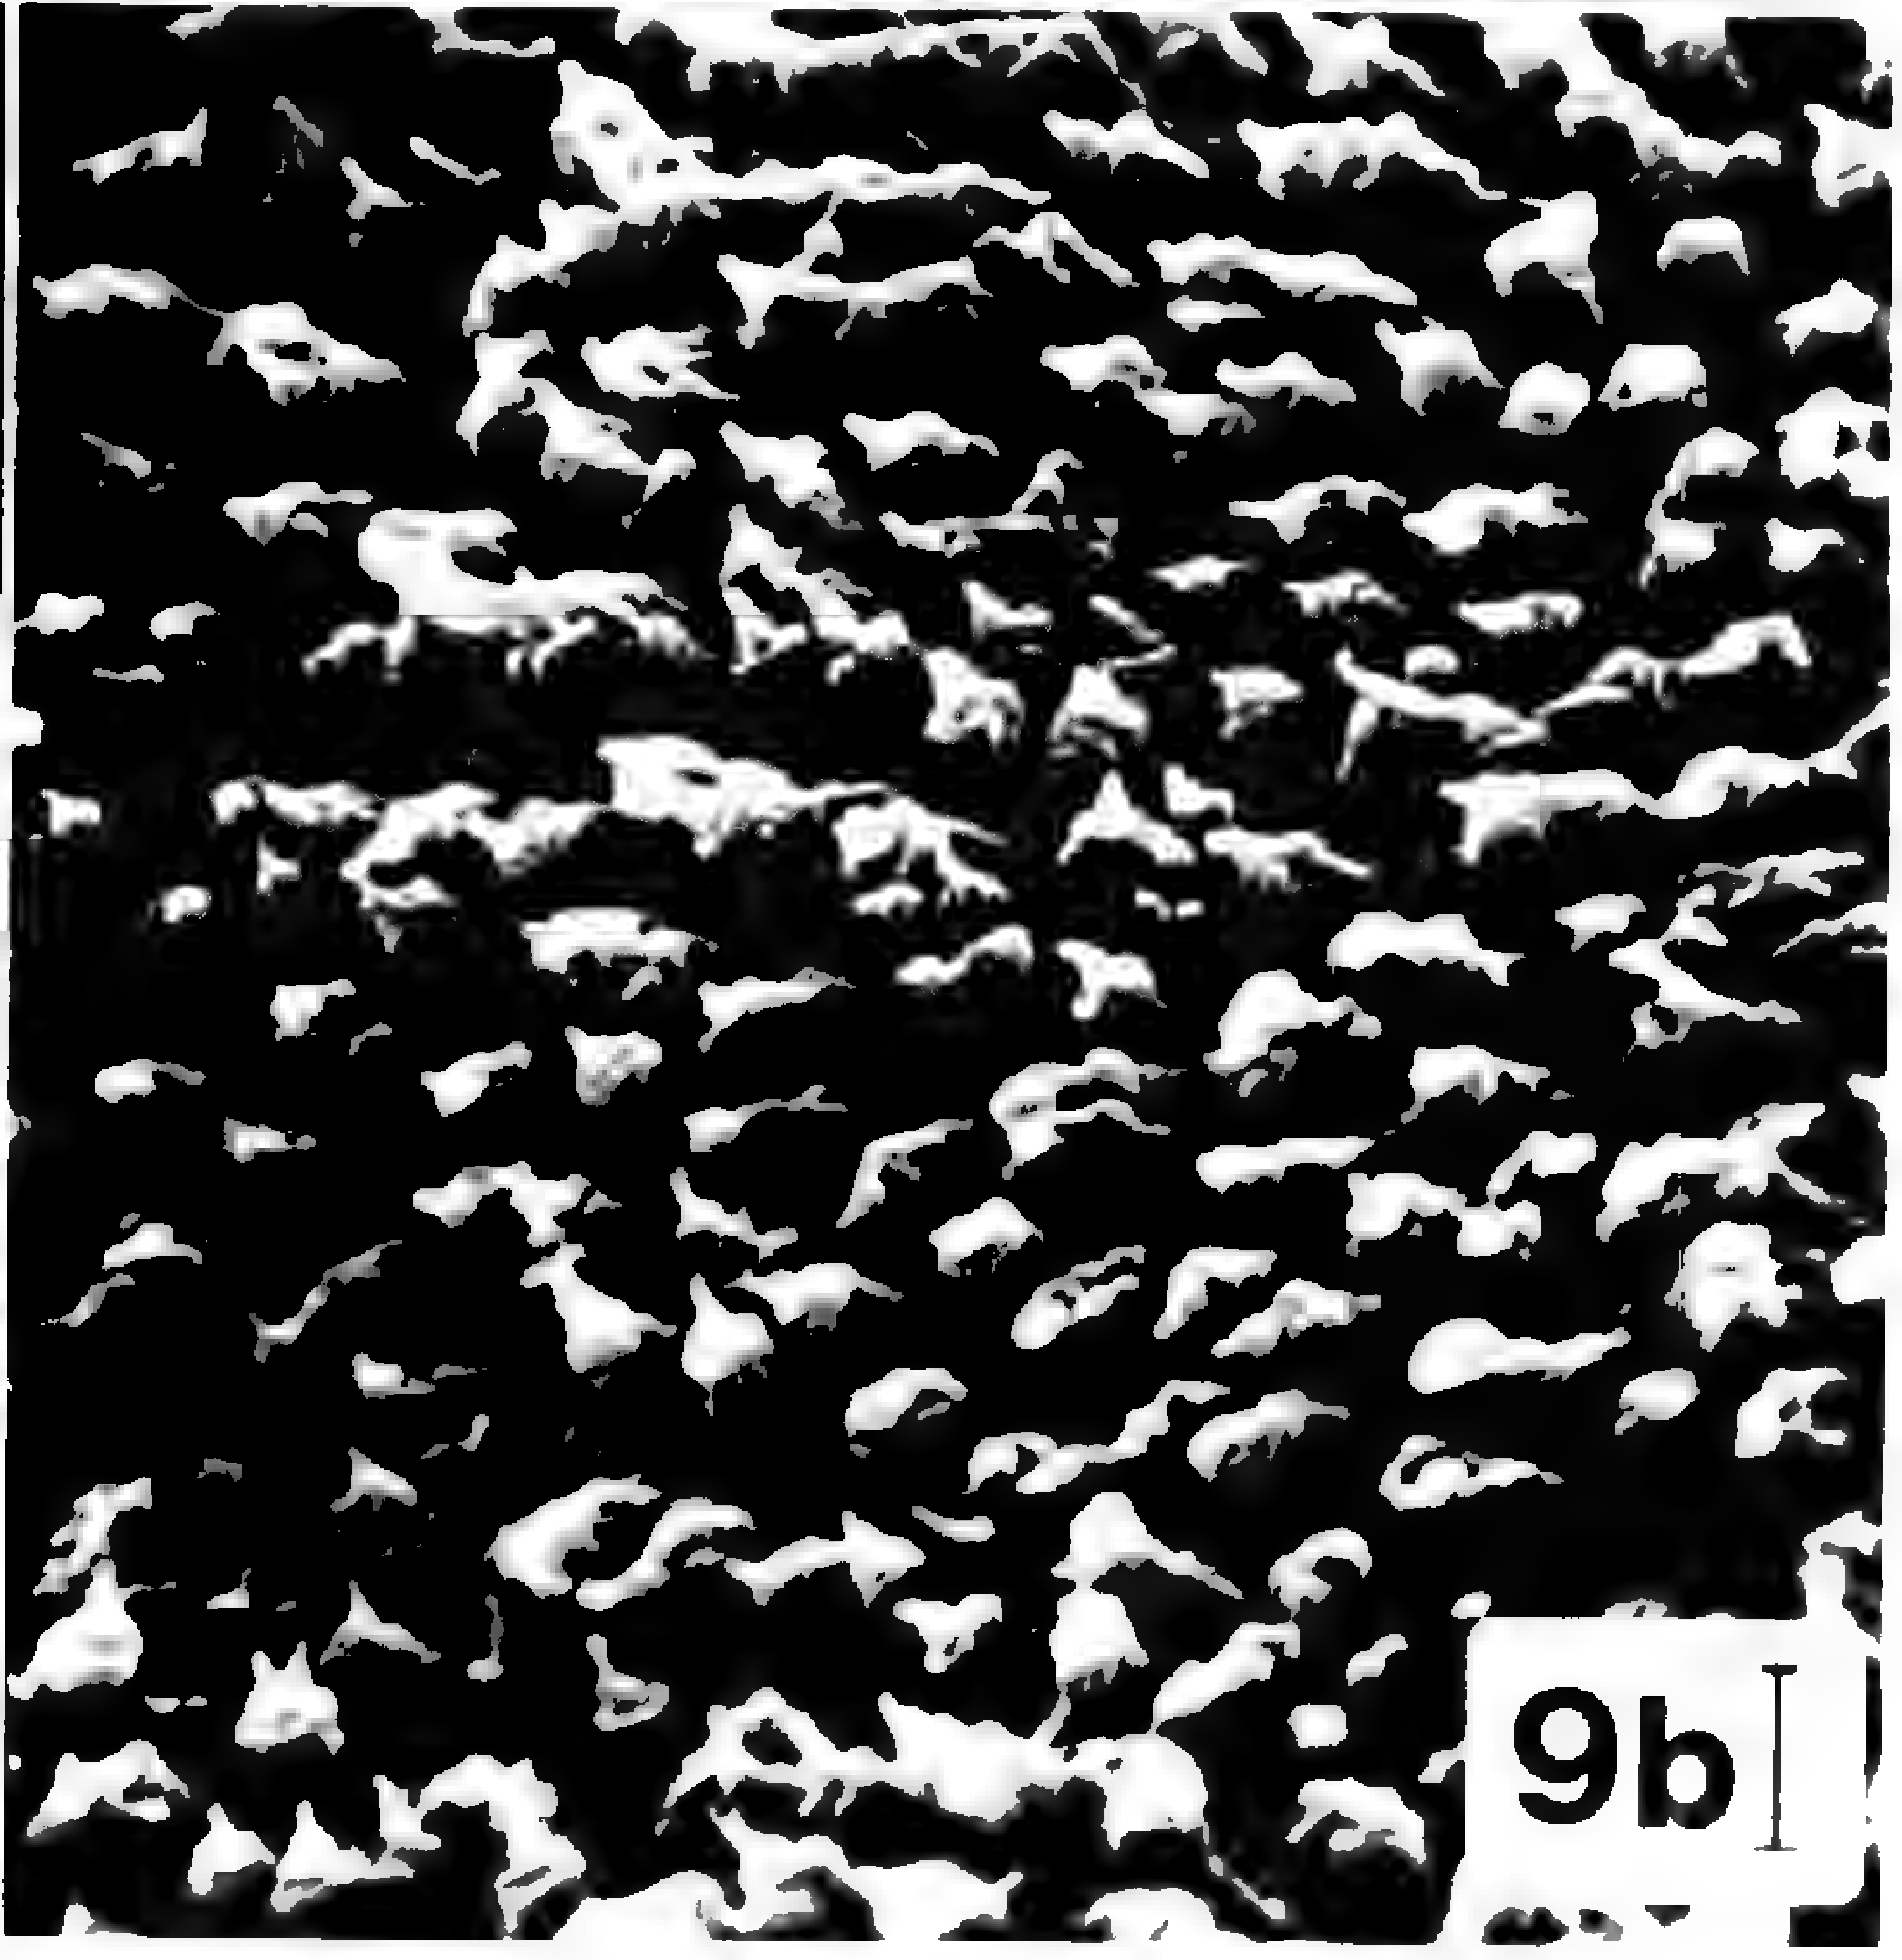
8a



8b



9a



9b

of air and thus can be called anemophilous. *Hydrilla* has heavy pollen actively propelled through the air and is not dependent on air movements; it is, therefore, not strictly speaking "wind pollinated." Morphological and anatomical evidence indicates that the patristic relationships of *Limnobium* are to exclusively entomophilous genera *Hydrocharis*, *Ottelia*, and *Stratiotes*. The epi- and hypohydrogamous genera (within the framework of the Hydrocharitaceae) are not patristically close to *Limnobium* and are probably derived from a *Blyxa*-like ancestor. The genus *Blyxa* is essentially entomophilous or highly autogamous (Cook et al., 1981; Cook & Lüönd, 1983).

The evolution from entomophily to anemophily in *Limnobium* has most likely taken place within the aquatic environment. The expanded sepals, which hold pollen until wind carries it off, and the arched petals, which protect the pollen from waves and submergence, may be considered as elaborations connected with wind pollination and with the aquatic environment.

HYDROSTACHYDACEAE

This extraordinary monotypic family, reviewed by Cusset (1973), has about 22 species. The morphology of the flowers suggests anemophily (Fig. 5). The perianth is absent and a bract arrests the pollen, analogous to *Limnobium*. The carpel contains numerous seeds, an unusual feature in anemophily. No direct observations on pollination have been published.

JUNCAGINACEAE and LILAEACEAE

These two families are sometimes united. From the floral morphology they are wind pollinated, but I know of no direct observations. Some species have pollen-arresting mechanisms very like those in *Potamogeton*, and others have highly heteromorphic flowers (Fig. 14) (Posluszny et al., 1986).

PLANTAGINACEAE

The aquatic genus *Littorella* has obvious affinities to the terrestrial genera *Bougneria* and *Plantago*. Some species of *Plantago* show tendencies toward entomophily, but most are anemophilous. *Littorella*, however, shows further anemophilous specialization in having stalked male flowers and sessile, uniovulate female flowers.

POTAMOGETONACEAE and RUPPIACEAE

These two families are sometimes united. Most of the species of *Potamogeton* are wind pollinated, with erect, many-flowered spikes, spherical pollen grains, bisexual flowers with strong protogyny, and organs generally known as connective appendages to arrest the pollen and liberate it in the airstream after the female receptive phase (Fig. 15). *Potamogeton filiformis*, *P. pectinatus*, and others are pollinated below the water surface. This kind of pollination is described by Philbrick in this volume (pp. 836–841).

The pollination mechanism of *Groenlandia* has not, I believe, been critically described, but my own observations revealed that in spite of having rather short-stalked, two-flowered inflorescences, it is either autogamous or pollinated by wind and does not seem to be, as sometimes supposed, pollinated by floating pollen (epihydrogamous).

Ruppia is better known than the other genera; Verhoeven (1979) described the pollination in *R. cirrhosa* and *R. maritima* in detail. Both have curious elongated 'v'-shaped pollen grains (Fig. 16) that sometimes form chains. This might suggest hypohydrogamy, but the pollen is nonwettable and is liberated in bubbles; the stigmas are protected by the same bubbles. *Ruppia cirrhosa* is usually pollinated at the surface like *Elodea*, while *R. maritima*, in Europe, is usually pollinated in bubbles under water like *Potamogeton pectinatus*.

SPARGANIACEAE

A monotypic family having flowers arranged in unisexual heads with male heads above females (Fig. 17). All species are clearly wind pollinated (Cook & Nicholls, 1986, 1987), in spite of the fact that some syrphid flies specialize on *Sparganium* pollen as a source of food.

THURNIACEAE

It is not certain that this monotypic family deserves to be called aquatic. The floral structure suggests pollination by wind (Fig. 18) but no observations have been published.

TYPHACEAE

This monotypic family is relatively well documented and is clearly wind pollinated (Fig. 19; see Krattinger, 1975), even though syrphid flies may collect pollen adhering to the female inflorescence.

All species have single ovules in each flower; some species, however, have pollen in tetrads. This contradicts all previous theoretical predictions regarding the function of pollen tetrads in pollination. Nicholls & Cook (1986) found that pollen tubes from tetrads are capable of traversing from the stigma of one flower through air to the stigma of another (Fig. 20) and fertilizing neighboring flowers. This results in increased efficiency of gametes in effecting fertilization (measured as seed-set) compared with other species of *Typha* having single pollen grains.

CONCLUSIONS

About 79 angiosperm families and 380 genera contain aquatic species. Most of the data are to be found in Cook et al. (1974). Excluding the Podostemaceae, because its floral biology is so poorly known, 31.6% of the families and 42% of the genera are pollinated abiotically.

Of the abiotically pollinated genera, 18 (or 19 including *Potamogeton*) have wettable pollen and are pollinated under water; about seven genera are pollinated at the water surface. This leaves 119 genera (35.5%) exclusively wind pollinated. I have tried without success to find geographical correlations between pollination and distribution of aquatics; it seems that about one-third wind pollinated remains reasonably constant when one compares the Old and New worlds, Northern and Southern hemispheres, and Tropics and Temperate zones. Within particular plant communities or associations there are enormous differences in the proportion of wind-pollinated species as also found by Kugler (1971). Reedswamp and sedge-dominated communities are mostly made up of wind-pollinated plants. Also the plants of deep and permanent water are mostly abiotically pollinated; all the marine angiosperms, for example, are hydrogamous. Nevertheless, about two-thirds of all aquatic genera (and this probably also applies at the level of species) are biotically pollinated.

So little is known about the breeding systems of aquatic species that it is not possible to generalize on in- or outbreeding within the context of the mode of pollination.

Aquatic angiosperms have evolved from terrestrial ancestors. All available evidence suggests that the aquatic members of at least six families (Centrolepidaceae, Cyperaceae, Hydatellaceae, Juncaceae, Plantaginaceae, and Poaceae) have evolved from anemophilous ancestors. This translates to an

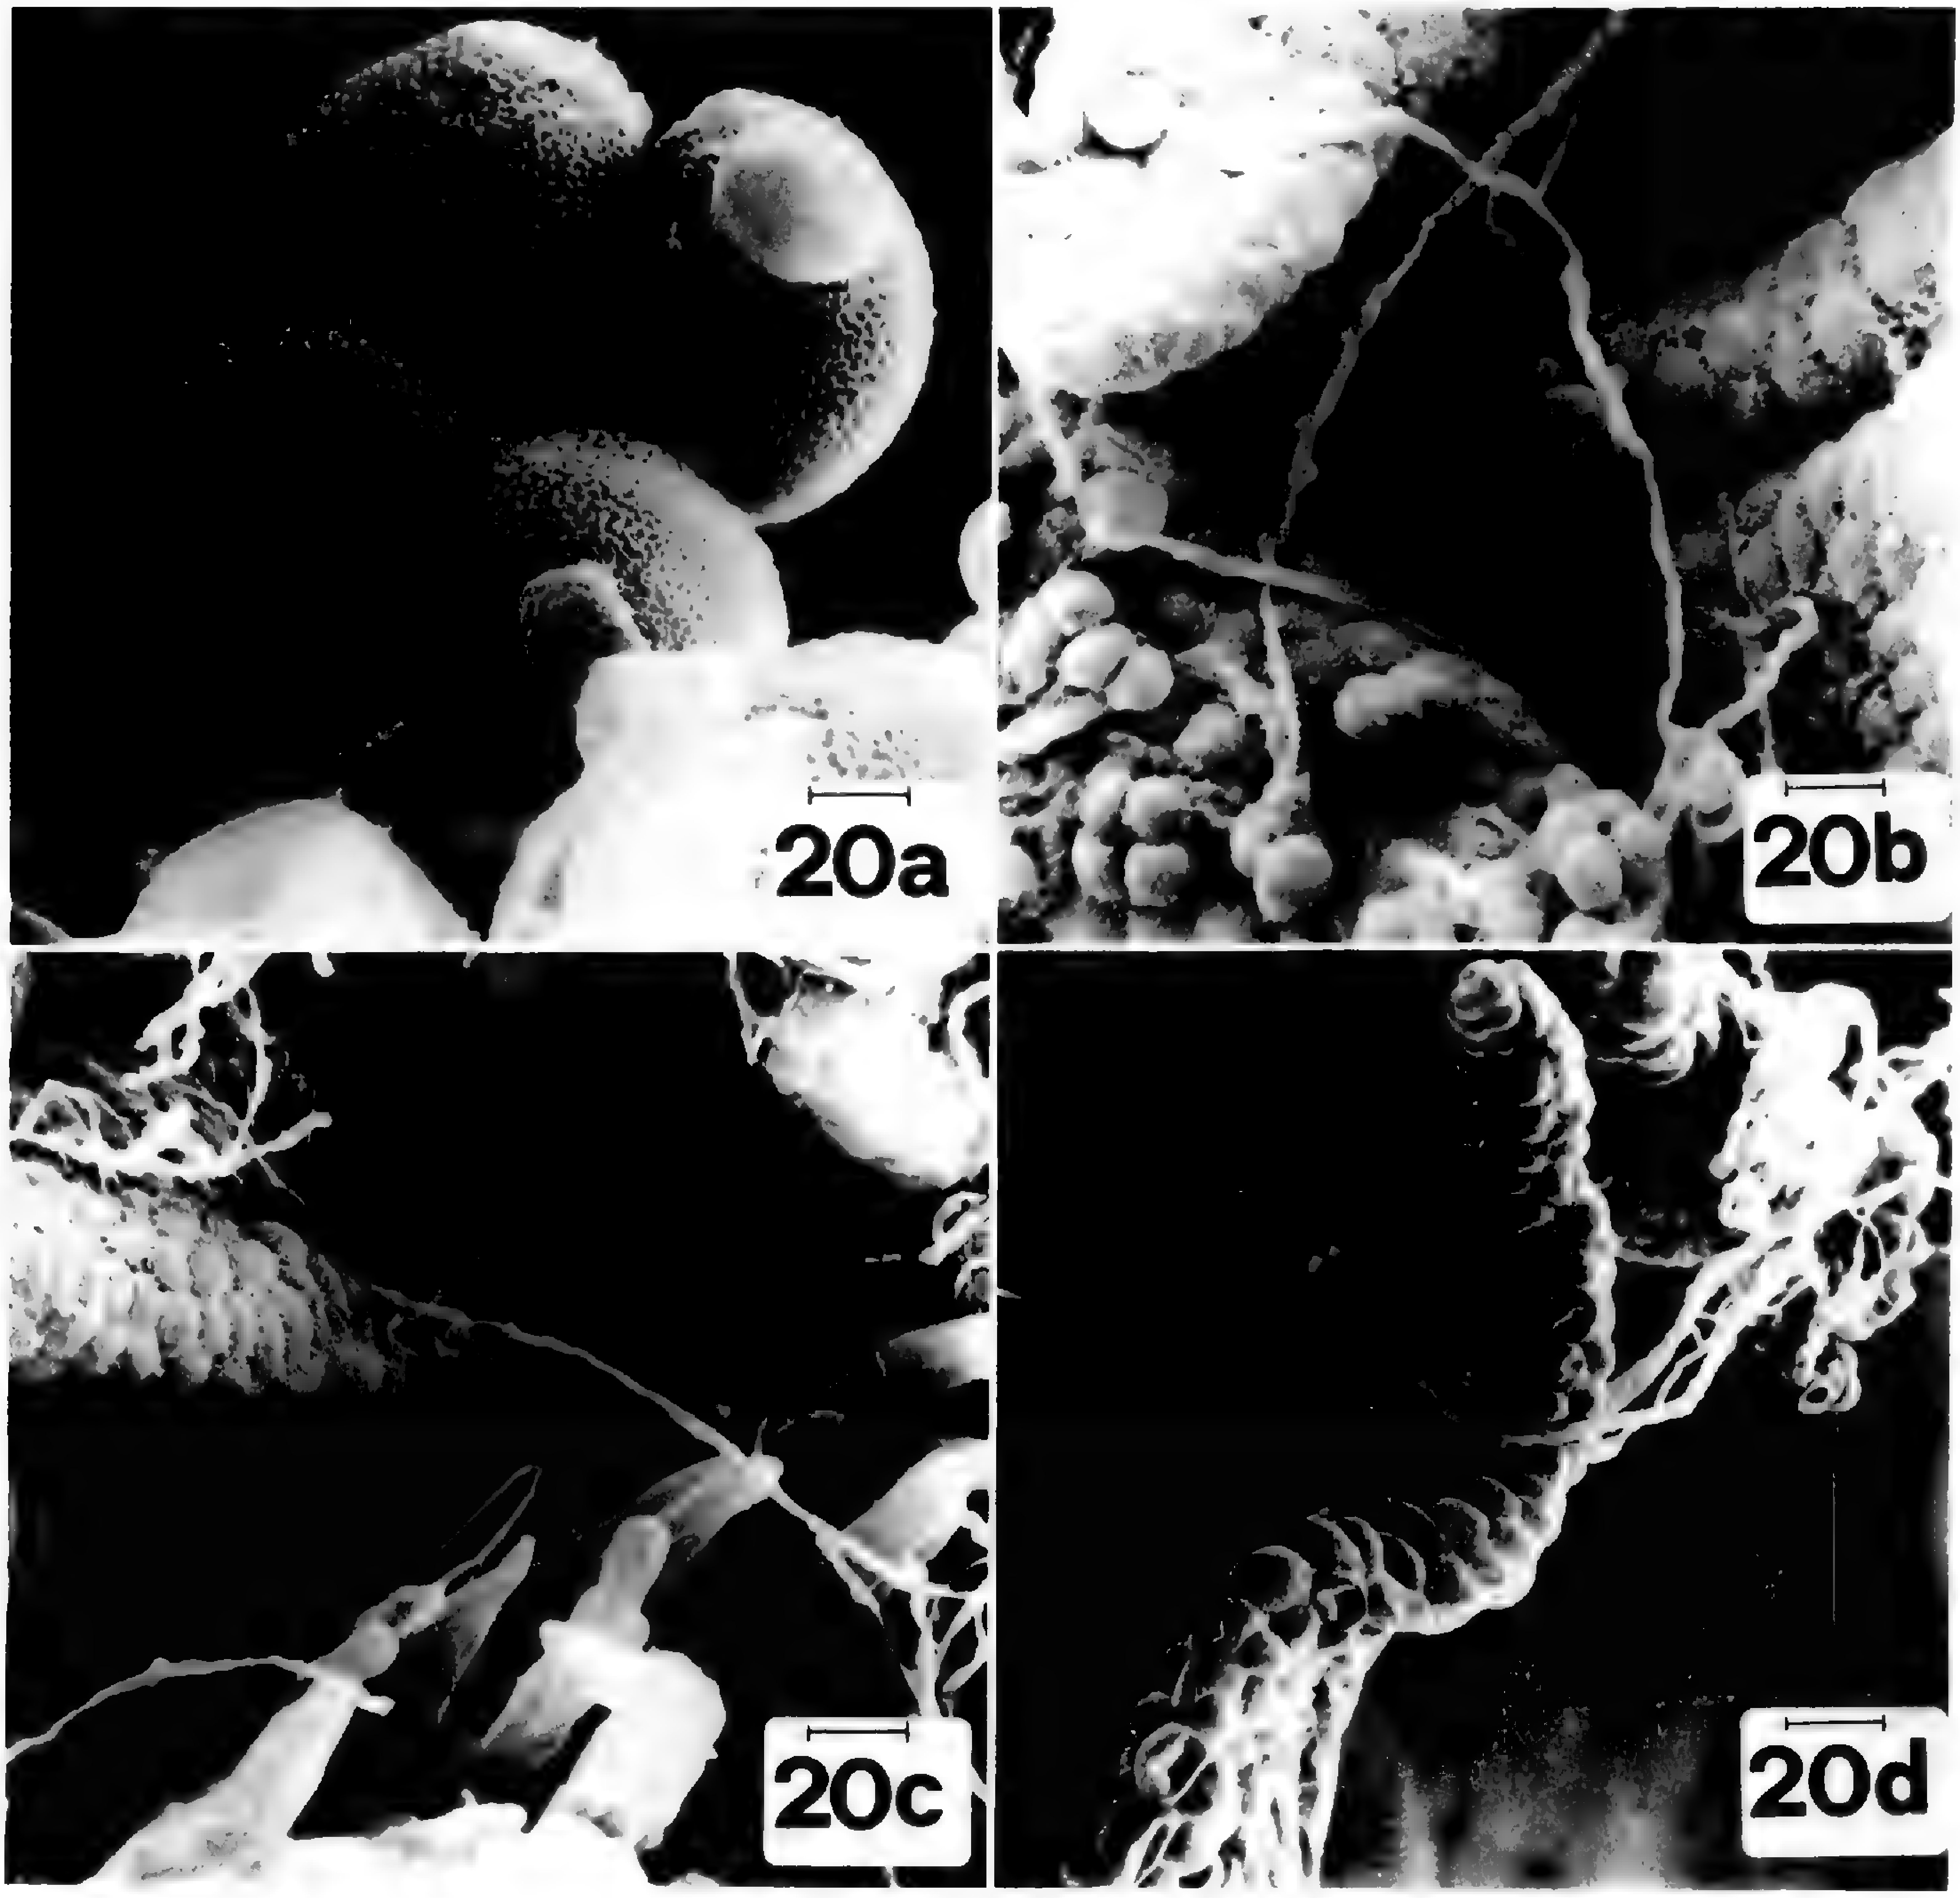

FIGURE 20. Typha latifolia.—*a. Pollen tetrad, two grains germinating. Scale bar = 5 μm.—b–d. Pollen tubes crossing from one stigma to another. b, scale bar = 3 μm; c, d, scale bar = 50 μm.*

estimate of at least 100 genera that brought anemophily with them into the aquatic milieu. This leaves a mere 19 genera where the anemophily may have evolved subsequent to the invasion of the aquatic habitat. When these 19 genera are examined a little closer, although they do not have any obvious terrestrial relatives, they mostly belong to exclusively anemophilous families (Callitrichaceae, Haloragaceae, Hippuridaceae, Hydrostachydaceae, Lilaeaceae, Potamogetonaceae, Ruppiaceae, Sparganiaceae, Thurniaceae, and Typhaceae).

In only *Brasenia* (Cabombaceae) and *Limnobium* (Hydrocharitaceae) is it very likely that the evolution from entomophily to anemophily has taken place in the aquatic environment. The genus *Hydrilla* (Hydrocharitaceae) is not strictly "wind" pollinated, because heavy pollen grains are actively propelled from the male flowers to the females. This mechanism relies on water and therefore probably evolved in water. However, it shows an alternative pathway to the evolution of anemophily.

From a total of 380 aquatic angiosperm genera, a minimum of two and a maximum of 19 may have evolved from entomophily to anemophily subsequent to the invasion of the aquatic habitat. From these numbers alone it does not seem likely that pollination by wind is a feature that is especially associated with life in the aquatic environment like, for example, the presence of gas spaces (lacunae) and hydropoten or the absence of lignin and/or stomata. Many aquatics clearly evolved from terrestrial groups that were already anemophilous; there is no evidence that any of these aquatics have returned to biotic pollen transfer. Taken as a whole, it is not possible to say that anemophily is particularly beneficial or detrimental to plants living in water. However, it is remarkable, when the different floral types illustrated in this contribution are compared, how many different strategies are adopted to guarantee transference of pollen by means of wind. There are no obvious trends among the wind-pollinated aquatics that indicate the pathway to hydrogamy. "Aquatic" anemophily is not different from "terrestrial" anemophily.

MORPHOLOGICAL STUDIES OF THE NYMPHAEACEAE SENSU LATO.
XVI. THE FLORAL BIOLOGY OF *BRASENIA SCHREBERI*[1]

Jeffrey M. Osborn[2,3] *and*
Edward L. Schneider[2]

ABSTRACT

Observations conducted in East Texas on the pollination biology of Brasenia schreberi *J. F. Gmel. confirm that anthesis is diurnal, with individual flowers opening and closing for two consecutive days. First-day flowers are morphologically and functionally pistillate. They are characterized by short, undehisced stamens and elongated, papillate stigmas that radiate outward over the perianths, providing an expanded surface area for pollen adherence. Second-day flowers are morphologically and functionally staminate. Staminal filaments are elongated, elevating the dehiscent anthers to a position above the centrally aggregated stigmas. Although self-pollination occurs, dichogamy prevents individual flowers from self-fertilizing.* Notiphila *cf.* cressoni *(Diptera; Ephydridae) was the most frequent insect visitor. Based on behavior and pollen loads, insect pollination is insignificant. The expanded stigmatic surface area, exserted stamens, and additional floral and vegetative features are adaptations for wind pollination. Data from pollen dispersal experiments indicate that anemophily is the primary mechanism of pollen transfer. This pollination mechanism is unique in the Nymphaeaceae sensu lato. Evidence from pollination biology, floral anatomy, seed anatomy, and embryology indicates a close evolutionary relationship between the Cabombaceae and Nymphaeaceae sensu stricto. Genera of the Nymphaeaceae s. str. and Nelumbonaceae exhibit a phyletic elaboration of the flower, whereas the Cabombaceae represent a phyletic reduction.*

Brasenia schreberi J. F. Gmelin is a monotypic genus with a wide but sporadic distribution in lakes, ponds, and slow streams. It occurs in eastern Asia, Australia, Africa, the West Indies, and South, Central, and North America. In North America the species ranges from Florida to East Texas, north to Prince Edward Island, southern Quebec, southern Ontario, and Minnesota. It also occurs in Idaho, California, north to British Columbia, and Alaska (Wood, 1959). Although *Brasenia* does not presently occur in Europe, fossil specimens are known (Srodon, 1935; Tralau, 1959; Jessen et al., 1959; Hall, 1978; Collinson, 1980). *Brasenia* is commonly known as water-shield, water-target, purple bonnet, and purple wen-dock and is a cultivated food source in Japan (Matsuda & Hara, 1985).

Brasenia is one of eight genera within the Nymphaeaceae sensu lato as circumscribed by Bentham & Hooker (1862). Subsequent workers have grouped the nymphaeaceous genera into various orders, families, and tribes (for review see Goleniewska-Furmanowa, 1970; Takhtajan, 1980; Cronquist, 1981). The opinions that the genera should be divided among three subfamilies or three families (Nymphaeaceae, Nelumbonaceae, and Cabombaceae) within the order Nymphaeales has been widely advocated on the basis of available data. A ninth genus, *Ondinea*, was described by den Hartog (1970) and placed within the Nymphaeaceae sensu stricto. This taxonomic alignment is supported based by studies of seed anatomy, floral morphology, and floral biology (Schneider, 1978, 1983).

In all systematic treatments, *Brasenia* has been allied with *Cabomba* on the basis of such shared morphological features as long, slender, sympodial stems; peltate floating leaves; small hypogynous flowers with apocarpous gynoecia, and few floral parts. Moseley et al. (1984), comparing anatomical

ANN. MISSOURI BOT. GARD. 75: 778–794. 1988.

and morphological features of the vegetative axes and flowers in *Cabomba* and *Brasenia*, suggested that the two genera are more distant taxonomically than envisioned by earlier workers (Vinogradov, 1967; Goleniewska-Furmanowa, 1970; Bukowiecki et al., 1972, 1974), a view also shared by Collinson (1980). Moseley et al. emphasized, however, that the taxonomic distance was not adequate to warrant dismantling the Cabombaceae. Richardson (1969) concluded that the floral vascular system (and by inference, the flower) of *Brasenia* exhibits a phylesis toward condensation and reduction from a more primitive, larger-flowered ranalian ancestor. Ito (1986a) determined that the ontogeny and anatomical construction of the receptacular vascular plexus, a feature common to all water lily genera, differs in the Cabombaceae from those found in the Nymphaeaceae s. str. Ito also considered the floral vasculature of *Cabomba* to be derived (via reduction in the number of stamens and carpels) from the type of vasculature found in the flower of *Brasenia*.

Numerous studies of *Brasenia* involving a diversity of features have been conducted including: seed anatomy and embryology (Weberbauer, 1893, 1894; Chifflot, 1902; Cook, 1906, 1909; Melikyan, 1964; Khanna, 1965; Corner, 1976); pollen morphology (Wodehouse, 1932; Ikuse, 1955; Ueno & Kitaguchi, 1961; Ueno, 1962; Meier, 1964; Walker & Doyle, 1975; Walker, 1976a, b; Clark & Jones, 1981; Batygina & Shamrov, 1983); xylem anatomy (Kosakai, 1968); karyology (Langlet & Söderberg, 1927; Okada & Tamura, 1981); chemical analyses (Nakahara, 1940; Riemer & Toth, 1970; Goleniewska-Furmanowa, 1970; Kakuta & Misaki, 1979; Sevilla et al., 1984); leaf development and anatomy (Goleniewska-Furmanowa, 1970; Kaul, 1976; Chen & Zhang, 1986); floral anatomy (Troll, 1933; Moseley, 1958; Khanna, 1965; Richardson, 1969; Moseley et al., 1984; Ito, 1986a); paleobotany (Hall, 1978; Collinson, 1980; Dorofeev, 1984); and general morphology and taxonomy (Lawson, 1888; Schrenk, 1888; Caspary, 1891; Keller, 1893; Raciborski, 1894; Schilling, 1894; Gwynne-Vaughn, 1897; Hill, 1900; Chrysler, 1938; Wood, 1959; Adams, 1969; Kristen, 1974; Ogden, 1974; Rao & Banerjee, 1979; Matsuda & Hara, 1985). Little attention, however, has been given to the floral (pollination) biology of the genus. Tokura (1937) investigated the blooming of *Brasenia* in Japan and was the first to record the movements of floral parts during the two-day anthesis period. Tokura suggested that flowers on the first day of anthesis are pistillate, while on the second day staminate, during which time large quantities of pollen are released. Tokura noted the importance of the increased height of second-day, pollen-releasing flowers above those of the first-day, pollen-receptive flowers from the standpoint of pollen transfer but did not suggest the vector(s) for pollination. Schneider & Jeter (1982) reported "*Notiphila*-like" flies functioning as pollinators in populations of *Brasenia* growing in East Texas.

This investigation is part of a continuing series of studies designed to contribute new evidence for determining relationships among water lily genera. It is the objective of this study to: (1) confirm and amplify observations on floral morphology and floral behavior during anthesis of *Brasenia*; (2) elucidate the mechanism(s) of pollen transfer and relate floral morphology to pollination syndrome(s); and (3) compare the pollination biology of *Brasenia* with other genera of Nymphaeaceae s.l. This may contribute to a better understanding of the phylogeny of this angiosperm family, which occupies a basal, pivotal systematic position in many old and modern classification schemes.

MATERIALS AND METHODS

SITE DESCRIPTION

Observations on the floral biology of *Brasenia* were conducted during the summers of 1986 and 1987 in Toledo Bend Reservoir, Sabine County, Texas. Extensive populations of *Brasenia* exist in numerous coves throughout the reservoir. This study was conducted in a cove of six surface hectares adjacent to the Willow Oak Recreation Area. The water level within the reservoir fluctuated widely throughout the study period. The depth of water in which *Brasenia* grew ranged from 0.5 to 2.5 m.

FLORAL CYCLE

Ten flowers in various stages of anthesis were tagged with numbered fluorescent orange corks by securing them to peduncles with nylon fishing line. Heights of the floral structure above and below water level were measured over four consecutive days. Measurements were made from the base of the receptacle to the water level. In addition, sepal, petal, staminal, and stigmatal positions were observed.

CAGING TREATMENTS

Exclusion treatments were accomplished by placing floating cages over emergent flowers for the duration of anthesis. Flowers were tagged with fluorescent corks attached to the peduncle for fruit retrieval. Different experiments were identified by color-coded survey ribbons stapled to corks. Cages consisted of 950-ml styrofoam and plastic drinking cups mounted inversely on 21-cm^2 styrofoam sheets. The center portion of the styrofoam base was removed to allow placement of cages over flowers. Two types of cages were used: one to exclude all abiotic and biotic pollen vectors, and a second to exclude only biotic vectors. Abiotic and biotic exclusion cages were made from clear plastic cups (transparent cages). Biotic exclusion cages were produced using styrofoam cups with four rectangular windows cut out around their circumferences. Windows were covered with 1-mm^2 fiberglass mesh screen glued to the styrofoam cups (mesh cages). Transparent cups were mounted on 2.5-cm-thick styrofoam, while mesh cups were mounted on 1.3-cm-thick styrofoam sheeting to maximize flower exposure through the mesh windows above the styrofoam base. Both types of cups were mounted to the styrofoam bases with water-insoluble glue.

Three control groups, each consisting of 25 second-day flowers, were tagged during intervals throughout the study period to determine natural seed set. An additional control group, consisting of 25 flowers that had morphologically short stigmas, was also tagged. Each exclusion treatment involved various floral manipulations of 25 first-day flowers and their subsequent seed production to check for the following:

Parthenocarpy (Group A). Flowers were covered prior to anthesis with transparent cages and emasculated. Emasculation involved the removal of undehisced anthers on the first day of anthesis. Cages were observed periodically throughout anthesis to check flower position and condition.

Autogamy (Group B). Flowers were covered with transparent cages and left undisturbed.

Stigmatic receptivity (Group C). (1) Flowers were covered with transparent cages and emasculated. First-day stigmas were dusted copiously with pollen transferred mechanically from uncaged pollen-releasing flowers. (2) Flowers were covered with transparent cages and emasculated. Pollen was transferred mechanically to second-day stigmas.

Allogamy (Group D). (1) Geitonogamy. Flowers were covered with transparent cages and mechanically cross-pollinated on the first day with pollen from uncaged flowers from the same plant. (2) Xenogamy. Flowers were covered with transparent cages and cross-pollinated on the first day with pollen from uncaged flowers from different plants.

Anemophily (Group E). (1) Flowers were covered with mesh cages and left undisturbed. (2) Flowers were covered with mesh cages and emasculated.

POLLEN DISPERSAL AND TERMINAL SETTLING VELOCITY

The presence of wind-borne *Brasenia* pollen was determined using an Andersen 0101 particle-size air sampler (Andersen, 1958). In addition, dispersed pollen was quantified by measuring distance and angle of dehiscence from pollen-releasing flowers. Measurements were made using calibrated poster boards 71.5 × 56 cm. Black poster boards (pollinometers) were marked in increments of 10 cm and 20° from the midpoint of one edge (Fig. 1). Circles equal in size to an average stigmatic surface area of a first-day flower were drawn into distance-angle segments. Boards were laminated and mounted on 2.5-cm-thick styrofoam.

Individual pollinometers were placed downwind from single pollen-releasing flowers with the peduncle at the 0° mark between 0800–1200 hours. All additional pollen-releasing flowers from the surrounding 3-m radius were removed. Pollinometers were retrieved after total anther dehiscence, and the number of pollen grains within each circle was quantified using a hand lens. Samples were taken on two separate days, six trials per day. Wind-speed measurements were taken using a Taylor anemometer. Results were analyzed using Student's *t*-test and regression analyses.

Stigmas were viewed with a dissecting microscope to detect the presence of pollen. These included stigmas on uncaged first-day flowers in close proximity and downwind of pollen-releasing flowers and uncaged first-day flowers not adjacent to pollen-releasing flowers. Comparisons were made of pollen quantity on stigmas of flowers in each condition. Additionally, pollen distribution was observed (e.g., more grains on leeward or windward surfaces).

The terminal settling velocity of freshly collected *Brasenia* pollen was determined utilizing the stroboscopic photography techniques of Niklas (1984).

POLLEN–OVULE RATIOS AND POLLEN VIABILITY

The number of pollen grains/flower was determined by suspending all pollen from 10 anthers in a 0.5-ml solution of aniline-blue in lactophenol and counted using a hemacytometer (Cruden, 1977). Pollen–ovule ratios were calculated assuming a mean number of 28 anthers and 12 carpels (24

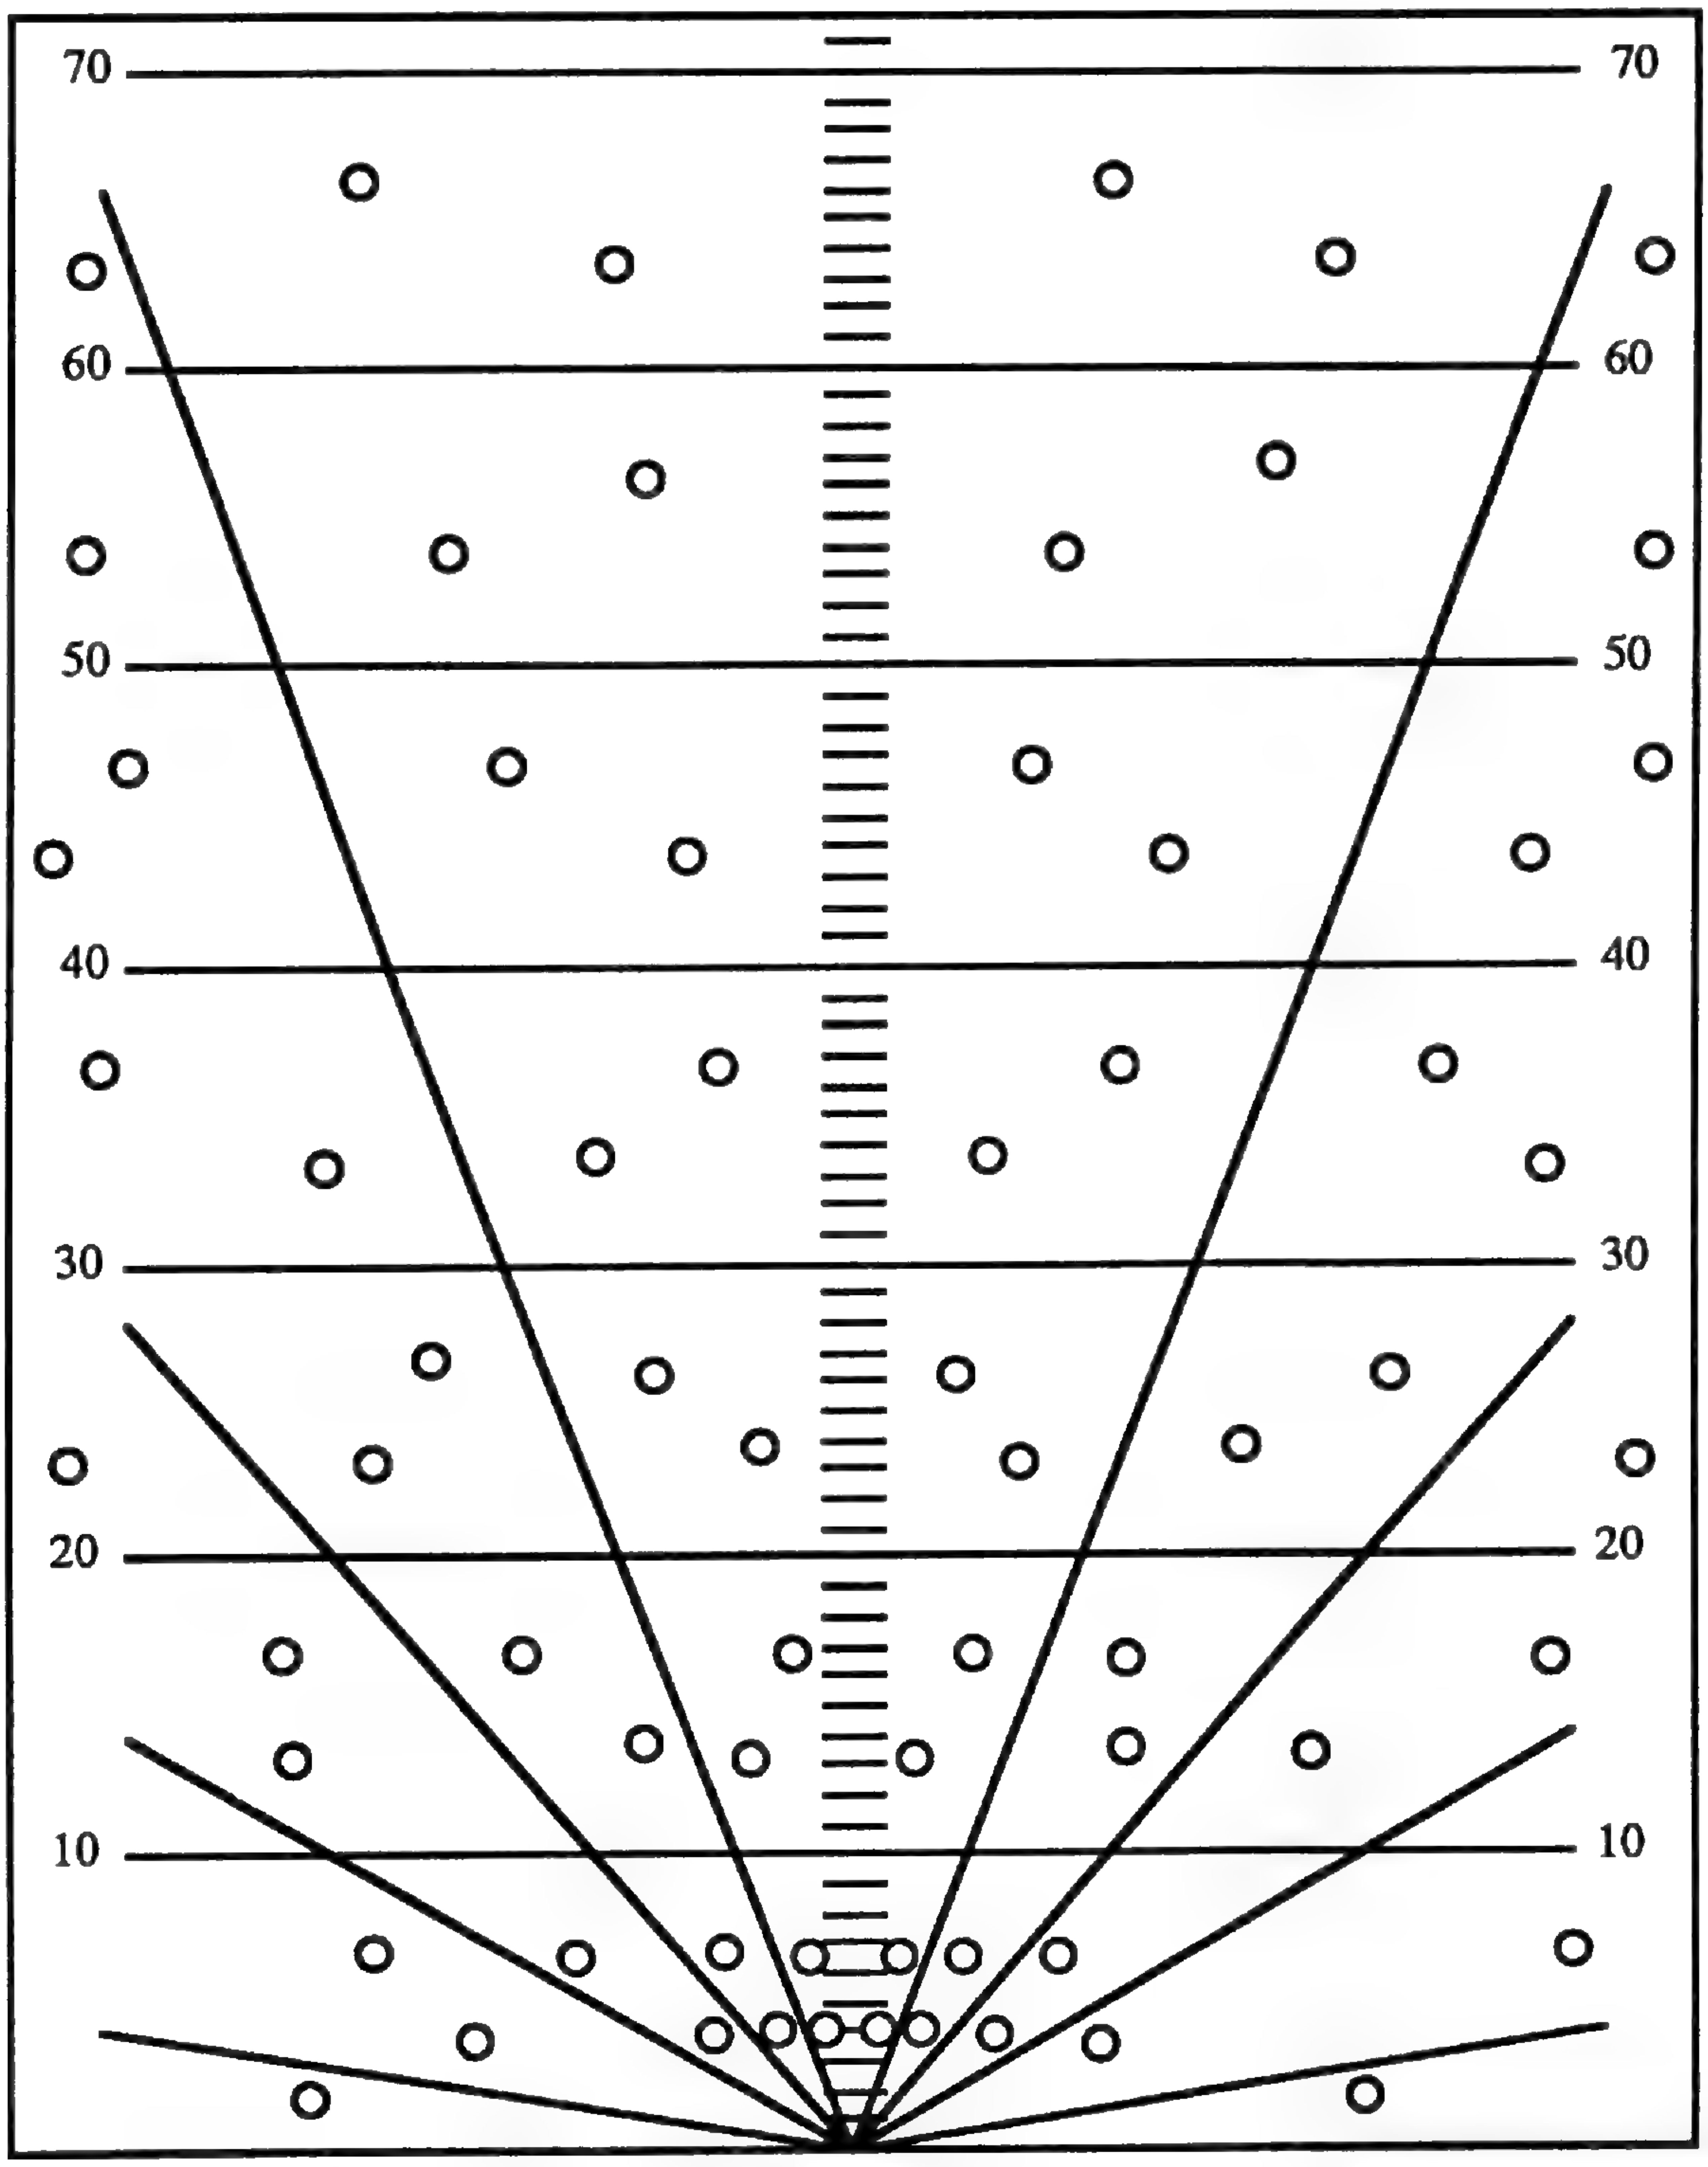

FIGURE 1. *Pollinometer. Circles represent the average stigmatic surface area of first-day flowers. Seventy cm scale.*

ovules) per flower. Pollen viability was determined using aniline-blue in lactophenol staining.

FLORAL DENSITY

The distributional density of flowers was determined by counting the total number of first- and second-day flowers within ⅛-m frames in a random stratified design.

FLORAL SECRETIONS

The presence of floral secretory tissues was determined using neutral red stain as an indicator (Esau, 1965; Vogel, 1966). Fresh first- and second-day flowers were placed in neutral red for three to six hours. After excess stain was removed by lightly washing with water, the flowers were examined using a dissecting microscope.

ULTRAVIOLET REFLECTANCE AND ABSORPTION

Ultraviolet (UV) photographs using black and white Kodak Plus X film, 125 ASA, and a Kodak Wratten ultraviolet filter No. 18A were made of first-day and second-day flowers and leaves in sunlight. Second-day flowers were photographed prior and subsequent to anther dehiscence.

ANTHOPHILOUS VISITORS

Observations were made to determine diversity, frequency, behavior, and extent of pollen loads of various insect visitors. Insects on flowers and leaves were collected using kill jars with ethyl acetate and were preserved in 70% ethanol. Voucher specimens are housed at SWTSU.

SCANNING ELECTRON MICROSCOPY

Floral and fruit specimens were investigated with a Cambridge S90 scanning electron microscope (SEM). Tissues were fixed for 24 hours in 2% glutaraldehyde in 0.1 M cacodylate buffer, pH 7.2. Samples were washed with the buffer and postfixed in 1% osmium tetroxide for three hours, then stored in the buffer. Floral specimens were dehydrated in acidified dimethoxypropane (Postek & Tucker, 1976; Linn et al., 1977) and critical-point dried. Seeds were immersed in acetone and placed in an ultrasonicater for five minutes and air dried. Pollen grains were pipetted onto filter paper and air dried. Floral and seed specimens were sputter-coated with gold or gold–palladium and then mounted on aluminum stubs with colloidal graphite. Pollen grains were mounted by inverting finely polished stubs covered with Mikrostik® onto filter papers with the dried pollen and then sputter-coated.

OBSERVATIONS

HABIT

Brasenia is a rhizomatous, aquatic perennial. The rhizomes bear axillary buds, adventitious roots, and leaves at each node. Leaves are alternate, long-petioled, and centrally peltate. Young leaves are involute in bud. Mature leaf blades are floating and oval to elliptic with entire margins. Submerged stems, petioles, and abaxial leaf surfaces are heavily coated with a layer of transparent mucilage, as are young plant parts such as axillary buds and juvenile leaves (Fig. 2).

Flowers of *Brasenia* are about 2 cm in diameter, dull purple, and emergent. They are borne singly on long, mucilage-coated peduncles and possess linear-lanceolate perianth parts with three petaloid sepals and three petals. All perianth members bear antrorse, adaxial trichomes (Fig. 3).

The androecia of flowers within the study site are composed of 24–33 stamens with filiform filaments and four apical microsporangia. Dehiscence is latrorse in the study populations. Pollen grains are elliptic, monosulcate, and have faintly scabrate ornamentation (Fig. 4). The pollen–ovule ratio of *Brasenia* is 9,238 ± 625 (95% C.I., N = 11), and 98% of the pollen is viable.

Flowers are hypogynous with apocarpous gynoecia of 10–14 carpels in Toledo Bend populations. These are characterized by relatively short styles and by linear, extremely papillate stigmas with abaxial stigmatic crests (Figs. 5, 6). Ovaries contain one or two anatropous and crassinucellate ovules. Placentation ranges from laminar to dorsal (Richardson, 1969) to median (Ito, 1986a).

Fruits are aggregate and subtended by a persistent perianth. Each simple fruit is indehiscent, one- or two-seeded, and surrounded by a leathery pericarp. Peduncles bearing aggregate fruits abscise, float to the surface, and drift. Eventually, simple fruits detach from the receptacle, float on the water's surface where they are carried by wind and wave actions, and then sink to the pond bottom.

The seeds are ovoid (Fig. 7) and at their apex possess a pyramidal structure with a central micropyle (Fig. 8). The seed coat surface is composed of irregularly digitate cells. Seeds contain small amounts of endosperm, copious perisperm, and haustorial tubes. Embryos are minute, with two broad hemispherical cotyledons (Fig. 9).

FLORAL CYCLE

The floral structure of *Brasenia* is diurnally emergent over a three-day period. On the first day of emergence, the flower is in bud and covered with mucilage (Fig. 10). Individual flowers bloom for two consecutive days. On the first day, flowers are morphologically pistillate; they are characterized by short, undehisced stamens and elongate, papillate stigmas radiating outward over the re-

flexed perianth (Fig. 11). Flowers submerge at the end of the first day. On the second day, the flowers are morphologically staminate; the filaments have elongated, elevating the dehiscent anthers to a position at or above the now centrally aggregated stigmas (Fig. 12). The perianth occupies a position similar to that of first-day flowers. At the end of the second day, flowers again submerge. Third-day flowers remain submerged but occasionally occur at the water surface. These flowers are nonfunctional, characterized by closed perianth parts with protruding senescent anthers. Aggregate fruits develop below the water surface (Fig. 13). Fruit development occurs in four to six weeks early in summer and as quickly as two weeks in the late summer.

During the course of fieldwork, morphological variation was observed among flowers. Aside from typical features described above, several *Brasenia* flowers had short stigmas which did not conspicuously radiate over the perianth (Fig. 14).

Individual flowers vary in position above and below the water level. General trends of the floral cycle can be identified, however (Fig. 15). Anthesis begins at 0630–0730 hours on both the first and second days. First- and second-day flowers reach maximum height above water at 1300–1400 hours. Second-day flowers are generally elevated to a higher position, with anther dehiscence occurring at 0830–1100 hours.

As first-day flowers close, the gynoecia and perianths gradually change position. When flowers are at peak height, stigmas begin to arch centrally until they completely aggregate at the time flowers close and submerge. Perianth members begin to close gradually at 1300–1400 hours, with the corolla closing prior to the calyx.

CAGING TREATMENTS

Results from caging experiments are reported as percentage seed set (Table 1). The percentage values are conservative because they were calculated assuming two ovules (seeds) per carpel (simple fruit) within carpels remaining on aggregate fruits at time of retrieval. They do not take into account

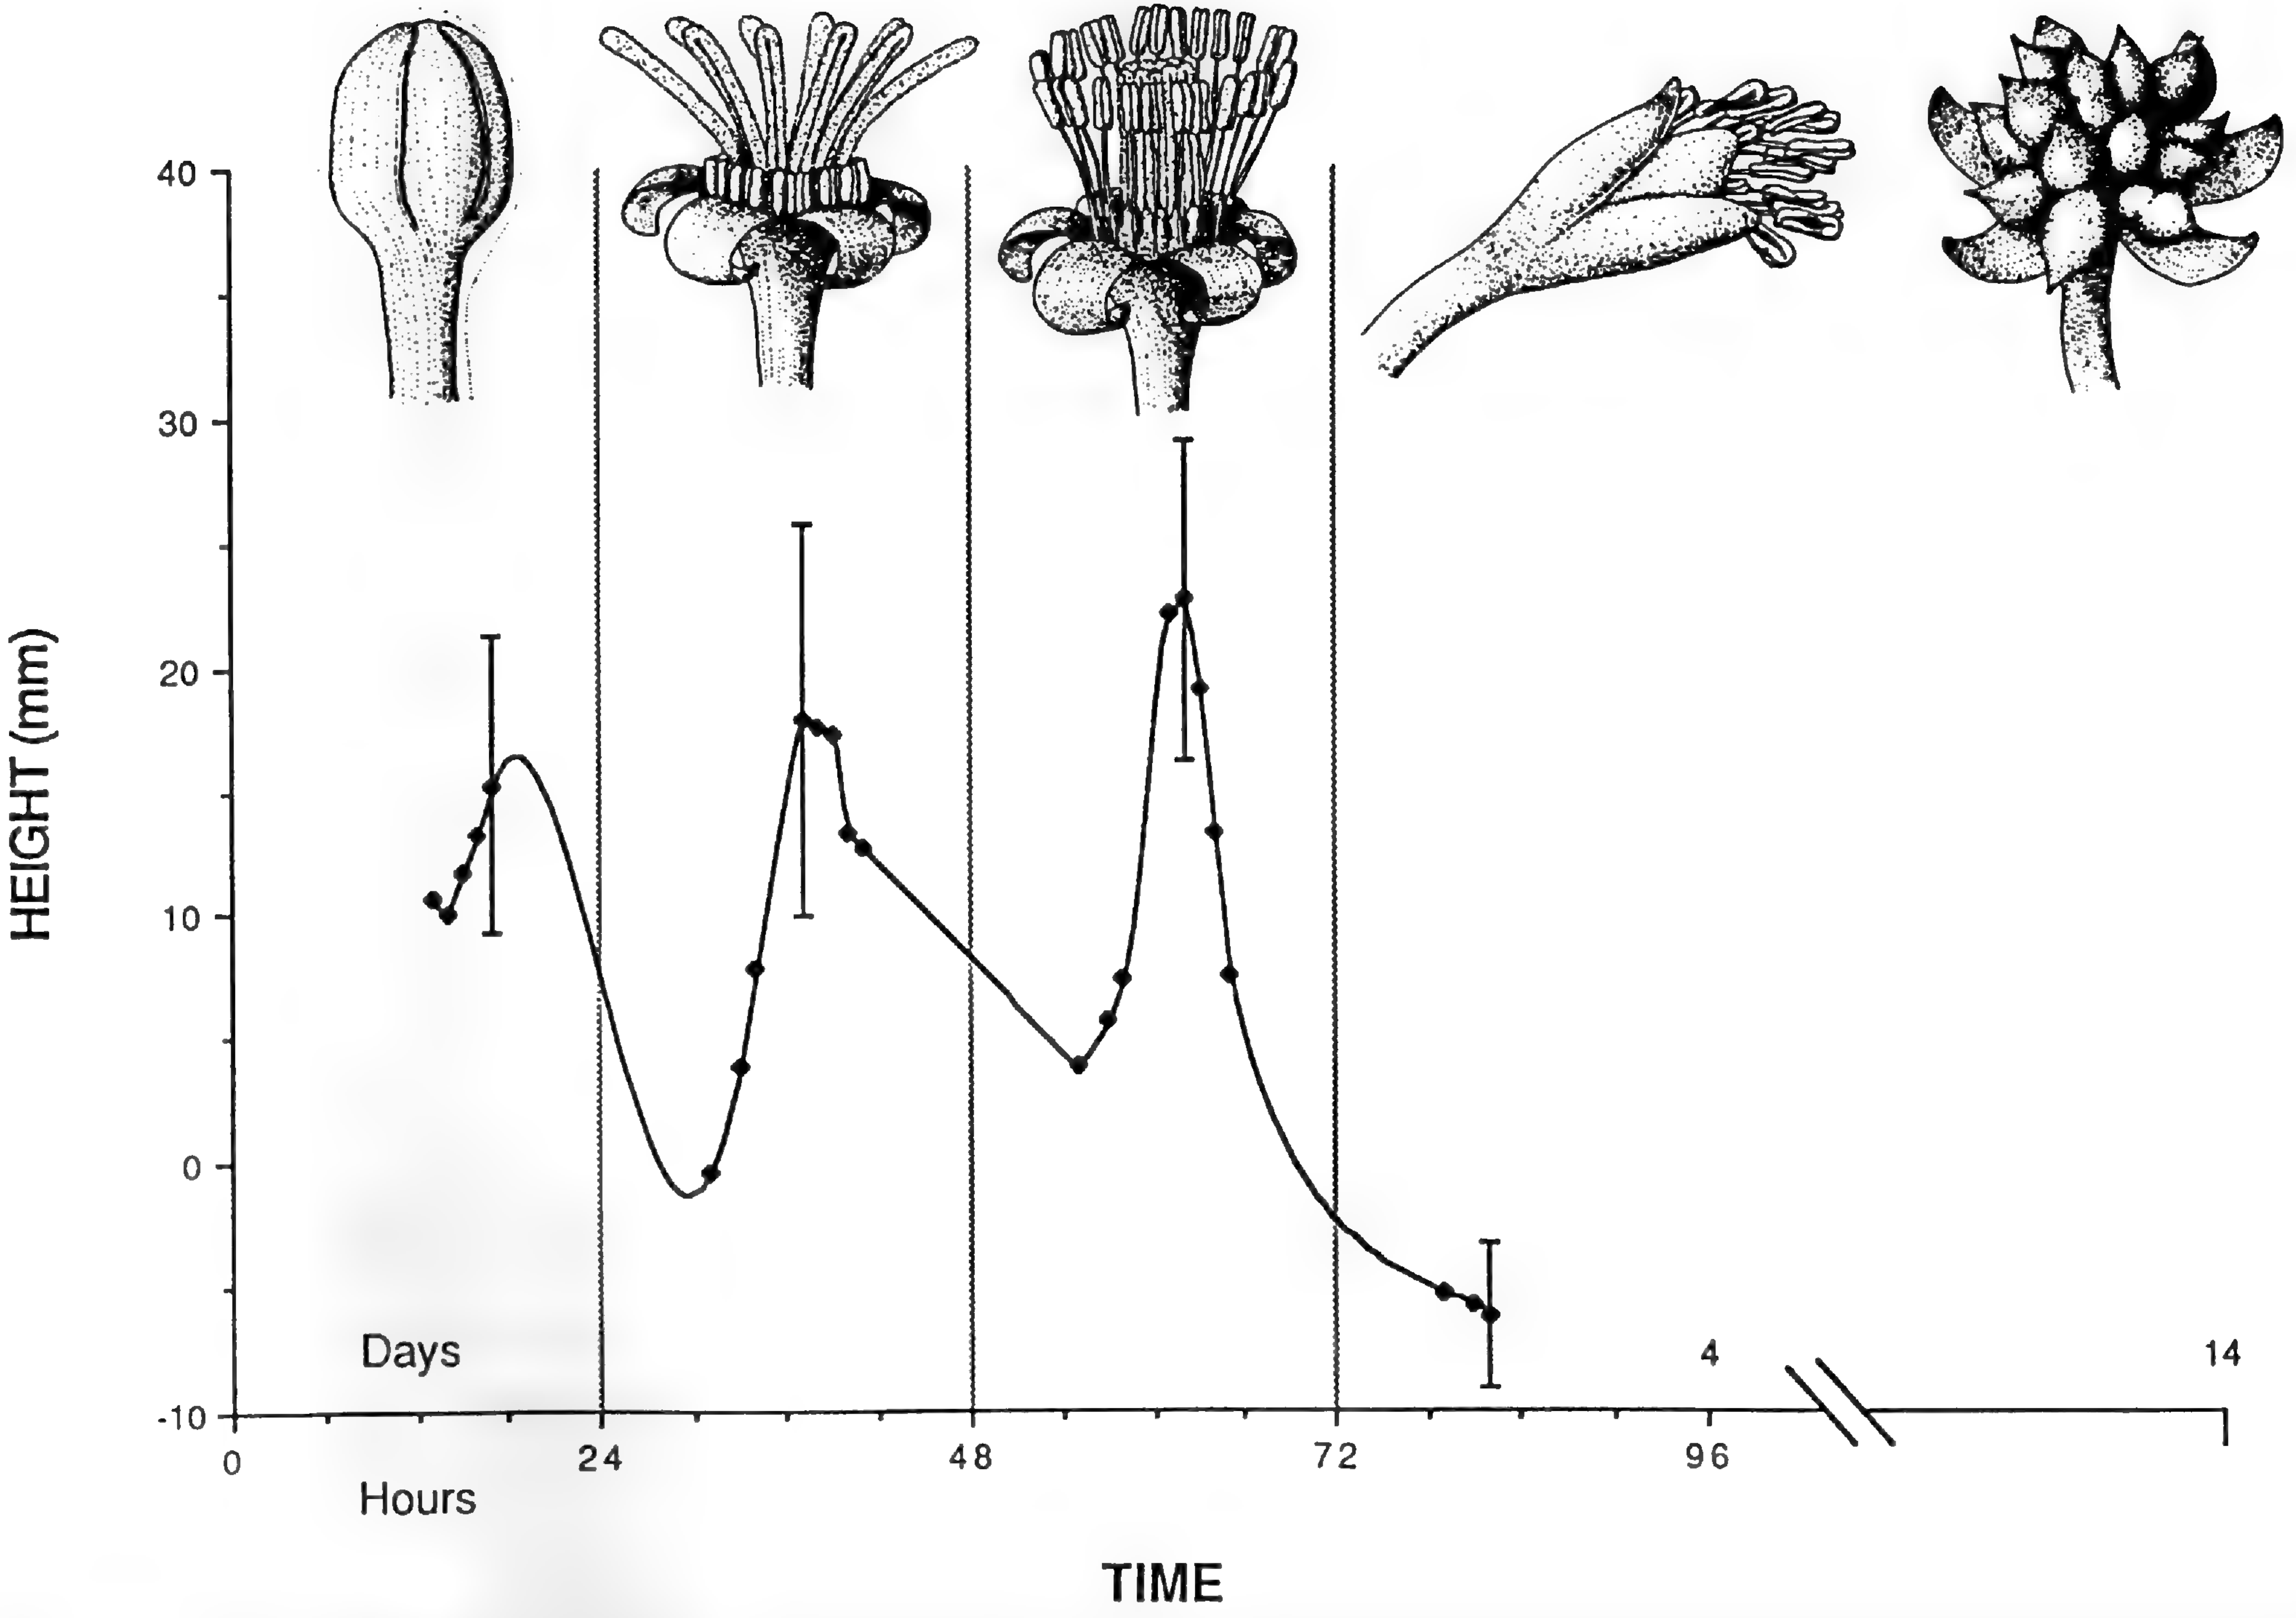

FIGURE 15. *Floral cycle of* **Brasenia** *illustrating changes in floral morphology and position above or below water level. Error bars represent average 95% confidence intervals of all values from each day; buds C.I. = 6.06, first-day flowers C.I. = 7.92, second-day flowers C.I. = 6.41, and third-day flowers C.I. = 2.83. Best-fit curve was computer generated.*

TABLE 1. *Percentage seed set from caging treatments conducted on separate trial dates.*

any carpels that had abscised prior to retrieval or carpels with only one ovule.

The results of exclusion treatments indicate that apomixis and autogamy did not occur (Groups A and B). Self-pollination did occur in treatment B, however, based on the observation of pollen on the stigmas. Flowers artificially pollinated on the first day and second day of anthesis (Group C) produced seeds. Flowers pollinated on the first day of anthesis exhibited greater seed set than those pollinated on the second day. These data indicate first-day flowers are receptive to pollen and should be considered functionally pistillate. Second-day flowers are functionally staminate. The results of experiment D, determination of allogamy, revealed that *Brasenia* is compatible with pollen of both geitonogamous and xenogamous origins. Only one of three trials from the mesh cage treatments (Group E) set seed. It is believed that minimal seed set in flowers subjected to this treatment occurred because the cages alter the aerodynamics of the floral structure (Niklas, pers. comm.) and the mesh screen probably inhibits the passage of pollen grains.

The three control groups of morphologically "typical" flowers yielded varying seed set (Table 1). This variation may be attributed to differences in wind speed and distributional density of flowers on each sample date. Flowers with short stigmas produced few seeds despite their occurrence in the same population as the "typical" control group.

POLLEN DISPERSAL AND TERMINAL SETTLING VELOCITY

Measurements with the Andersen particle sampler revealed that *Brasenia* pollen was airborne. Pollinometer experiments indicated the mean number of pollen grains dispersed from second-day (pollen-releasing) flowers decreases with distance. The numbers of grains at subsequent 10 cm intervals on each trial date were significantly different, with the exceptions of the 0–10 and 60–70 cm intervals. These differences can be attributed to wind velocity. Average wind speeds on respective sampling dates differed by a factor of five. Dispersion of pollen can be described exponentially (Fig. 16). A regression analysis of dispersed pollen grains exhibited correlation coefficients of $r = 0.99$ and $r = 0.85$ at 8 kph and 1.6 kph, respectively.

Pollen on the stigmas of a variety of flowers was also observed. First-day flowers that were downwind of and within 0.5 m of second-day flowers had abundant pollen on their stigmas. Those grains were primarily restricted to windward stigmas. Pol-

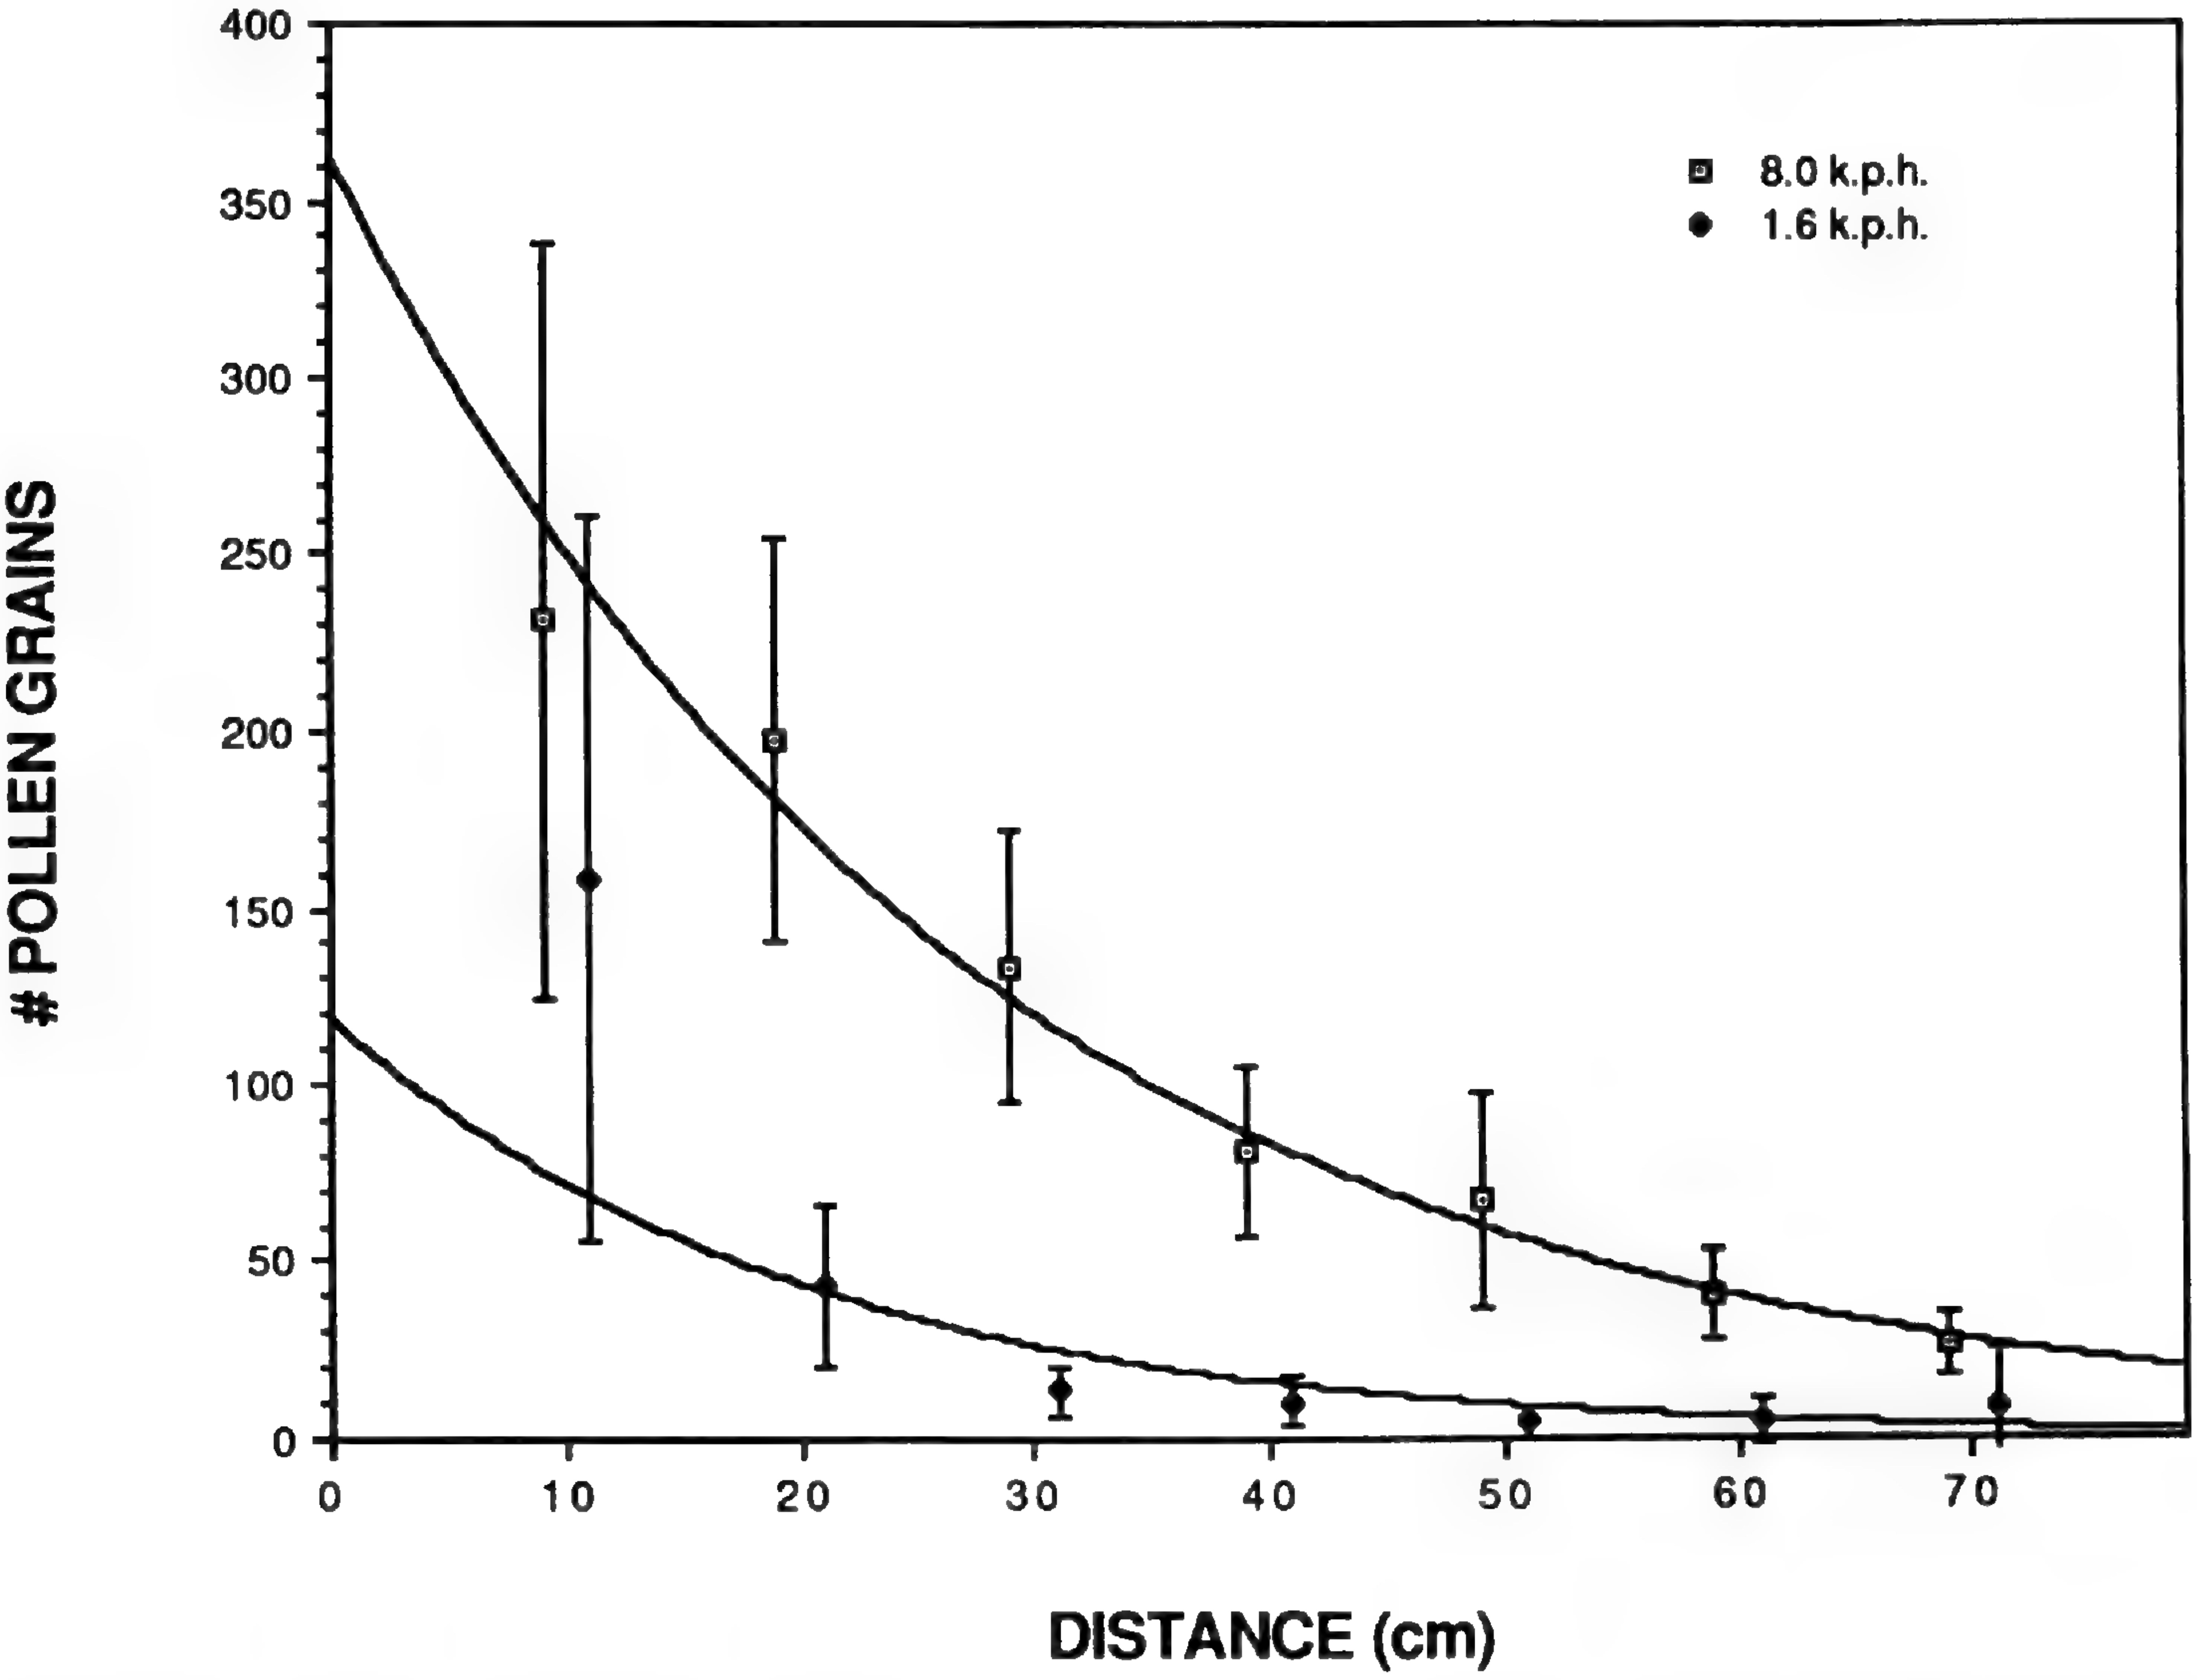

FIGURE 16. *Regression analysis of pollen grain deposition from pollinometer experiments. At 8 kph,* y = *367.9*10^ (0.02*x*),* r *value of 0.99; and at 1.6 kph,* y = *112.7*10^ (0.02*x*),* r *value of 0.85. Error bars represent 95% confidence intervals; best-fit curves were computer generated.*

len-receptive first-day flowers that were 2–3 m from second-day flowers exhibited very low quantities of pollen, if any, on their stigmas. The terminal settling velocity of *Brasenia* pollen was calculated to be 7.7 ± 0.8 (95% C.I., N = 21) cm/sec.

FLORAL DENSITY

Of four sample plots, the mean numbers of flowers/m^2 ± 95% C.I. were as follows: 110 ± 22; 82 ± 26; 73 ± 17; and 36 ± 14.

FLORAL SECRETIONS

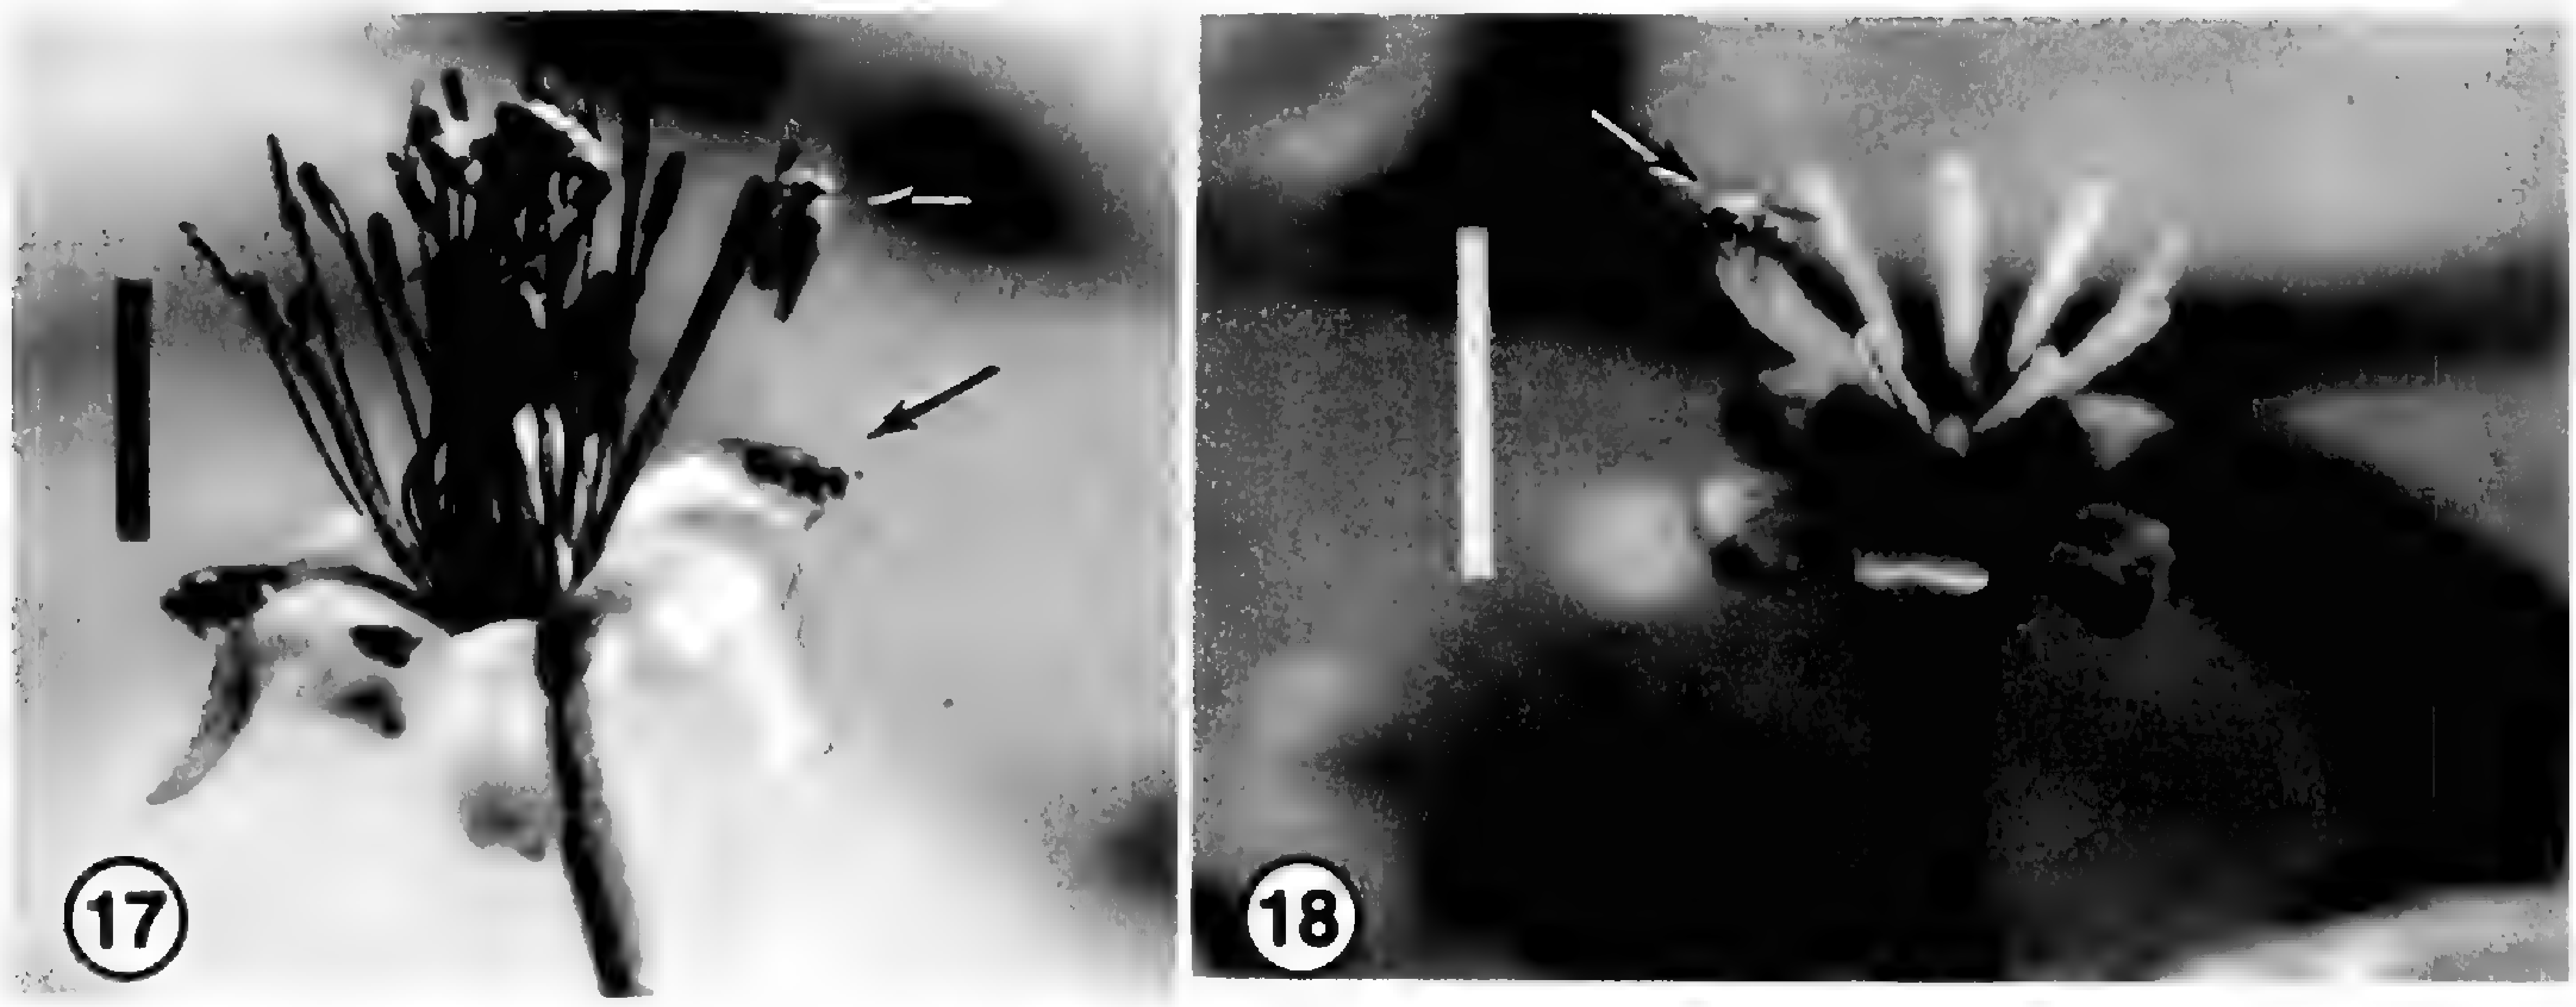
Neutral red staining revealed the absence of nectaries. The numerous perianth trichomes stained indicated a secretory role.

ULTRAVIOLET REFLECTANCE AND ABSORPTION

The inner surfaces of dehisced anthers are UV reflective. Adaxial (emergent) leaf surfaces are UV absorptive.

ANTHOPHILOUS VISITORS

A variety of insects visit flowers of *Brasenia*, including *Donacia cincticornis* Newman (Coleoptera; Chrysomelidae), *Perigaster cretura* Herbst (Coleoptera; Curculionidae), *Notiphila* cf. *cressoni* Cresson (Diptera; Ephydridae), *Apis mellifera* L. (Hymenoptera; Apidae), and various odonates. The most frequent and abundant visitor was *Notiphila* cf. *cressoni*. *Notiphila* primarily visited staminate flowers and there foraged for pollen either directly from the dehisced anther sacs or from the adaxial surface of the reflexed perianth where pollen accumulates (Fig. 17). Grooming and copulatory acts were also frequently observed. Pistillate flowers were rarely visited by flies, but upon their brief visitations, members of *Notiphila* would typically land on the elongated stigmas or reflexed perianth (Fig. 18). Additionally, flies commonly foraged for



FIGURES 17, 18. *Insect visitors of* Brasenia.—*17. Post-dehiscent second-day flower with* Notiphila *cf.* cressoni *foraging for pollen.*—*18.* Notiphila *on stigma of first-day flower. Scale bars = 1 cm.*

the abundant airborne pollen that had become deposited on the adaxial surfaces of leaves. Microscopic examinations of dipteran bodies indicated that pollen loads were minimal except around the bases of the legs where body hairs are more dense. The stickiness of *Brasenia* pollen was not determined. Other insects were only occasional floral visitors and cannot be considered pollinators.

DISCUSSION

FLORAL CYCLE

Field observations of *Brasenia* confirm that anthesis is diurnal, with individual flowers opening and closing for two consecutive days. First-day flowers are morphologically pistillate; second-day flowers staminate. Caging experiments (Table 1) indicate that stigmas of first-day flowers are receptive to pollen and those of second-day flowers generally are not. Thus floral structure and function are correlated. Caging experiments further reveal that *Brasenia* flowers set seed only with pollen from an allogamous origin (sensu Faegri & van der Pijl, 1979). Although individual flowers are self-pollinating, seeds are not produced. It is unlikely that a genetic mechanism of self-incompatibility is responsible for the lack of seed set. Abundant seed production from geitonogamous pollinations is indicative of self-compatibility. In the populations studied, self-fertilization (autogamy) is prevented by dichogamy.

WIND POLLINATION

In the populations studied, *Brasenia* is predominantly anemophilous. This conclusion is reached by correlating data and observations of the following: pollinometer experiments, floral densities, number of viable pollen grains produced, flower position above water level, terminal settling velocity of pollen, and floral morphology. The pollinometer experiments reveal that *Brasenia* pollen is dispersed over a relatively short distance. Therefore, for successful pollination by wind, the flowers must be closely grouped and produce a significant amount of viable pollen. As has been shown, floral density can exceed 100 flowers/m^2 and viable pollen production > 200,000 grains/flower. The elevated position of second-day flowers above first-day flowers, together with a pollen terminal settling velocity of 7.7 cm/sec., further enhances the dispersal distance of *Brasenia* pollen. Direct observations of pollen on stigmas of first-day flowers downwind of pollen-releasing flowers at distances of < 1 m and > 2 m support the above conclusion. Large pollen–ovule ratios, as discovered in *Brasenia*, are also characteristic of wind-pollinated taxa (Faegri & van der Pijl, 1979).

Whitehead (1983) identified several "idealized conditions" that need to be met by a plant species if wind pollination is to be successful. The floral and vegetative morphologies of *Brasenia* are adapted for anemophily. Table 2 summarizes those adaptations of *Brasenia* in comparison with other anemophilous plants. Floral anomalies (e.g., short stigmas), however, are not as well adapted for reception of wind-borne pollen. This accounts for the low seed set in flowers with short stigmas (Table 1) compared with typical flowers.

Additionally, observations of infrequent insect visitations between first-day and second-day flowers, despite insect abundance, and minimal pollen loads negate entomophily as a primary mechanism of pollen transfer in this study site.

TABLE 2. *Comparison of* Brasenia *adaptations with Whitehead's "idealized conditions" for anemophily.*

Whitehead	*Brasenia*
There is production of large numbers of pollen grains.	Greater than 221,700 pollen grains are produced per average flower.
Pollen grains possess appropriate aerodynamic characteristics, are typically 20–40 μm in size, and have terminal settling velocities of 2–6 cm/sec.	Pollen grains are elliptic, smooth, within "ideal" size range (36.3 × 47.6 × 36.9 μm),[1] and have a terminal settling velocity of 7.7 cm/sec.
The probabilty of pollen's entrainment in moving air is maximized due to flower and inflorescence structure and their location on the plant.	Second-day (staminate) flowers possess elongated filaments that elevate dehiscent anthers; perianth parts are reflexed and stigmas are centrally aggregated out of the path of ambient air.
Stigmatic surfaces are structured and positioned to maximize collection efficiency.	First-day (pistillate) flowers possess elongated, papillate stigmas which radiate outward over the perianth providing an increased surface area for pollen adherence.
Pollen release is timed within both the season and the day to maximize the possibility of pollen capture by receptive conspecifics downwind.	Pistillate flowers are fully open and generally elevated lower than staminate flowers at the time of anther dehiscence.
There is a relatively close spacing of compatible plants.	Flowers exhibit relatively dense distribution, up to 110/m² during peak anthesis, and are both geitonogamous and xenogamous.
Plants possess a vegetational structure that is relatively open to minimize filtration of pollen by nonstigmatic surfaces.	Vegetative organs are either submerged or floating; the only emergent structures are floral.
The range of wind velocities ensures pollen transport and minimizes its downwind dispersion.	Pollen can be dispersed at least 70 cm at wind speeds as low as 1.6 kph.

[1] Ueno & Kitaguchi (1961).

OCCURRENCE OF INSECTS

The frequency, abundance, and behavior of *Notiphila* flies on second-day flowers and leaves are related to their life history and association with the other nymphaeaceous genera, *Cabomba* and *Nymphaea* (Van der Velde et al., 1978; Van der Velde & Brock, 1980; Willmer, 1982), in the study site. Members of *Notiphila,* while foraging on nectar and pollen, function as the primary pollinators of *Cabomba* (Schneider & Jeter, 1982). In *Nymphaea* the flies forage on pollen and occasionally sponge stigmatic fluid, but native halictid bees are pollinators of the diurnal Toledo Bend species of this genus.

We view the relationship of *Notiphila* with *Brasenia* as one of herbivory in which flies mainly forage for pollen and utilize the flower to groom and mate. The flies forage for pollen in anther sacs only after the majority of pollen grains have been wind dispersed and the inner UV reflective walls, which aid in the attraction of the flies, are exposed. As the flies move about the dehiscent androecium and pollen-covered perianth surface, a small quantity of pollen accumulates on their legs. This minute pollen load can be attributed at least in part to the smooth walls of the *Brasenia* pollen. Occasional visits to pistillate flowers may facilitate transfer of minimal pollen; therefore, *Notiphila* should only be considered an incidental pollinator. The occurrence of flies and their role as incidental pollinators, together with floral variations such as shortened stigmas, suggest a possible evolutionary shift from anemophily to partial myophily (ambophily; Stelleman, 1984).

POLLINATION BIOLOGY OF THE NYMPHAEACEOUS SENSU LATO FAMILIES

This investigation provides the first documentation of anemophily in the Nymphaeaceae s.l. Traditionally, wind pollination has been interpreted as derived in the angiosperms (Whitehead, 1969; Faegri & van der Pijl, 1979). Dilcher (1979), Dilcher & Kovach (1986), and Crane & Dilcher (1984), however, have shown that several extinct lower- to mid-Cretaceous flowering plants had the reproductive morphology to accommodate pollination by both wind and insects. The occurrence of anemophily in the Nymphaeaceae s.l., a taxon traditionally viewed as primitive and entomophilous, dictates that the phylogeny of this group be re-examined.

Cabombaceae. Several studies (e.g., Kosakai, 1968; Goleniewska-Furmanowa, 1970; Bukowiecki et al., 1972; Okada & Tamura, 1981; Ito, 1986a, 1987) suggest *Cabomba* and *Brasenia* share sufficient characteristics to warrant maintenance of the Cabombaceae. From a classical viewpoint, it could be argued that the presence of perfect flowers, a perianth, the occurrence of foraging flies, and some UV reflectance in *Brasenia* are remnants of a former entomophilous condition which has more recently specialized for wind pollination. An alternative hypothesis, that anemophily is primitive, could also be argued. Support for this viewpoint comes from the fossil record in which Tertiary pollen of *Brasenia* exhibits the same morphological features as extant *Brasenia* pollen (Jessen et al., 1959). Although pollen alone is not a definitive indicator of pollination biology, modern *Brasenia* pollen is adapted for wind pollination (Table 2). Because fossil and extant pollen are morphologically similar, comparable functions can be postulated.

We do not view these two hypotheses as completely exclusive of each other. A third line of reasoning, that the cabombaceous ancestor had the reproductive morphology to facilitate both wind and insect pollination, could be advocated. An ancestor with dual pollination capabilities would explain the long anemophilous history as suggested by fossil pollen and the occurrence of the entomophilous features noted above. An extension of this third concept suggests that the pollination syndromes in extant *Brasenia* and *Cabomba* are specialized. Phylesis in *Cabomba*, therefore, would have involved a reduction and stabilization in the number of androecial and gynoecial members, as evidenced by the vasculature studies of Ito (1986a), and the appearance of a distinct, colorful perianth possessing nectaries to enhance a myophilous pollination syndrome (Schneider & Jeter, 1982). Here, pollination is achieved by the appropriate positions of the pollen-receptive stigmas in first-day flowers (Fig. 19L) and pollen-dehiscent anthers in second-day flowers (Fig. 19K) above the petaliferous nectaries where *Notiphila* flies sponge secretions. The elongated stigmatic surfaces which radiate above the recurved perianth in first-day flowers of *Brasenia* (Fig. 19N) enhance collection of airborne pollen. In second-day flowers (Fig. 19M), the elevation of anthers above the recurved perianth promotes pollen dispersal.

A recent cladistic analysis of the Nymphaeales by Ito (1987) indicates *Ceratophyllum* has association with *Brasenia* and *Cabomba*. Les (1986) has proposed that the hydrophilous pollination mechanism of *Ceratophyllum* (Jones, 1931) is derived from anemophily. The occurrence of wind pollination within the Cabombaceae warrants continued examination of the suggested relationships among *Ceratophyllum*, *Brasenia*, and *Cabomba*.

Nymphaeaceae s. str. Some investigations (Collinson, 1980; Moseley et al., 1984) indicate *Brasenia* shares more affinities with the Nymphaeaceae s. str. than with *Cabomba*. We do not support dismantling the Cabombaceae. It is our opinion that data from pollination biology, floral anatomy, anatomy of fossil and extant seeds, and embryology support a common ancestry hypothesis. The Nymphaeaceae s. str., unlike the Cabombaceae and Nelumbonaceae, possess completely syncarpous gynoecia. When correlated with an evolutionary shift from hypogyny in *Nuphar*, through perigyny in *Nymphaea*, to epigyny in *Barclaya*, *Euryale* (Kadono & Schneider, in press), and *Victoria*, flowers of this family exhibit an overall elaboration. This elaboration consists of an increase in size and number of floral parts and stigmatic surface area facilitated by radial extension of the carpels and by the appearance of specialized organs (e.g., staminodia and carpellary appendages). This family, like the Nelumbonaceae, is entomophilous except for the cleistogamous flowers of *Barclaya* (Fig. 19D), *Euryale* (Fig. 19C), and some species of *Nymphaea*.

The flowers of *Nuphar* (Fig. 19I, J) have a close relationship with beetles of the genus *Donacia*, which complete their life cycle in association with the plant, during which time they facilitate pollination (Schneider & Moore, 1977). Diurnal flowers of *Nymphaea* and *Ondinea* are specialized for washing pollen from the body of foraging native bees. This is accomplished by the production of stigmatic fluid on the first day of anthesis (Fig. 19F, H; Conard, 1905; Schmucker, 1933; Prance & Anderson, 1976; Schneider, 1979, 1982a, b, 1983; Meeuse & Schneider, 1980; Schneider & Chaney, 1981; Capperino & Schneider, 1985). The pollination biology of nocturnally flowering species of *Nymphaea* is largely unstudied, but cantharophily is known (Cramer et al., 1975; Wiersema, 1987).

Large, nocturnal flowers of *Victoria* are adapted for pollination by *Cyclocephala* beetles. Beetles

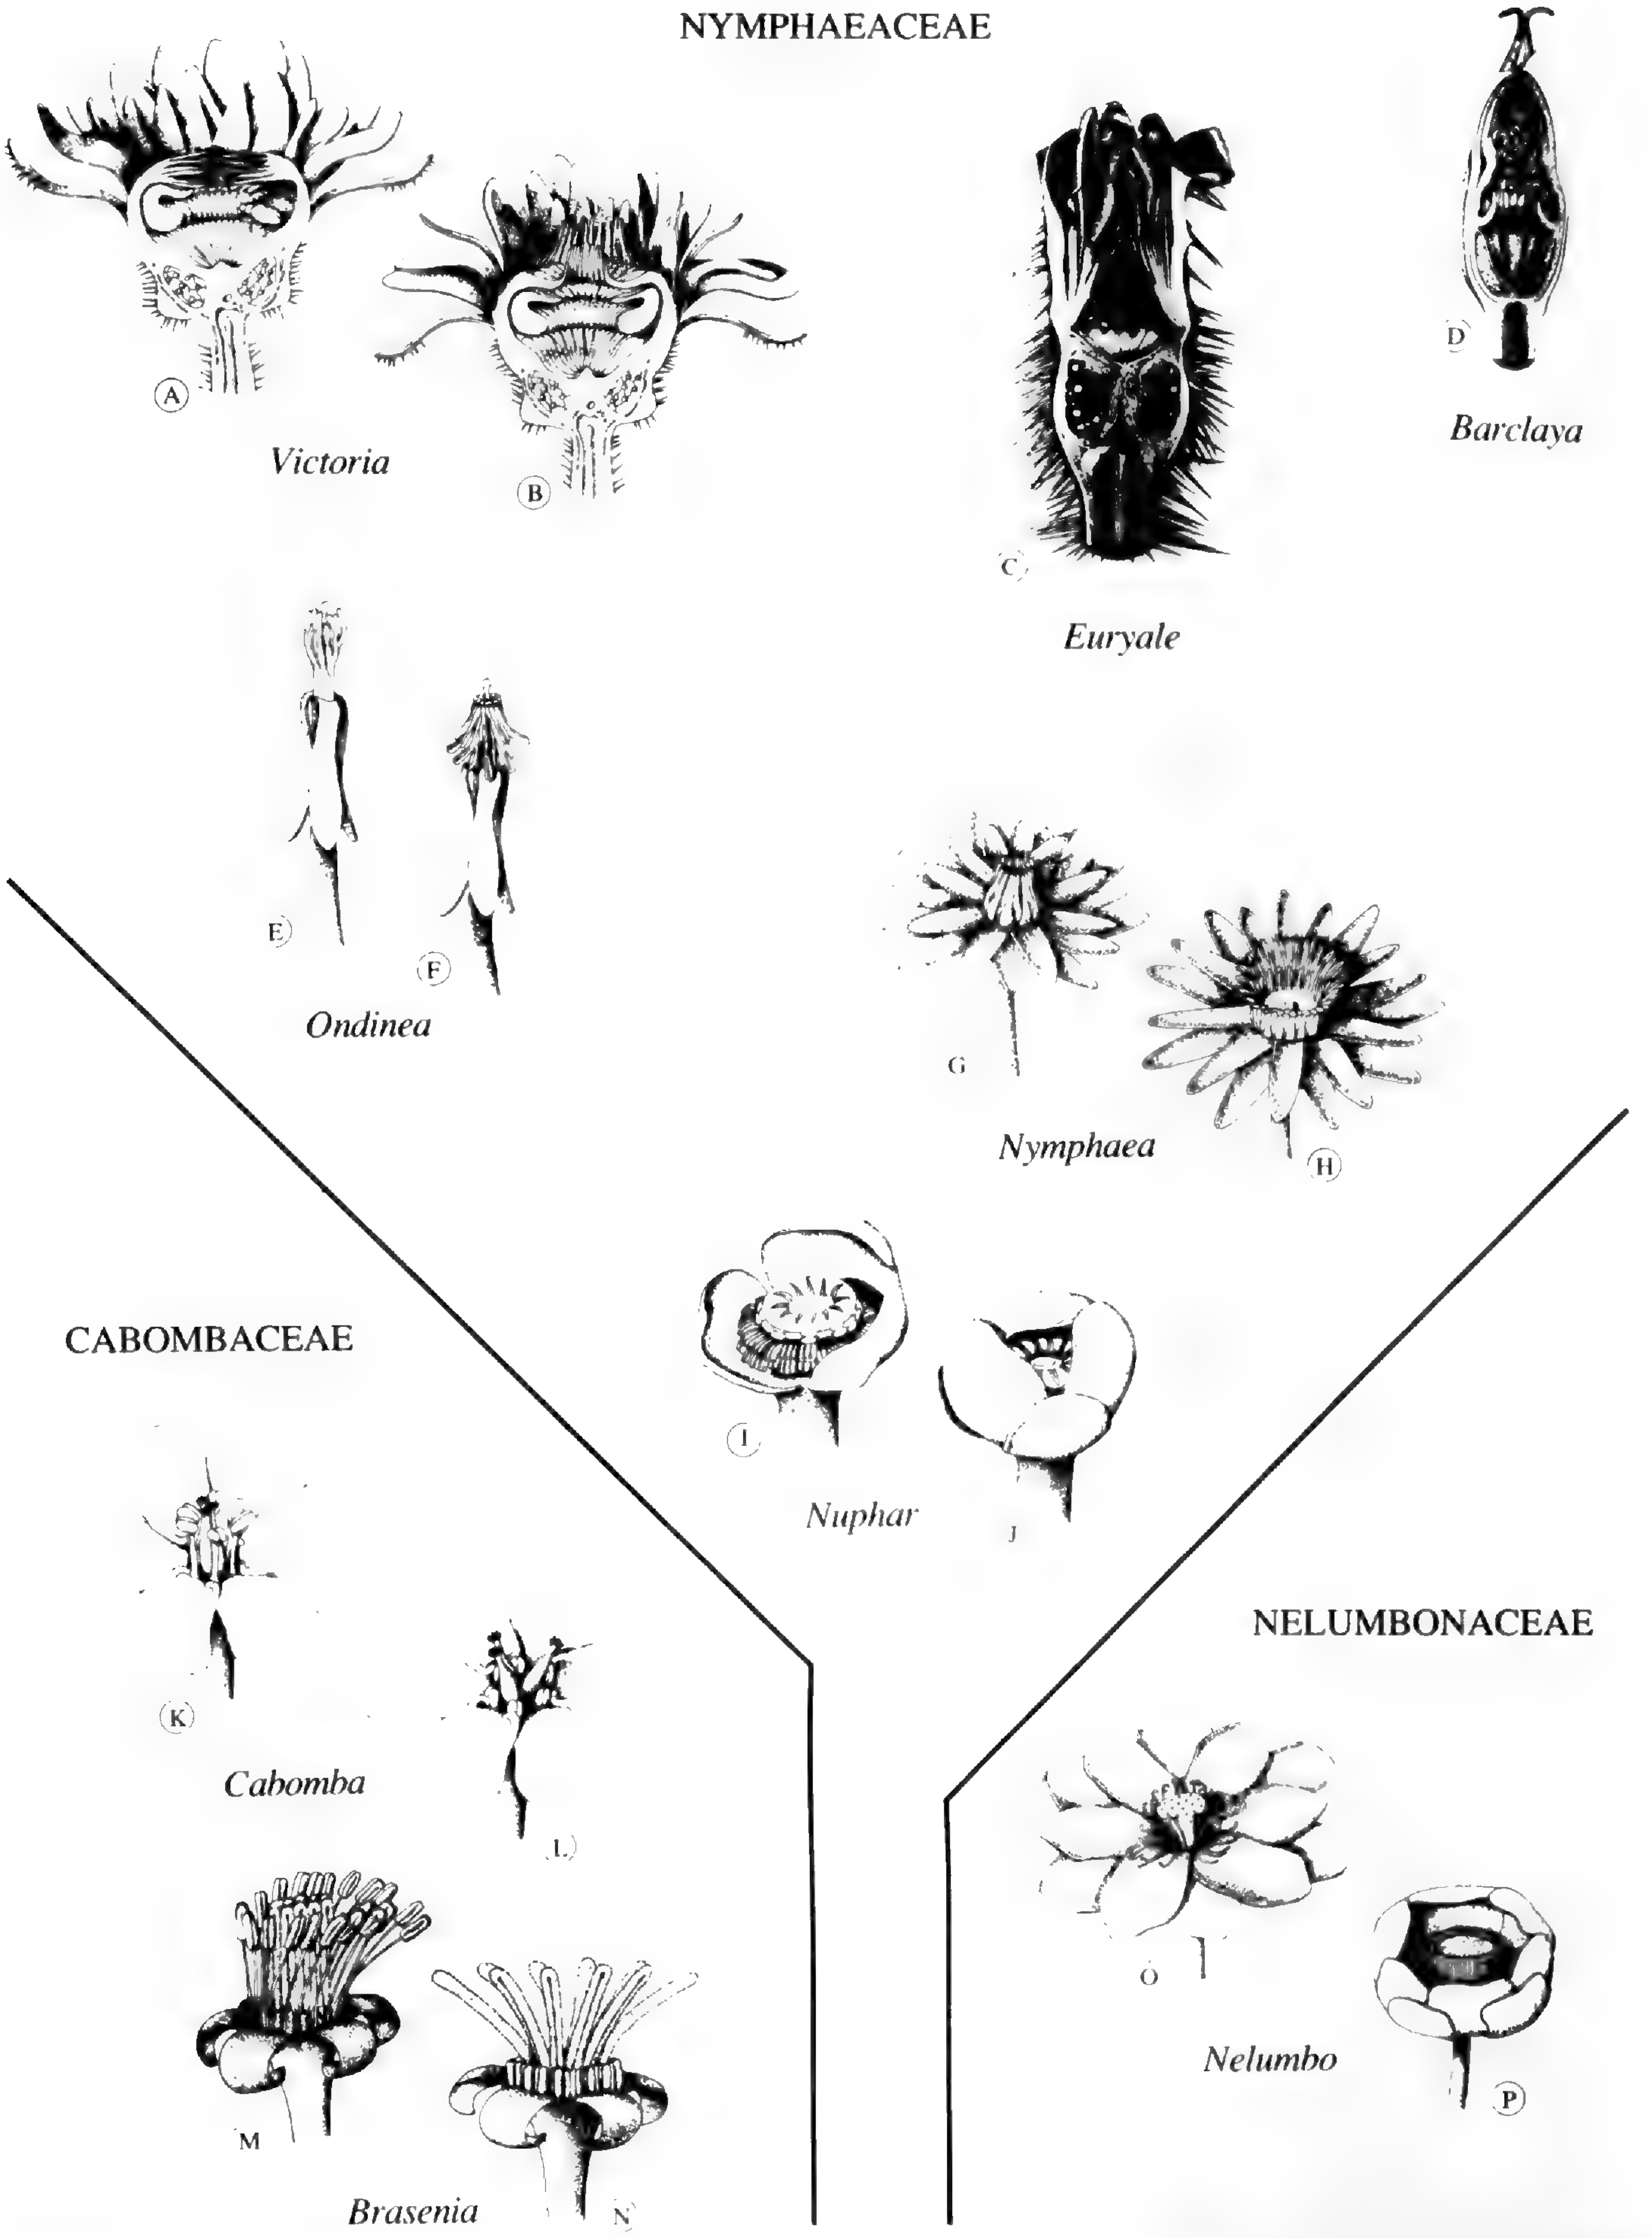


FIGURE 19. *Comparative morphologies of first-day (pistillate) and second-day (staminate) flowers of the Cabombaceae (first-day, L, N; second-day, K, M), Nymphaeaceae s. str. (first-day, B, C, D, F, H, J; second-day, A, E, G, I), and Nelumbonaceae (first-day, P; second-day, O). Note: flowers not drawn to scale.*

are attracted by the white color and fragrance of first-night flowers. The diffusion of fragrance is accelerated by a rise in floral temperature due to the thermogenicity of carpellary appendages (Fig. 19B). Pollination is achieved when pollen-covered beetles crawl about the inner stigmatic cup. While "trapped" within the flower, beetles forage on starch-rich carpellary appendages (Fig. 19A). As beetles emerge from second-evening flowers they become dusted with pollen from the now-dehiscent anthers and, once again, are attracted to first-evening flowers (Knoch, 1899; Valla & Cirino, 1972; Prance & Arias, 1975; Schneider, 1976; Lovejoy, 1978).

Nelumbonaceae. Separation of *Nelumbo* from the Nymphaeaceae s.l. into the Nelumbonaceae has been justified on numerous grounds, including seed anatomy (Collinson, 1980) and floral anatomy/morphology (Moseley & Uhl, 1985; Ito, 1986b, 1987). Despite this separation, *Nelumbo* displays a floral behavior similar to that of chasmogamous flowers of the Cabombaceae and Nymphaeaceae s. str. in which first-day flowers are pistillate (Fig. 19P) and second-day flowers are staminate (Fig. 19O). Flowers of *Nelumbo* are principally adapted for cantharophily (Schneider & Buchanan, 1980), although bees and flies (Sohmer & Sefton, 1978) also transfer pollen. Moseley & Uhl (1985) suggested that the flower of *Nelumbo* represents an evolutionary elaboration in response to cantharophily.

Comparative studies of the reproductive biology of Cabombaceae, Nymphaeaceae s. str., and Nelumbonaceae, when viewed in conjunction with structural aspects of the flower, suggest that evolution within these families has involved both floral reduction and elaboration as a result of adaptive evolution in response to abiotic and biotic vectors. This concept is consistent with other angiosperm taxa as indicated by the fossil record (Basinger & Dilcher, 1984).

REPRODUCTIVE BIOLOGY OF *NYMPHAEA* (NYMPHAEACEAE)[1]

John H. Wiersema[2]

ABSTRACT

Several reproductive strategies have evolved within the genus Nymphaea. *Sexual reproduction is mostly protogynous; flowers are open two to several days (depending on the species), with pollen release usually commencing on the second day. The five subgenera of* Nymphaea *exhibit differences in floral biology. There is considerable variation in the timing of flower opening, floral odor, flower color, and the form and function of various flower parts. These differences may contribute to genetic isolation between species both through temporal separation of flowering and attraction of different pollinators. While sexual reproduction in many species is dependent on xenogamy or geitonogamy, other species have adaptations to promote autogamy. No species of* Nymphaea *is known to be agamospermous, but several other modes of asexual reproduction are exhibited: detachable tubers, stolon formation, and proliferations of floral and foliar tissue. Wide-ranging tropical species all avoid being totally reliant on pollinators by employing one or more reproductive alternatives to outcrossing; clearly some obligate outcrossers are limited in their colonizing by pollinator availability. The most important of these reproductive alternatives is autogamy. Wide-ranging temperate species, which mostly rely exclusively on outcrossing for sexual reproduction, probably avoid pollinator limitations by utilizing a broader range of pollinators.*

Nymphaea is the largest and most widely distributed genus in the Nymphaeales. About 40 species of waterlilies, as they are commonly known, are distributed on all continents except Antarctica. The classification of Conard (1905), still generally accepted, recognizes five subgenera: the north-temperate subgenus *Nymphaea*, neotropical subg. *Hydrocallis*, and paleotropical subg. *Lotos* of the syncarpous group and the Australian subg. *Anecphya* and pantropical subg. *Brachyceras* of the apocarpous group. The success of this genus as determined by number of species and distributional range is due to several factors. Its age, dating probably from mid Tertiary (Collinson, 1980), may be one factor; however, other nymphaeaoid genera of comparable age have not demonstrated the same degree of evolutionary divergence. Another factor is its specialized but widely available ecological niche. Waterlilies almost invariably inhabit still or gently flowing water over rich organic substrates. In stable aquatic habitats they root in water too deep for competing emergent vegetation. Their floating leaves, in addition, outcompete submersed leaves for light. A few other genera are competitors for this niche, including primarily nymphaeaceous genera such as *Nuphar*, *Brasenia*, and *Nelumbo*, and the distantly related genus *Nymphoides*. None of these, however, has attained the species radiation and global distribution of *Nymphaea*.

According to Gupta (1978, 1980) polyploidy, structural chromosome changes, and gene mutations have played important roles in the evolution of *Nymphaea*. The poor development of isolating mechanisms is also mentioned as being responsible for the high incidence of natural and artificial interspecific hybridization. However, such mechanisms are not altogether absent. Certainly ecological factors help isolate certain species from others, such as the alkaline-tolerant *N. tuberosa* Paine from the more acidophilic *N. odorata* Aiton, or the slightly halophilic *N. rudgeana* G. Meyer from less salt-tolerant species, or the riparian *N. potamophila* Wiersema from lacustrine species. Geographical isolation has also been a factor, such as separating *N. alba* L. of Europe from the North American *N. odorata*.

This paper, in discussing the reproductive biology of *Nymphaea*, focuses on several potential external mechanisms for reproductive isolation. Internal mechanisms (terminology from Grant, 1981) no doubt are important in promoting the hybrid breakdown and sterility often observed in *Nymphaea* (Gupta, 1978) but are outside the scope of this discussion. Differences within and among the

subgenera with regard to floral odor, flower color, the timing of floral responses, and the form and function of various flower parts may contribute to genetic isolation between species. Isolating mechanisms are probably more important for tropical and subtropical species, since their densities tend to be greater than those in temperate areas. After focusing on these potential isolating mechanisms, several adaptations relating to asexual reproduction in *Nymphaea* will be discussed, thereby permitting an evaluation of the various reproductive strategies found among waterlilies.

FLORAL BIOLOGY

Some general aspects of floral biology in *Nymphaea* should be presented. The flowers consist of 4 sepals, 7–40 petals, 20–700 stamens, and 5–47 carpels, the latter forming a ring embedded in cup-shaped receptacular and appendicular tissue to which the appendicular organs are attached laterally. The upper surface of each carpel contributes a ray of stigmatic tissue to the stigmatic disk, which tops the ovary, and this ray usually terminates abaxially in a free appendage termed the carpellary appendage or carpellary style.

Sexual reproduction is mostly protogynous. First-day flowers generally open slightly less than on later days, with the stamens and carpellary appendages, if present, spreading to permit insect visitors access to the stigmatic region. The tips of the stamens form a circular wall or palisade around a central pool of stigmatic fluid. Although variable in quantity, I have observed this fluid in all species thus far examined. It reportedly contains a surfactant primarily responsible for washing pollen from the bodies of insect visitors, but also possibly contributing to their frequently observed drownings. In second-day flowers the sepals, petals, and most of the stamens reflex fully. Anther dehiscence occurs in second-day flowers, with the stigmatic fluid drying up at or by this time. Insects are generally free to forage for pollen due to the dryer nature of the stigma and the incurving of the inner stamens and carpellary appendages over the stigmatic region. Pollen-covered insects that subsequently visit first-day flowers effect pollination. In many species first-day flowers open slightly later than on subsequent days. This ensures that insect visitors will first visit pollen-releasing flowers prior to their entrance into pollen-receptive flowers (Schneider, 1979; Meeuse & Schneider, 1980; and pers. obs.).

Floral odor. Although numerous authors have commented on the differences in floral odor among various waterlily species (Conard, 1905; Cramer et al., 1975; Prance & Anderson, 1976; Meeuse & Schneider, 1980), which range from inodorous to lightly fragrant or strongly pungent, nothing is known of the chemistry of the odor-producing compounds or their potential in attracting certain taxa of pollinators. The importance of floral odor seems to be greatest for night-blooming species, which can rely less on flower color to attract pollinators. Most members of the night-blooming subg. *Hydrocallis* emit considerable odor that is detectable for some distance. These species are probably pollinated by Coleoptera (Cramer et al., 1975; Prance & Anderson, 1976; Prance, 1980; Wiersema, 1987), in contrast to members of the day-blooming subgenera *Anecphya*, *Brachyceras*, and *Nymphaea*, which appear to be pollinated by Hymenoptera or Diptera (Van der Velde et al., 1978; Schneider & Chaney, 1981; Schneider, 1982a, b; Capperino & Schneider, 1985). The latter group has typically far less odorous flowers, with odors appearing to differ qualitatively from those of subg. *Hydrocallis*. In subg. *Anecphya*, no odor is known (Conard, 1905; Schneider, 1982b). Strong odors have not been observed in *N. lotus* L. of the night-blooming subg. *Lotos*, although nothing is known regarding insect pollinators in this subgenus.

Schneider (1982a) has hypothesized that in subg. *Hydrocallis* the highly developed carpellary appendages may help volatilize odors. A darkening of these appendages and sometimes the staminal bases is frequently observed as flowering progresses, suggesting that chemical activity may be taking place. Olfactory tests with *N. jamesoniana* Planchon support this, but additional tests are needed. In the inodorous subg. *Anecphya*, carpellary appendages are absent.

Flower color. Considerable variation in petal coloration is evident among waterlily species. Flower color is, however, relatively constant among night-blooming species, with all species of subgenera *Hydrocallis* and *Lotos* having white or nearly white petals. An exception to this trend is found in the red-flowered *N. rubra* Roxb. ex Andrews, but recent evidence suggests that this is an apomictic "species" that may not undergo sexual reproduction (Mitra & Subramanyam, 1982). Certain species of the other syncarpous subgenus, the diurnally flowering subg. *Nymphaea*, have also yielded pink- to red-flowered forms under rare circumstances (Conard, 1905; Elkins, 1970; Erixon, 1980), white being the usual petal color in all species involved. However, *N. mexicana* Zucc. of this subgenus has yellow petals. The neotropical members of subg. *Brachyceras* are also primarily white-petaled (pale blue fading to white in *N. elegans* Hook.); those of the paleotropics are predominantly blue-petaled, although both white- and yellow-petaled species are known (Conard, 1905; Mendonça, 1960; Hutchinson & Dalziel, 1966).

Little evidence exists to evaluate the importance of flower color in *Nymphaea* in attracting different pollinators. The presence of blue and yellow color forms may be an adaptation favoring pollination by hymenopterans or dipterans, which pollinate similarly colored flowers in other plant groups (Proctor & Yeo, 1972). Schneider and colleagues have examined pollinators of the white-flowered *N. odorata* (Schneider & Chaney, 1981), the blue-flowered *N. elegans* (Schneider, 1982a), and the yellow-flowered *N. mexicana* (Capperino & Schneider, 1985). Insect visitors to all of these diurnally flowering species included Hymenoptera, Diptera, and Coleoptera, indicating that the same classes of pollinators appear to be attracted to all three flower colors. As all of these observations have come from Texas, more observations on pollinators throughout the ranges of these species, especially in situations where they coexist, are needed in order to evaluate better the importance of flower color as a factor in reproductive isolation. Valuable observations toward a resolution of this question could be made in south-central Africa where all three color forms occur.

Temporal responses. Timing of floral responses may be important in determining which pollinators are associated with a particular species, insofar as activity levels of potential pollinators may vary throughout the day or night. Species that utilize the same pollinators could still be reproductively isolated through temporal separation of flowering, which seems to provide a partial if not total barrier to gene flow between certain species. For day-blooming North American species of subg. *Nymphaea* (Fig. 1A), flowers of the widespread *N. odorata* open just after dawn and close around noon or shortly thereafter (Conard, 1905, Pennsylvania; Schneider & Chaney, 1981, Texas; Wiersema & Haynes, 1983, Alabama). In the northern portion of its range its distribution overlaps that of *N. tetragona* Georgi, whose flowers are open from just before noon to around 5:00 P.M. (Conard, 1905, cultivation in Pennsylvania).

The sequence of floral opening proceeds from the sepals and outer petals gradually inward to the inner stamens and requires ½–1 hour, as does floral closure. First-day flowers (pollen-receptive) generally open slightly later than those of subsequent days. The important times to consider are the periods when the stigmas of first-day flowers are accessible to potential pollen donors and the stamens of later flowers accessible to potential pollen acceptors. Allowing for the adjustments just mentioned, it is probable that complete temporal separation exists between *N. odorata* and *N. tetragona*, although field data are needed from areas of sympatry to support this assumption. Similarly, *N. mexicana*, whose flowers open ca. 11:00 A.M. and close ca. 4:00 P.M. (Conard, 1905, cultivation in Pennsylvania; Wiersema & Haynes, 1983, Alabama; Capperino & Schneider, 1985, Texas), achieves some degree of temporal separation from *N. odorata*, with which it is sympatric over parts of the southeastern United States. Less than an hour overlap appears to be present in the flowering schedules of these two species, which have different-colored flowers, and occasional natural hybrids occur (Ward, 1977, Florida and Georgia; Wiersema & Haynes, 1983, Alabama). On the other hand, the flowering schedules of *N. odorata* and the closely related *N. tuberosa* (Conard, 1905, Pennsylvania) overlap considerably (3–4 hours), and not surprisingly, their taxonomic relationship remains confused (Conard, 1917; Monson, 1960; Williams, 1970).

Available information on the day-flowering species of subg. *Brachyceras* in the New World (Conard, 1905; Prance & Anderson, 1976; Schneider, 1982a) indicates considerable overlap in the flowering schedules of the three species (Fig. 1B). Data are lacking for most Old World taxa of this subgenus.

Considerable information on flowering schedule in the nocturnally flowering, neotropical subg. *Hydrocallis* has been gathered from outdoor cultivation in Alabama (Wiersema, 1987). Cultivated samples of those species obtained from two or more regions exhibited little variation in flowering schedule. Among most species sufficient overlap in flowering time was observed to negate the importance of this feature as a barrier to genetic exchange between species (Fig. 1C). This is particularly true of species that complete flowering before midnight. Species, such as *N. amazonum* C. Martius & Zucc. and *N. prolifera* Wiersema, whose flowers remain open after midnight, are provided some degree of genetic isolation. In *N. prolifera* second-day flowers, although opening at dusk, remain mostly inaccessible to pollinators due to delayed reflexing of the inner petals and stamens until after midnight, when flowers of most other species have closed. In *N. amazonum* floral responses reach their greatest specialization. First-day flowers open fully and close during the two hours just preceding dawn. Second-day flowers open at dusk, remain open throughout

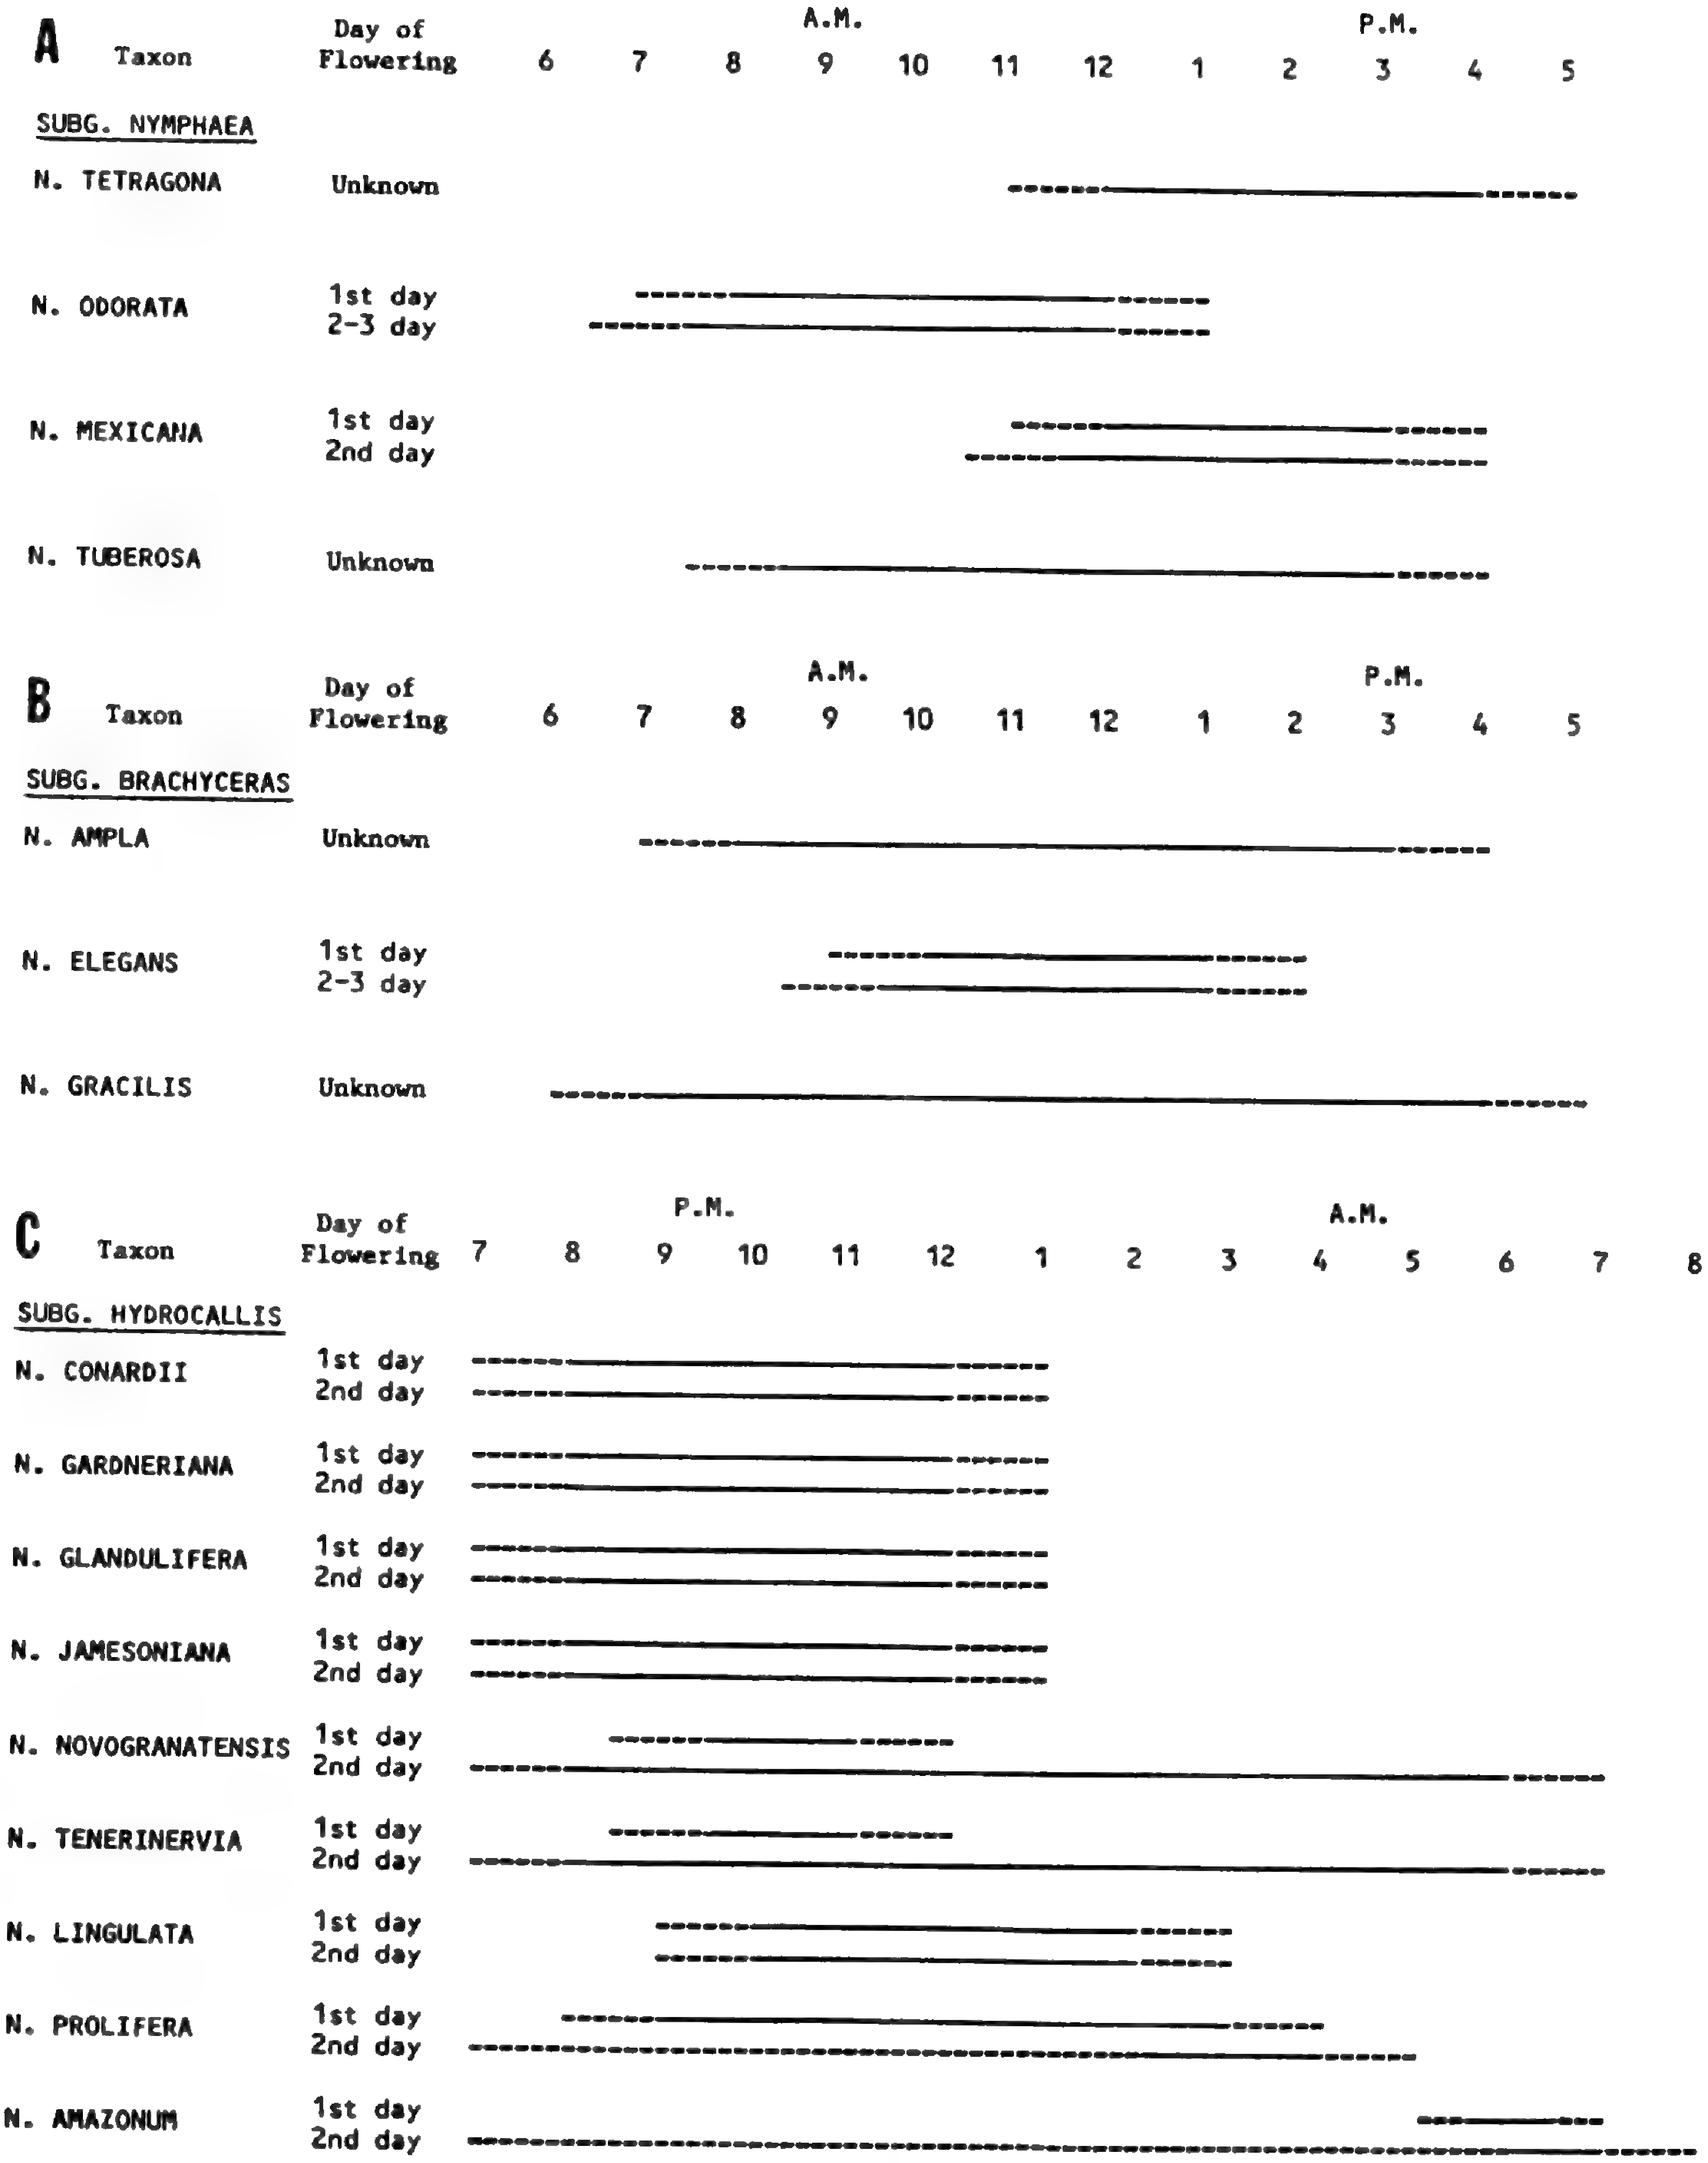

FIGURE 1. *Flower-opening times for selected species of* Nymphaea. *Data sources indicated in text. Dashed lines = partially open flowers, solid lines = fully open flowers.—A. North American species of subg.* Nymphaea.—*B. Neotropical species of subg.* Brachyceras.—*C. Subg.* Hydrocallis.

the night, and close in the early dawn. Their anthers do not dehisce until a few hours before dawn when cross-pollination[3] of first-day flowers is possible. Thus *N. amazonum* is effectively isolated reproductively from other species of subg. *Hydrocallis* even though it may make use of the same pollinators (Cramer et al., 1975).

Floral responses in the night-blooming subg. *Lotos* have received little or no attention. Flowers here reportedly open at dusk and remain open until ca. 11:00 A.M. the following morning (Conard, 1905; Hutchinson & Dalziel, 1966; Wiersema, 1982). First-day (pollen-receptive) flowers of *N. lotus* I observed in cultivation did not open for this lengthy period, but were open for only a few hours around midnight. If these observations are consistent with natural populations, for which scrutinous data are lacking, then cross-pollination in some species of this subgenus could occur only at night, with the diurnal portion of flowering on later days, providing no opportunity for successful cross-pollination.

No evidence suggests that seasonal separation of flowering periods exists in *Nymphaea*. Waterlilies usually commence flowering once sufficient vegetative growth has occurred and continue flowering throughout the growing season. In many populations of *N. prolifera* and *N. lasiophylla* C. Martius & Zucc., however, normal flowers are replaced by tuberiferous flowers (see page 801) during part or all of the growing season. This does not seem to be temporal separation of flowering but rather a shift from sexual to asexual reproduction, the former not being successful in areas where this phenomenon has been observed.

In many species the flowering cycle is extended, with anther dehiscence continuing into a third or fourth day. Species with extended flowering cycles increase the percentage of pollen-releasing (or functionally male) flowers relative to first-day (or functionally female) flowers. Thus the percentage of insect visits involving female flowers would be reduced, but larger pollen loads might be found on insects (Capperino & Schneider, 1985). A longer flowering cycle might also attract more pollinators to a population by displaying a greater number of open flowers.

Other floral modifications. A number of additional morphological or behavioral differences in flowers have been noted among waterlilies. The functional significance of many of these has yet to be determined. Perhaps the foremost among them relates to the carpellary appendages, which are absent in subg. *Anecphya*, triangular to tapering in subgenera *Nymphaea* and *Brachyceras*, and most strongly developed in subgenera *Lotos* and *Hydrocallis*, the only night-blooming subgenera, where they are linear to highly clavate. They attain a length of nearly 3 cm in some flowers of *N. oxypetala* Planchon of subg. *Hydrocallis*. The structural differences in these appendages among species of *Nymphaea* suggest differences in function. Hypotheses concerning the function of the carpellary appendages have suggested that they may serve as a source of food, a source of heat, or a source of volatile odor-producing compounds (Meeuse & Schneider, 1980; Prance, 1980; Schneider, 1982a, b). Similar structures in the related genus *Victoria* Lindley, which exhibits a night-blooming beetle-pollination syndrome, are known to have both thermogenic and nutritive functions (Knoch, 1899; Valla & Cirino, 1972; Prance & Arias, 1975). An additional function of undetermined importance for such appendages in *Nymphaea* may be to control access to the stigmatic disk. In first-day flowers the appendages are erect or spreading, allowing free access to the stigmatic region; however, in second-day and later flowers they are incurved over the stigma. In species such as *N. lotus* of subg. *Lotos* or *N. amazonum* of subg. *Hydrocallis*, they completely cover the stigma. In many species, especially diurnal species with less-developed appendages, the inner stamens form part of this barrier.

It has been suggested that the carpellary appendages may play a role in deepening or broadening the pool of stigmatic fluid and thus improving the ability of flowers to wash pollen from the bodies of insect visitors. However, *N. gigantea* Hook. of subg. *Anecphya*, which lacks carpellary appendages, does not appear to exhibit any reduction in the size of the stigmatic pool (Schneider, 1982b). Comparisons of the quantity of stigmatic fluid among *N. elegans*, *N. odorata*, and *N. mexicana* by Capperino & Schneider (1985) contradict this hypothesis as well, as flowers of *N. elegans*, with the least-developed appendages, produce the greatest amount of fluid.

In the pantropical, diurnally flowering subg. *Brachyceras*, the stamens bear prolonged connective appendages in many species. These appear to form the inner surface of an oil-covered and very

---

[3] As some species of *Nymphaea*, including *N. amazonum*, are clonal, cross-pollination as here used may involve either xenogamy or geitonogamy, in contrast to self-pollination involving autogamy.

slippery circular palisade surrounding the central pool of stigmatic fluid in first-day flowers. Insect visitors that enter this region inevitably fall into the stigmatic pool where pollen is washed from them. The same result is achieved in the diurnally flowering subg. *Anecphya* by means of the large number of weakly supported, nodding stamens having narrow filaments, which form an almost insurmountable wall around the stigmatic region (Schmucker, 1932; Meeuse & Schneider, 1980).

Flowers of certain species of *Nymphaea* are characterized by abundant sclereids in some floral parts. In *N. caerulea* Savigny of subg. *Brachyceras*, elongate bipolar or acicular sclereids are found in the stamens (Chifflot, 1902). In several species of subg. *Hydrocallis*, such acicular sclereids are abundant throughout the staminal tissue, and in a few species they are evident in the stigmatic ray tissue as well. In *N. oxypetala* of this subgenus, tiny spherical sclereids are produced in and apparently released from staminal tissue adjacent to the anther sacs (Chifflot, 1902; Wiersema, 1987). Asterosclereids and trichosclereids are also found in the floral tissues of certain species (Malaviya, 1962). All of the sclereids mentioned above are impregnated with calcium oxalate crystals. It has been suggested that the asterosclereids or trichosclereids may provide support (Conard, 1905; Malaviya, 1962) or internal water recovery (Schanderl, 1973). Neither of these explanations is sufficient to explain the spherical sclereids found in stamens of *N. oxypetala* or perhaps the great abundance of acicular sclereids in stamens in other members of subg. *Hydrocallis*. That these structures may help deter beetle predation on floral parts has not been investigated.

Differences in pollen morphology exist within *Nymphaea*. The pollen of night-blooming and presumably beetle-pollinated subgenera is smoother than the highly puckered or ornamented pollen of the three diurnally flowering subgenera, which are apparently pollinated by bees and/or flies (Wiersema, 1987).

Waterlily seeds also vary. Those of temperate members of subg. *Nymphaea* are completely devoid of surface papillae, whereas those of tropical subgenera usually bear numerous surface papillae in various arrangements. A basic difference between the environmental requirements of temperate vs. tropical seeds is that the former must be adapted to endure colder (and perhaps freezing) temperatures, whereas the latter must often withstand periods of drought. Indeed, seeds of most temperate species exhibit little resistance to drought (Conard, 1905), and those of many tropical species do not tolerate freezing. It is hypothesized that the surface papillae may be important in conferring drought resistance to tropical seeds, perhaps by absorbing water. It is interesting to note that *N. mexicana*, a subtropical member of the mostly temperate subgenus *Nymphaea*, has papillose seeds.

A number of waterlily species produce seeds without cross-pollination. In those thus far examined, autogamy rather than agamospermy has been responsible (Wiersema, 1987). Two different methods are employed in producing seeds autogamously. One involves homogamy, the early dehiscence of stamens on the first day of flowering when the stigma is receptive to pollen. I have observed this in *N. jamesoniana* and *N. lingulata* Wiersema of subg. *Hydrocallis* and *N. ampla* (Salisb.) DC. of subg. *Brachyceras*, and it has been reported for *N. alba* of subg. *Nymphaea* (Heslop-Harrison, 1955). The second method involves maintaining the receptivity of the stigma in second-day flowers, such that pollen being released at the normal time can effect self-pollination. This method is apparent in several taxa of subg. *Hydrocallis*, such as *N. amazonum* subsp. *amazonum*, *N. conardii* Wiersema, and *N. rudgeana*. Autogamy has also been reported among other members of subg. *Brachyceras*, such as *N. caerulea* and *N. stellata* Willd. (Conard, 1905). In the latter species and in *N. ampla* (Prance & Anderson, 1976), reports have suggested pollen release in buds.

With the exception of the reports concerning autogamy in the temperate day-flowering *N. alba*, all other reports of autogamy involve tropical diurnally and nocturnally flowering species. No records of autogamy are known for subgenera *Lotos* or *Anecphya*.

ASEXUAL REPRODUCTION

A number of asexual modes of reproduction are employed by waterlily species. The most widespread is stolon formation, as in *N. lotus* of subg. *Lotos*; *N. amazonum*, *N. gardneriana* Planchon, *N. lasiophylla*, *N. lingulata*, and *N. tenerinervia* Caspary of subg. *Hydrocallis*; and *N. mexicana* of subg. *Nymphaea*. In *N. mexicana*, stolons are of greater diameter and develop an unusual terminal perennating structure at the end of the growing season. This structure consists of a compact series of leaf buds from which hang several starch-laden roots reminiscent of a bunch of bananas, hence the common name "banana waterlily."

Several other members of subgenus *Nymphaea*, namely *N. odorata*, *N. tuberosa*, *N. alba*, and *N. candida* J. S. Presl, possess horizontal rhizomes in contrast to the erect rhizomes of all other species. Several shoots may eventually develop from a single horizontal rhizome. On the main rhizome of *N. tuberosa* small tuberous shoots develop which, due to a constricted area at their base, are readily detachable and serve as propagules.

Two other forms of asexual reproduction have been observed, one involving proliferation of floral tissues, the other proliferation of leaf tissues. In the former, all but the outermost appendages of flowers are aborted, and an enlarged tuber is formed centrally which gives rise to whorls of leaves and additional tuberiferous flowers. A few orders of branching may result, leading to the formation of a large number of small tubers. The tubers readily abscise, float briefly, and eventually become rooted and develop into mature plants. This process occurs regularly in the neotropical *N. lasiophylla* and *N. prolifera* of subg. *Hydrocallis* (Wiersema, 1987). Similar abortive flowers have been reported in other syncarpous *Nymphaea* (Bose, 1961; Mohan Ram & Nayyar, 1974; Majeed Kak, 1977; Mitra & Subramanyam, 1982) but only as an unusual occurrence. This is a very effective method of reproduction and dispersal, particularly in *N. prolifera*, which commonly inhabits lowland savannas subject to periodic flooding.

Proliferation of leaf tissue occurs in *N. micrantha* Guillemin & Perrottet of subg. *Brachyceras*. In this species new plants are formed on the upper surface of a leaf opposite the insertion of the petiole. These develop extensively only after the leaf is detached from the parent plant (Conard, 1905; Hutchinson & Dalziel, 1966). The effectiveness of this reproductive process is unknown. *Nymphaea micrantha* is found only in west tropical Africa.

EVALUATION OF REPRODUCTIVE STRATEGIES

Perhaps the best way of evaluating the overall reproductive strategies of waterlilies is to examine distributional ranges of various species as reflections of their colonizing abilities. Reproductive strategy is one of several factors that contribute to distributional success. Table 1 provides a ranking of temperate, subtropical, and tropical species derived from their natural ranges. Such a measure cannot account for differences in population frequency within ranges, hidden instances of artificial dispersal, or problems of questionable taxonomy; however, it is still useful. Table 1 also provides information on the reproductive alternatives employed by each species, insofar as information is available. All of these species are assumed to be capable of normal sexual outcrossing. Several questionable species from the paleotropics have been excluded.

Two elements seem to be important in interpreting the colonizing ability of a given species, its dispersal capability, and its ability to become established and persist in a new location. In cases involving overland dispersal, seeds are the probable dispersal units and waterbirds the likely agents. Although most aspects of seed release appear to be similar among the various species, the number of seeds per fruit and the size of the seeds are two variables that could affect dispersal capability. *Nymphaea tetragona*, which is dispersed solely by seeds, has comparatively large seeds with relatively few per fruit, two traits that could potentially retard dispersal. However, *N. tetragona* has the broadest distribution of any species. Even *N. mexicana*, having the largest seeds (almost twice as large) with the fewest per fruit of any *Nymphaea* species, has been successfully dispersed along the Gulf Coast of North America. The smallest and probably most numerous seeds are found in *N. jamesoniana*, the most widely distributed neotropical species. Thus there appears to be little relationship between these seed variables and dispersal capability, which appears to be adequate for most species.

If dispersal factors do not appear to limit overall distribution, then factors relating to establishment must be considered more important. Ecological factors certainly affect germination, seedling development, and successful maturation of a colonizing species. If these initial barriers can be overcome, establishment and long-term survival in a new environment become heavily dependent on reproductive ability.

Several key observations can now be made with reference to Table 1. All ten of the most widely distributed tropical species utilize at least one reproductive alternative to total reliance on xenogamy or geitonogamy. In seven of the ten this alternative is autogamy. Of the ten most narrowly distributed species, only one is known to be autogamous. As already mentioned, reproductive strategy is one of several factors that affect overall species distributions. However, in terms of distributional success for tropical *Nymphaea* species, autogamy seems to be the most important reproductive alternative.

The importance of autogamy to tropical waterlily species is to provide for seed production in the absence of potential pollinators and to enhance seed production when xenogamy or geitonogamy become inefficient. It also would eliminate the need for a second individual in colonizing situations; however, this obstacle is easily overcome by clonal or

multiple-flowered individuals, as there is no evidence of self-incompatibility in *Nymphaea*. In the neotropics several night-blooming species of subg. *Hydrocallis*, such as *N. prolifera*, *N. gardneriana*, *N. lasiophylla*, and *N. tenerinervia*, rarely produce seeds in natural populations, although they are capable of seed production if cross-pollinated (Wiersema, 1987). Reports on pollinators in this subgenus have implicated only scarab beetles of the genus *Cyclocephala* Latreille (Cramer et al., 1975; Prance & Anderson, 1976; Prance, 1980; Wiersema, 1987). Asexual reproduction has seemingly allowed the four species mentioned to exist in areas where these pollinators are absent. Further overland expansion from such sites is probably more difficult in the absence of seed production. Nonautogamous species without asexual alternatives would be completely restricted by pollinator availability. The narrow distribution of most tropical species in this latter category suggests that pollinator distribution may be an important element in restricting their spread.

The paleotropical and widespread *N. lotus* and *N. nouchalii* Burm. f. of the night-blooming subg.

Lotos have not been observed to be autogamous, however. To account for the distributional success of these taxa either: a) autogamy has gone undetected, b) the pollinators utilized are more widely distributed or a range of pollinators is used, or c) stolons are more effectively employed in dispersal than in other waterlily species. A fourth possibility, that of human dispersal, may account for some of this distribution, as these species are cultivated, and the existence of *N. lotus* in the neotropics has been attributed to artificial introduction (Wiersema, 1982). However, floristic accounts have considered them indigenous throughout most of their paleotropical ranges.

In temperate species, all of subg. *Nymphaea*, autogamy is clearly not as important in conferring distributional success, as it has been observed only in one species. With the exception of the detachable tubers produced by *N. tuberosa*, seeds are the only effective dispersal agent produced in this subgenus. How then are the limits of pollinator availability overcome by wide-ranging temperate species? These diurnally flowering species either employ pollinators that are more widely distributed or utilize a range of pollinators. The latter explanation is probably correct, in view of the variety of insect visitors reported for day-blooming species in temperate regions (Robertson, 1889; Conard, 1905; Meeuse & Schneider, 1980; Schneider & Chaney, 1981; Schneider, 1982a; Capperino & Schneider, 1985), but it needs to be confirmed with comprehensive studies of species–pollinator relationships.

Pollinator relationships of most tropical day-blooming species in subgenera *Anecphya* and *Brachyceras* remain to be assessed; however, in subg. *Brachyceras* autogamy has become an important alternative to total reliance on outcrossing.

REPRODUCTIVE BIOLOGY OF SELECTED AQUATIC PLANTS

Robert R. Haynes[1]

ABSTRACT

Aquatic weeds are species that inhabit bodies of water in such quantities that they either interfere with man's usage or become a health hazard by serving as a breeding area for insects, especially mosquitoes. These plants are most often introduced species. They increase in numbers mostly by vegetative reproduction, including stem or leaf fragmentation, budding, or turion formation. For dioecious species in which only one sex occurs in an area, vegetative means are the only methods of reproduction. Monoecious species or species with perfect flowers often produce viable seeds, which usually are not important for increasing the population size, as they are deposited in large mats and do not get enough light or other requirements for germination. Some species that reproduce sexually, such as Eichhornia azurea, *are self-sterile, but others, such as* Eichhornia crassipes *or* Ottelia alismoides, *are self-compatible.* Ottelia alismoides, *in fact, almost always is self-pollinated. Before the flowers open, the pollen tubes grow to the stigma from the anther. The flower eventually opens, but fertilization has already occurred. Pollination may be by insects (e.g.,* Hydrocharis morsus-ranae*) or by wind (*Potamogeton nodosus*); or it takes place at the surface of water by contact between stigma and anther (*Lagarosiphon*), by airborne pollen (*Hydrilla verticillata*), or by water-borne pollen (*Elodea canadensis*); or pollination may occur underwater (*Najas minor*).*

Aquatic weeds are species that inhabit bodies of water in such quantities that they either interfere with man's usage or become a health hazard by serving as a breeding area for insects. Such species are often introduced. Cook (1987) discussed 12 species that he considered to be the most notorious aquatic invaders and pointed out that only one, *Trapa natans*, relies on sexual processes for its reproduction and spread. Of the remaining 11, he noted that only *Myriophyllum spicatum*, *Najas minor*, and *Pistia stratiotes* regularly develop seed in their native and adventive ranges. *Salvinia molesta* is a sterile hybrid, and the rest have well-developed self-incompatibility mechanisms.

An understanding of their reproductive biology, both sexually and vegetatively, is important in developing methods of control for aggressive species. Aquatic flowering plants have pollinating systems ranging from those independent of the aquatic environment, such as wind and animal, to varying degrees of adaptation to the aquatic environment, beginning with pollination at the surface of the water, to underwater pollination with the pollen adhering to the surface of air bubbles, to a totally aquatic system in which pollen sinks in the water. The following selected list of aquatic weeds begins with the least adapted to the aquatic environment and terminates with the most adapted.

INSECT POLLINATED

Eichhornia crassipes (C. Mart.) Solms-Laub. (Pontederiaceae). Water-hyacinth.

Water-hyacinth is a free-floating annual or perennial with rosettes, well-developed stolons, and swollen to bulbous petiole bases. It is native to tropical South America but has been introduced ornamentally into warmer parts of all continents for its showy blue flowers (Barrett, 1982; Cook, 1987). *Eichhornia crassipes* spreads vegetatively by daughter rosettes that form rapidly on brittle stolons and separate from floating mats quite easily (Barrett, 1979).

Water-hyacinth is tristylous and self-compatible (Barrett, 1979). Barrett (1980a) studied fertility of nine clones of *Eichhornia crassipes* from different regions of the world. Eight of the nine populations flowered regularly during the study period and the ninth flowered frequently following the study period. Artificial crosses, both selfed and outcrossed, were made with each clone that flowered during the study period, totaling 2,546 crosses. Of these, 94.7% produced capsules, with an average of 143.3 seeds per capsule. All populations exhibited a high degree of self-compatibility, although degree of seed production varied among clones. Percentage of capsule set was significantly higher

---

ANN. MISSOURI BOT. GARD. 75: 805–810. 1988.

among all of the out-crossed than among all of the selfed plants.

A similar amount of seed production has been found in natural populations (Barrett, 1980b). He studied open-pollinated and artificially pollinated plants from 19 populations, with capsule production ranging from 72.3% to 100% per month for artificial pollinations, whereas it ranged from 8.1 to 68.7% for open-pollinated plants. Seeds per capsule were considerably fewer in open-pollinated ones, ranging from a mean of 3.1 to 40.8 per capsule, compared with artificially pollinated ones of 74.1 to 188.7 per capsule.

According to Barrett (1980b), *Eichhornia crassipes* can begin flowering 10–15 weeks after germination, soon for a perennial. One inflorescence with 20 flowers has the potential of producing 3,000 seeds, and up to four inflorescences can be produced by a single rosette during a 21-day period. Since flowering in subtropical to subtemperate regions may occur over five to nine months, the species can produce astronomical numbers of seeds. Regardless, most individuals in natural populations are probably produced vegetatively.

Seedlings were observed in only three of the 19 populations studied by Barrett (1980b). Apparently, seeds produced in dense floating mats of water-hyacinth either sink to the bottom or accumulate in the mat. Shading from the mats or low light levels coupled with low temperatures in deep water prevent the seeds from germinating.

Eichhornia azurea (Sw.) Kunth (Pontederiaceae). Rooted water-hyacinth.

Rooted water-hyacinth is an attached perennial with distichous, linear submersed leaves and elliptic to obovate floating leaves. The inflorescence is a compact spike of blue flowers, each having erose perianth lobes and a bilobed yellow spot in the center of the upper lobe. Vegetative reproduction is by chance fragmentation of the robustly branched stems (Barrett, 1978). The species is native to the Neotropics (Horn, 1987) and has been introduced to various regions as an ornamental (Barrett, 1978).

Unlike *Eichhornia crassipes, E. azurea* is tristylous and partially self-sterile. Barrett (1978) artificially selfed long-styled forms with the low-level anthers. Only 12% fruit set occurred. In contrast, when mid-level anthers were utilized, 94% fruit set occurred. A semihomostylous race has been observed in Costa Rica. This one has one whorl of anthers about the same level as the stigma. High seed set occurs when pollen from this anther whorl is used for selfing.

Ottelia alismoides (L.) Persoon (Hydrocharitaceae). Duck-lettuce.

Duck-lettuce is an annual or perennial from attached basal rosettes, with long-petiolate orbicular to ovate leaves. The flowers are borne singularly in solitary spathes terminating long scapes. They are perfect or very rarely imperfect (Cook & Urmi-König, 1984b), fragrant, and have staminodia that are important in attracting insect visitors. Cook (1982) indicated that, although no field observations have been published, the species is almost certainly insect pollinated. He also indicated that it is highly self-compatible and occasionally cleistogamous.

The plants are weeds of rice fields in the southern United States (Dike, 1969), Italy, and Southeast Asia (Cook & Urmi-König, 1984b). Increase in population size is apparently by seed, since no specialized means of vegetative propagation occurs (Cook & Urmi-König, 1984b).

Egeria densa Planchon (Hydrocharitaceae). Brazilean-elodea.

Brazilean-elodea is a rooted perennial with cauline leaves that are mostly in whorls of four. The flowers are imperfect and solitary on axillary peduncles that project the flowers to or above the water surface. Staminate and carpellate flowers contain glistening green functional nectaries. The flowers are frequently visited by small Diptera (Cook & Urmi-König, 1984a), but there is no evidence yet as to whether these insects are important in pollen transfer, since seed-set is so rare in nature and in cultivation.

Egeria densa is native to southeastern Brazil, Uruguay, Argentina, and possibly Paraguay. The species has been introduced into North America, Europe, Asia, Africa, and Australia. Only in warm temperate and cool subtropical climatic regions has it developed into an aquatic weed. Outside its native range, only in Chile are carpellate flowers known (Cook & Urmi-König, 1984a). No specialized overwintering structures are produced. Stem fragments root readily and develop into new shoots, so rapidly that the species often quickly overgrows a lake. Spread of *Egeria densa* probably results from its popularity in aquaria.

Hydrocharis morsus-ranae L. (Hydrocharitaceae). European frogbit.

European frogbit is a free-floating, stoloniferous perennial with basal, petiolate leaves. The flowers are borne in spathes and terminate pedicels that project the flower well above the spathe. Cook (1982) indicated that the carpellate flowers possess staminodia modified into nectaries that secrete a nectar attractive to insects. The staminate flowers appear quite similar to the carpellate flowers but lack these nectaries. They apparently offer no reward, but rely on mimicking the nectar-bearing carpellate flowers for insect attraction.

Hydrocharis morsus-ranae first appeared in the Western Hemisphere in 1932 at the Ottawa Botanic Garden, where it was cultivated (Dore, 1968). It was first noticed as an escape in 1939 in the Rideau Canal, from which it spread into the Ottawa and St. Lawrence rivers (Dore, 1968) and into the United States in 1974 (Roberts et al., 1981). This spread may have been by seed and by hibernacula. Cook & Lüönd (1982b) indicated that the species can grow from one hibernaculum to cover an area of one meter in diameter in one season.

Pistia stratiotes L. (Araceae). Water-lettuce.

Pistia is a monotypic genus of rosulate-leaved, free-floating, stoloniferous plants occurring in subtropical and tropical Africa, Asia, and America. The leaves are densely short-pubescent and surround a single terminal spathe that has the spadix adnate to its median line. The plants are monoeceious, with staminate and carpellate flowers on one spadix.

Cook (1987) indicated that the species is probably mostly self-pollinated, possibly by insects. Wilson (1960) stated that in Florida the ovary of water-lettuce tends to enlarge and become inflated, but no seeds are produced. He suggested that this lack of seed-set is probably due to absence of pollinators. His suggestion would tend to support Cook's view of the species being insect pollinated.

Pistia is important because of its vegetative reproductive capabilities. New plants are produced at the ends of the stolons and are separated from the parent plant by fragmentation. The species can reproduce rapidly enough to clog waterways.

WIND POLLINATED

Potamogeton nodosus Poiret (Potamogetonaceae). Floating pondweed.

Potamogeton nodosus is a perennial from elongate rhizomes with long-petiolate, lanceolate submersed and floating leaves with cuneate bases. The inflorescence is a compact spike held above the surface of the water (Haynes, 1978).

The species can cover huge areas of lakes in the southern United States. There are probably only one or a few clones, as *Potamogeton nodosus* increases in number mostly by rhizome growth. Pollination is predominantly anemophilous (Philbrick & Anderson, 1987). As such, the species is adapted for outcrossing.

Myriophyllum spicatum L. (Haloragaceae). Eurasian milfoil.

Eurasian milfoil is a submersed, rooted, stoloniferous perennial with whorled pinnately compound leaves and emergent imperfect flowers. The plants are monoecious and wind pollinated.

Myriophyllum spicatum is native to northern Eurasia (Cook, 1987) and has spread into the Western Hemisphere from Ontario and Quebec south to Florida and west to Wisconsin, Oklahoma, Texas, and Mexico, as well as to British Columbia, Washington, and California (Aiken, 1981). The species has often choked waterways (Coffey & McNabb, 1974), but in some places dramatic decline in the number of plants has occurred (Bayley et al., 1968; Elser, 1969) to the extent that the species no longer poses an environmental problem in these places.

Spread of Eurasian milfoil is mostly by vegetative fragment and seed (Cook, 1987).

POLLINATION AT SURFACE OF WATER

Hydrilla verticillata (L. f.) Royle (Hydrocharitaceae). Hydrilla.

Hydrilla is a perennial, rooted plant with the lower nodes having opposite leaves and the upper nodes having whorls of three to eight leaves. The flowers are imperfect and are produced singly in the leaf axils. Carpellate flowers are sessile with an elongating hypanthium that projects the perianth and stigma to the water's surface. As the hypanthium elongates, the perianth is forced open by a gas bubble (Cook & Lüönd, 1982a). Upon reaching the water surface, the perianth lobes open further, forming a funnel that is underwater below and open to the air above. The stigmas are at the bottom of this funnel. The subsessile staminate flower buds are released from the spathe by pedicel abscission and float on the surface at about a 45° angle. An hour or more after the bud is released, the perianth segments retract slightly, with each anther adhering to the convex part of the perianth. Soon the perianth spreads horizontally on the water surface; shortly after this the stamens suddenly spring from a horizontal to a vertical position; the anthers burst and scatter pollen in the air. As the pollen falls, most grains land on the water and are lost for reproductive purposes, but some fall into the funnel-shaped perianth of a carpellate flower, contacting a stigma. This is apparently a risky method of pollination, but, according to Cook & Lüönd (1982a), seed production is adequate to maintain hydrilla populations in areas that dry out and where hibernacula are not produced, or at least have not been observed.

Most increase in plant density is by hibernacula, which occur in two forms. The first form is from erect stems and is olive green and ovoid-conical with spreading apices that give the structure the appearance of a sandbur. Hibernacula of the second type are brown, subterranean structures that appear as minute potatoes at the tips of long, stringy, white, leafless rhizomes. Cook & Lüönd (1982a) indicated that the first type has food reserves in leaves, whereas the second has food reserves in swollen stem tissue.

Lagarosiphon major (Ridley) Moss (Hydrocharitaceae). African-elodea.

African-elodea is a rooted submerged perennial with alternate leaves. The flowers are from axillary, solitary spathes. The staminate spathes enclose many pedicellate flower buds, whereas the carpellate spathes contain only one sessile flower.

The staminate flower buds are released and rise to the water surface, remaining closed for a short while before eventually opening by the reflexing of perianth parts. The open flower, with three fertile horizontal and three sterile erect stamens, floats on the reflexed perianth. The staminodia function as a sail.

Carpellate flowers are projected to the water surface by an elongate hypanthium (Healy & Edgar, 1980). A meniscus is formed on the water surface by the carpellate flower, which then is slightly below the surface but with the styles protruding above the surface film. As staminate flowers move along the water, propelled by staminodia sails, one flower eventually tips into the meniscus, thereby causing a horizontal fertile stamen to contact an erect stigma.

Lagarosiphon has become an important weed in New Zealand, where it is replacing *Elodea canadensis* that has attained its maximum density and is declining (Healy & Edgar, 1980). Only carpellate plants are known in New Zealand, however, where it spreads by vegetative fragments.

Elodea canadensis Michaux (Hydrocharitaceae). Canadian-pondweed.

Canadian-pondweed is an attached species with cauline leaves in whorls of three. The flowers are axillary, imperfect, and elevated to the water surface by an elongate pedicel on the staminate flower and by an elongate hypanthium on the carpellate flower. The carpellate flower opens by recurving of the sepals and petals, which float on the water surface. The styles spread between the sepals and then recurve, with the tips usually becoming submersed. Upon reaching the surface, the staminate flower opens by the sepals and petals spreading there. The anthers dehisce in an upright position, scattering the pollen onto the surface of the water. Pollen floats on the water surface until it contacts a stigma, initiating germination.

Elodea canadensis is widespread in North America, where it is not known to become weedy. It was introduced into Europe in the early nineteenth century (Cook & Urmi-König, 1985), whereas the first record in Australia is 1931 (Aston, 1973). The European material has almost exclusively been carpellate plants. Vegetative reproduction is mostly from stem fragmentation. Not all nodes, however, are capable of rooting and developing a new plant.

SUBMERSED POLLINATION WITH POLLEN ADHERING TO AIR BUBBLES

Ruppia maritima L. (Potamogetonaceae). Ditch-grass.

Ditch-grass is an annual or perennial of brackish or saline waters with alternate leaves, these having the blades adnate to the stipules for the entire length of the stipules. The flowers are perfect and are produced in a capitate spike that is first enclosed by the sheathing leaf bases. The pollen is four times as long as broad, arcuate, swollen at the ends and at the center on the convex side, and three celled. Its exine is reticulate (Haynes, 1978). The gynoecium is of four or five distinct, stipitate carpels that have the gynophore elongating after anthesis. Pollination is mostly underwater. Following maximum peduncle elongation, the anthers dehisce underwater, releasing pollen that is trapped in air bubbles (Verhoeven, 1979). As the bubbles remain with an inflorescence for several hours, the pollen grains can only contact a stigma of that flower (Verhoeven, 1979), making self-pollination almost certain. Such a system insures ample seed set, which is important for an often annual species.

Out-crossing does occur occasionally in *Ruppia maritima*. Air bubbles, with their trapped pollen grains, break free from the inflorescence occasionally and rise to the water surface. Once on the surface, the bubble breaks, liberating the pollen grains, which float on account of trapped air in the reticulations of the exine. Should they contact a stigma that is at the water surface, cross-pollination occurs. More likely, however, these grains are blown from the *Ruppia* zone.

UNDERWATER POLLINATION

Zannichellia palustris L. (Zannichelliaceae). Horned-pondweed.

Horned-pondweed is an annual rooted plant with alternate, opposite, and occasionally whorled, linear leaves on the same plant. The flowers are imperfect, both staminate and carpellate in the same leaf axil. The carpellate flower is surrounded by a spathelike envelope and consists of four or five separate carpels, each with a funnel-shaped stigma. The staminate flower is outside the envelope, with a filament that projects the anther over the stigmas. Pollen is released in a gelatinous mass (Haynes & Holm-Nielsen, 1987) and falls directly into the funnel-shaped stigma, thus insuring self pollination.

Zannichellia is an annual without any vegetative perennating structure. It therefore depends entirely on seed production for surviving the unfavorable season.

Najas minor All. (Najadaceae). Water nymph.

Najas minor is a rooted, submersed annual with subopposite, serrulate leaves. The plants are monoecious, with flowers solitary in the leaf axils, the staminate flowers mostly above the carpellate ones. Pollination is entirely underwater. The pollen is heavier than water, and, after being released, it slowly descends through the water column, possibly contacting a stigma. Although this is not a system that insures pollination, seed set is very good.

The species occurs in northern Africa, Europe, Asia, and North America (Triest, 1987). In the past 50 years, it has become widespread in eastern North America (Haynes, 1977, 1979; Meriläinen, 1968), where it has become a troublesome weed in some areas. Increase in numbers is mostly from seed. Meriläinen (1968) suggested that the species has been spread by migrating waterfowl.

DISCUSSION

Some species of aquatic vascular plants have become weedy, especially in areas outside their natural ranges. These weedy species have posed environmental problems, either by interfering with recreation, such as by clogging waterways or by lowering the quality of fishing, or by forming breeding areas of noxious insects. Reproduction sufficient to overtake a body of water most often is vegetative, either by stem fragmentation or by production of hibernacula. Almost all species also, at least occasionally, undergo sexual reproduction. Most have very little adaptation for adequate transfer of pollen. Instead, they project the inflorescence above the water for either animal or wind pollination. A few, however, have developed methods of pollen transfer either at the water surface or underwater. Among these few, some, such as *Najas minor*, are annuals and depend entirely on seed production for maintaining the population.

POLLINATION POSTULATES AND TWO-DIMENSIONAL POLLINATION IN HYDROPHILOUS MONOCOTYLEDONS[1]

Paul Alan Cox[2] *and R. Bruce Knox*[3]

ABSTRACT

A set of pollination postulates are proposed to unify vector identification in pollination biology. These postulates were used to test theoretical predictions concerning two-dimensional pollination systems in Halodule, Halophila, Ruppia, Lepilaena, *and* Amphibolis. *The general syndrome of pollination on the water surface is illustrated by intertidal populations of* Amphibolis antarctica, *whose staminate flowers abscise during low spring tides and float to the surface where they dehisce, expelling a cottony mass of filamentous pollen. The pollen floats and forms search vehicles or pollen assemblages that collide with stigmas on the water surface. The search efficiency of large search vehicles was examined by video analysis of* Ruppia spiralis *pollination. Large search vehicles were found to be more likely to hit stigmas than small ones.*

Although the determination of the vectors responsible for transporting pollen from flower to flower is a central task of pollination biology, no standard criteria for vector determination exist. Historically, methodologies for vector determination range from careful ecological studies to conjecture based upon superficial examination of dried herbarium specimens or worse. As a result, the literature of pollination ecology is uneven in rigor. Perhaps since anthecology originated as a specialization of plant taxonomy, textbooks and reviews tend to favor claims with historical priority. Thus, even incorrect ideas are notoriously difficult to remove from the literature.

An example may be found in the literature concerning the pollination ecology of *Freycinetia arborea* Gaud. (Pandanaceae) in Hawaii. Pollination by rats was suggested by Degener (1930), who made no experiments or observations of pollinator visitation. No consideration was given to how *F. arborea* was pollinated before the introduction of rats to Hawaii by Polynesian colonists in 400 A.D. (Jennings, 1979). However, despite several previous detailed accounts of *Freycinetia* pollination in the Dutch, German, and English literature (see reviews in Cox, 1981, 1984), Degener's rather anecdotal sketch emerged as authoritative. Frequently cited in textbooks, but sometimes attributed to a secondary source (Proctor & Yeo, 1973), the story of rat pollination of *Freycinetia* thus began a life of its own. Each recounting of the story added to both its detail and apparent authenticity. Although the original report did not indicate the time of day that pollination supposedly occurs, this important detail later appeared in a major compendium (Faegri & van der Pijl, 1979). Degener (pers. comm.), however, never witnessed rat visitation but only inferred it from scratches on the floral bracts. Subsequent studies demonstrated such scratches to be caused by the introduced white-eyes that now pollinate *F. arborea.* Electron microscope analysis of bird specimens collected in the nineteenth century indicates that formerly pollination was mediated by now extinct honeycreepers (Cox, 1983a).

Such confusion in vector identification is reminiscent of disputes concerning pathogen determination in medicine in the 1850s. The prevailing theory was that diseases like tuberculosis are caused by a variety of climatic, environmental, and organic factors. However, Robert Koch (1880) proved that tuberculosis is caused by a single bacterium. His

TABLE 1. *Postulates.*

Koch's Postulates

1. Pathogen must be demonstrated in all cases of the disease.
2. Pathogen must be cultivated in pure culture.
3. Cultured pathogen must cause disease in healthy individuals.
4. Pathogen must be re-isolated from these infected individuals.

Pollinaton Postulates

In the field:

1. Pollen transfer from anther or pollen presentation apparatus to vector must be observed.
2. Pollen transport by vector must be observed.
3. Pollen transfer from vector to stigma must be observed.
4. Pollen deposited by vector on stigma must be demonstrated to effect fertilization.

rigorous methodology has since been encapsulated in a series of postulates named after him (Table 1). Brock (1966) and Harper (1978) have suggested that ecology could benefit from similar rigor.

Using Koch's postulates as a model, we propose a standard set of postulates for vector determination in pollination biology (Table 1). Our postulates require confirmation of each stage of the interaction between anther, vector, and stigma. We submit that unless these postulates have been met, the efficacy of a presumed vector in pollination has yet to be proven. We additionally suggest that all such determinations be made in the natural populations rather than in the laboratory, where unnatural conditions can deceive even the most careful investigators.

We used these pollination postulates to guide our studies of pollination in hydrophilous monocotyledons and to test previous theoretical predictions concerning two-dimensional pollination systems (Cox, 1983b).

THEORETICAL PREDICTIONS OF TWO-DIMENSIONAL POLLINATION SYSTEMS

The probability of a pollen grain reaching the stigma can be modeled for aquatic regimes where wind, currents, and orbital wave motion drive it along an essentially random path. In the simple case of a pollen grain tracing a Brownian path, it can be shown that the pollen grain will eventually hit any coplanar stigma, given enough time (Cox, 1983b; Hersch & Griego, 1969). However, in three dimensions there is a probability that a pollen grain on a random trajectory will not hit any given stigma even given an infinite amount of time. Since such fractal motion is recurrent in two dimensions but not three, it was predicted that selection will favor the evolution of two-dimensional pollination systems where such systems are possible, i.e., in aquatic regimes such as ponds, and intertidal regions (Cox, 1983b).

The theoretical effectiveness of two-dimensional pollination systems can be examined through the use of search theory (Cox, 1983b; Koopman, 1956). Of particular interest are the effects of pollen morphology on stigma encounter rates. The probability P of a pollen grain encountering a fixed stigma, if the pollen grain traces a random path in the same plane, can be shown to be

$$P = 1 - e^{-wL/A}, \tag{1}$$

where w is the width of the path swept by the pollen grain, L is the length of the search path, and A is the search area (Cox, 1983b). Hence at low encounter probabilities, even a small increase in the pollen grain diameter will result in a very large increase in probability of encountering a stigma. Of particular interest is the exponential nature of this function: at low encounter probabilities a doubling of pollen grain diameter will result in a more than two-fold increase in the probability of hitting a stigma.

From these theoretical considerations two general predictions can be made concerning hydrophily (water-pollination): 1) a 2-D pollination system will be more efficient than a 3-D system, and thus favored by natural selection if pollen and stigmas can be dispersed in the same plane; and 2) in a 2-D pollination system, pollen grains or aggregations of large dimension will be much more likely to hit stigmas than small ones. Following the nomenclature of search theory (Koopman, 1956; Cox, 1983b), such aggregations will hereafter be termed "search vehicles."

EMPIRICAL PROPERTIES OF TWO-DIMENSIONAL POLLINATION SYSTEMS

These theoretical predictions concerning two-dimensional pollination were tested in five different genera of marine and freshwater aquatic plants. In accordance with our postulates, we observed in each species the release of the pollen from the anther to the surface, transport of the pollen by the water surface, and deposition of the pollen from the water surface onto the stigma. We are currently studying the efficacy of fertilization under field conditions. Such confirmation is important

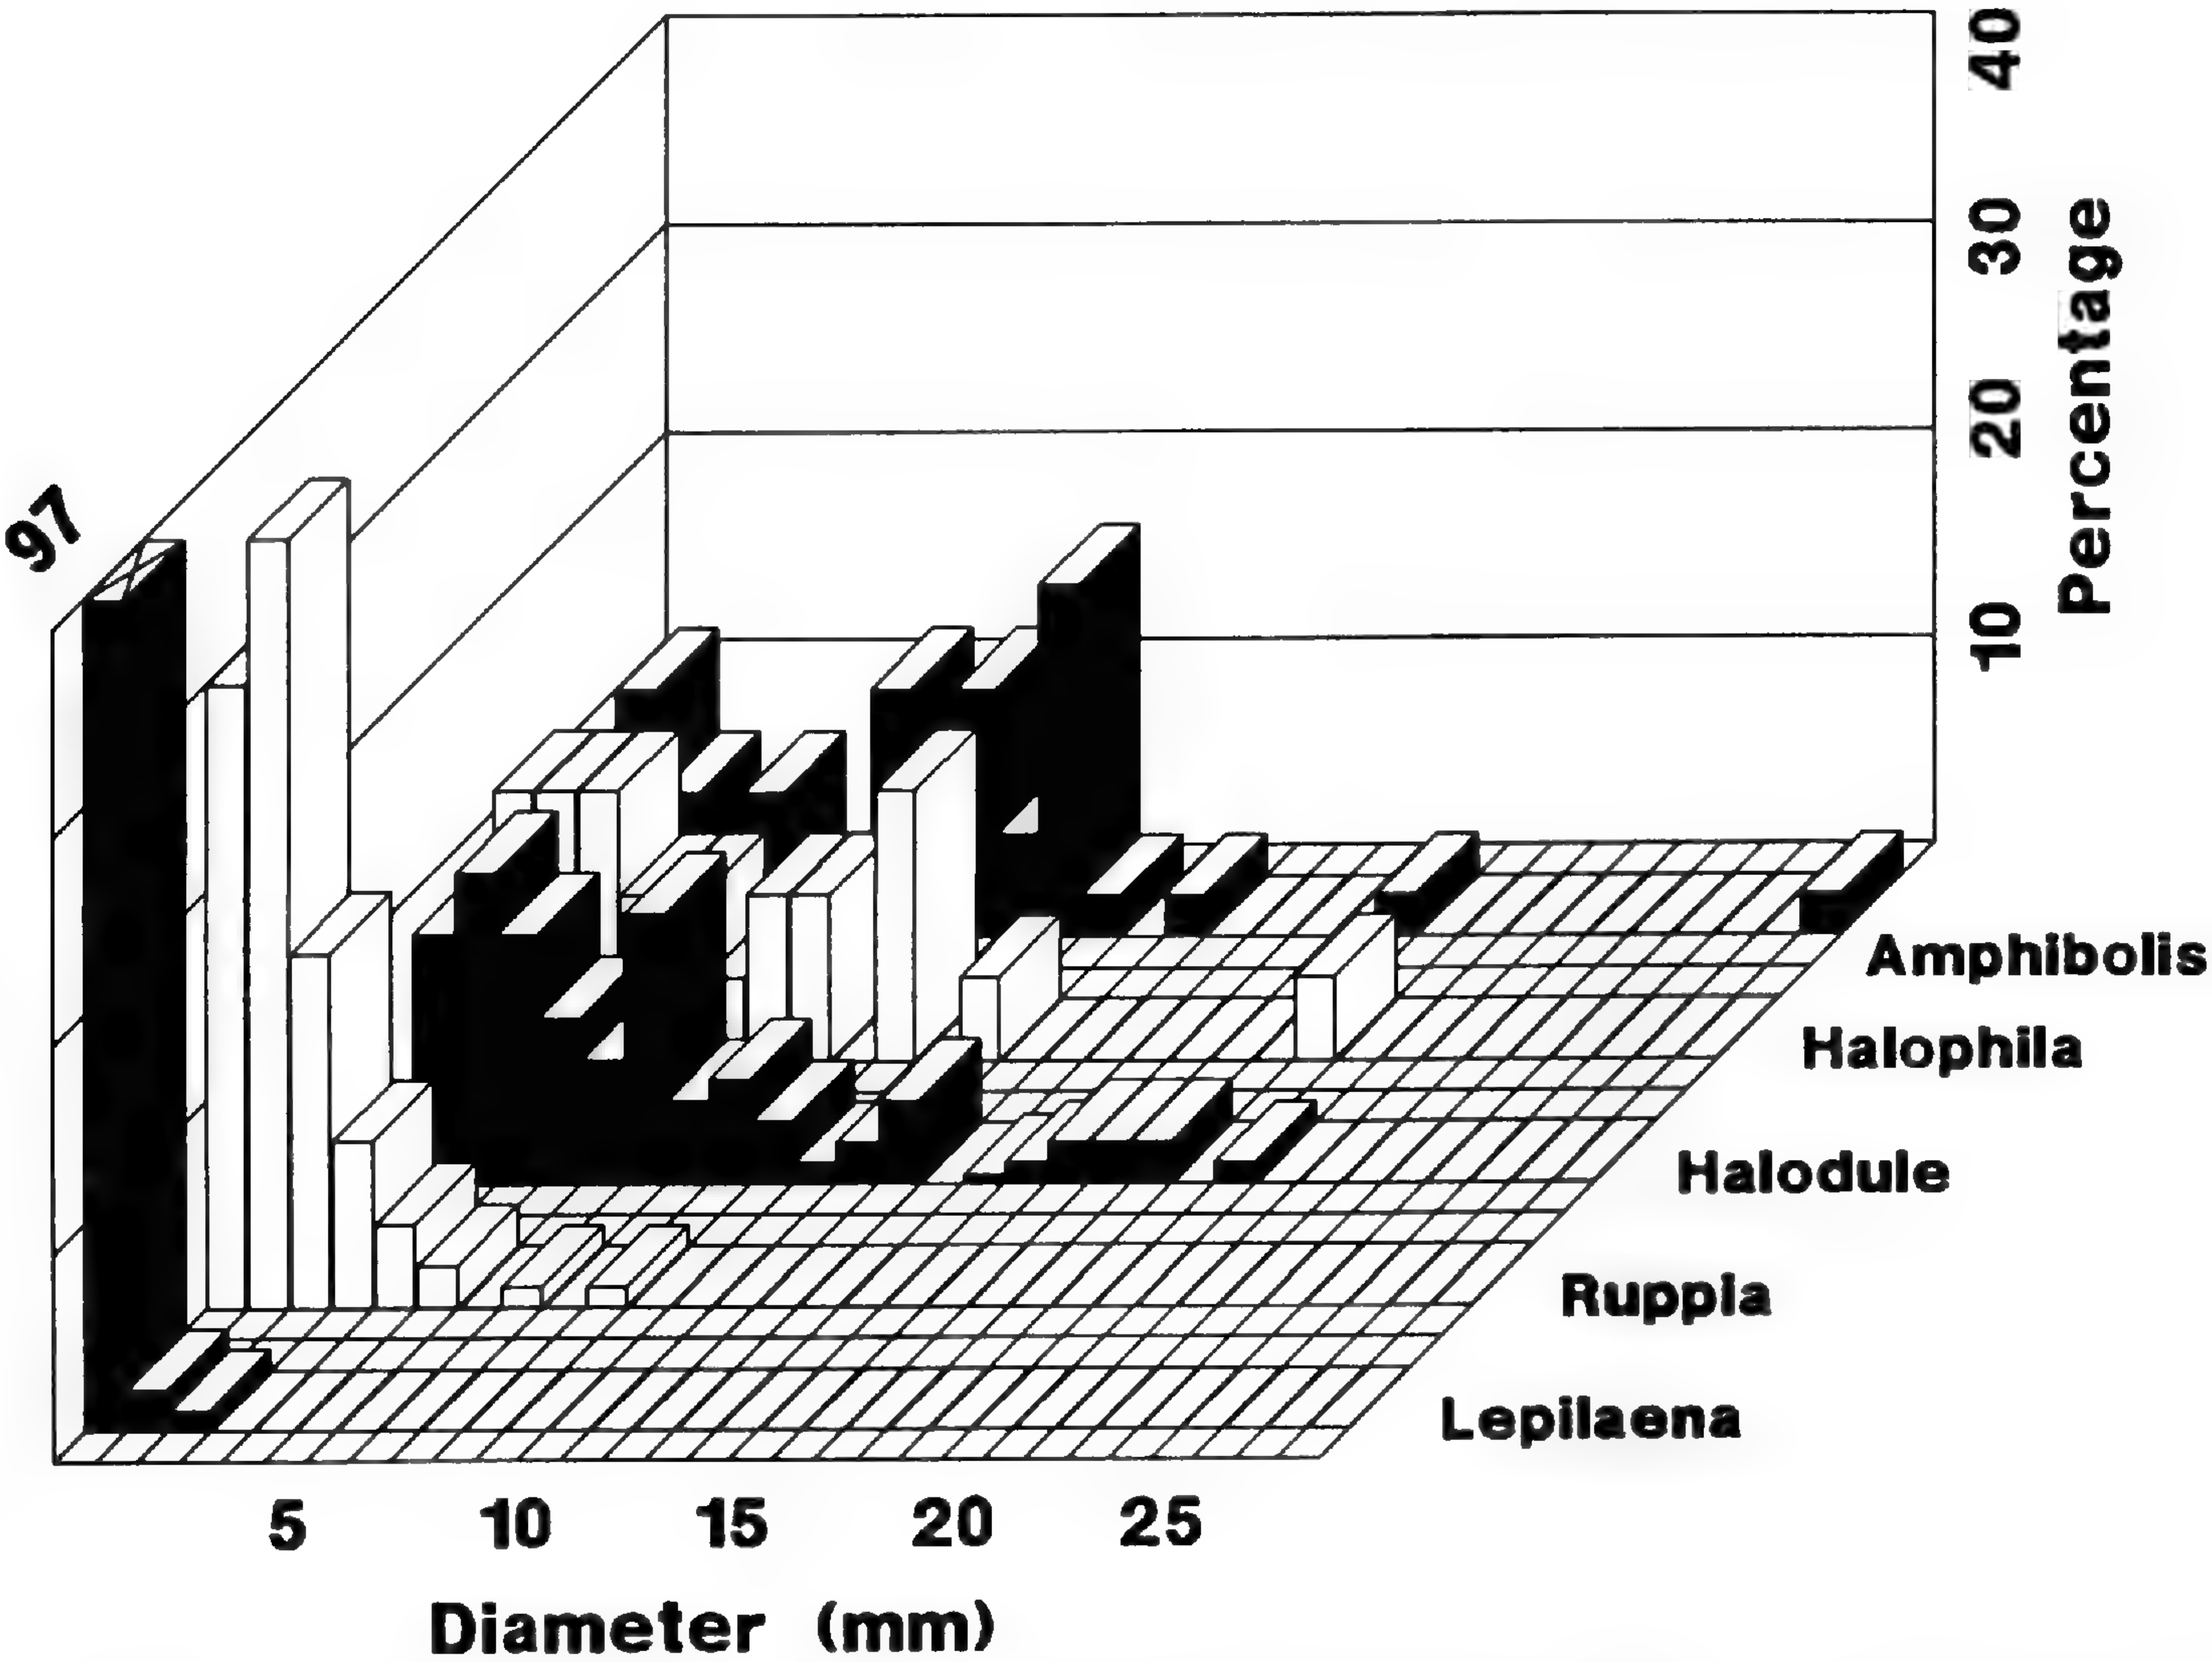

FIGURE 1. *Size distribution of floating search vehicles (pollen aggregations) from five genera of hydrophilous monocotyledons:* Halodule pinifolia *(median = 5,000 μm, N = 114)*, Halophila ovalis *(median = 8,000 μm, N = 17)*, Ruppia spiralis, *Altona, Victoria, population (median = 1,361 μm, N = 300)*, Lepilaena cylindrocarpa *(median = 338 μm, N = 172), and* Amphibolis antarctica *(median = 8,500 μm, N = 40)*.

because of the possibility of apomixis in some dioecious seagrasses, such as *Halophila stipulacea* (Forsk.) Aschers. (Hydrocharitaceae), where seed has been found to develop in pistillate cultures (McMillan, 1980).

Our study focused on genera in which pollen is transported in direct contact with the water. However, plants in which pollination occurs by the collision of floating staminate flowers with buoyant pistillate flowers, such as some genera of the Hydrocharitaceae, e.g., *Vallisneria, Nechamandra, Enhalus, Lagarosiphon,* or *Appertiella,* can also be said to have in effect two-dimensional pollination systems (Cook, 1982; Ernst-Schwarzenbach, 1945; Troll, 1931; Wylie, 1917; Cox, 1988a). Taxa also exist that have submarine two-dimensional pollination systems, such as *Thalassia testudinum* Banks ex Konig (Hydrocharitaceae), where pollen is released at the substrate surface and dispersed in negatively buoyant search vehicles (Cox & Tomlinson, 1988; Cox, in press). Pollination is submarine and essentially occurs along the plane of the substratum.

In the species we studied, e.g., *Halodule pinifolia* (Miki) den Hartog (Cymodoceaceae), *Halophila ovalis* (R. Br.) Hook. f. (Hydrocharitaceae), *Ruppia maritima* L. ex Dumort (Ruppiaceae), *Lepilaena cylindrocarpa* (Koernicke ex Walp.) Benth. (Zannichelliaceae), and *Amphibolis antarctica* (Labill.) Sonder & Aschers. ex Aschers. (Cymodoceaceae), we found pollination to occur on the water surface. In these species the pollen is hydrophobic and forms floating search vehicles that collide with the buoyant stigmas. However, the search vehicles are formed differently and are of different size in each species (Fig. 1). The pollen grains of *Halodule pinifolia*, for example, are filiform and link together in search vehicles that resemble snowflakes, while the pollen grains of *Lepilaena cylindrocarpa* are small, spherical, and dispersed in a floating mat of mucilaginous slime. The pollen grains of *Halophila ovalis* are oval and of medium size, but are dispersed in long floating mucilaginous tubes of thecal origin (Cox & Knox, 1986; Pettitt, 1980, 1981). These tubes link together to form featherlike search vehicles. *Ruppia spiralis* pollen grains have a boomerang shape, forming search vehicles by lining up side-to-side (Cox & Knox, 1986; Gamerro, 1968; Verhoeven, 1979; Van Vierssen et al., 1982). Similar evolutionary convergences can also be found in stigma morphologies: the marine genera have filamentous, smooth stigmas while the freshwater genera have small indusiate stigmas that create small depressions on the water surface. It therefore appears that there has been convergent evolution towards a surface pollination syndrome.

TWO-DIMENSIONAL POLLINATION IN *AMPHIBOLIS ANTARCTICA*

The pollination ecologies of *Halodule pinifolia, Halophila ovalis, Ruppia spiralis,* and *Lepilaena cylindrocarpa* will be reported in detail elsewhere (Cox & Knox, in press). However, many of the essential features of surface-pollinated taxa are illustrated by the pollination ecology of *Amphibolis antarctica,* a dioecious seagrass found in the waters of Western Australia, Southern Australia, Victoria, and Tasmania (Ducker et al., 1977; Aston, 1973).

Amphibolis antarctica plants produce solitary floral units (for discussions of floral terminology see McConchie et al., 1982; Tomlinson, 1982) at the ends of short lateral leafy branches with distichous phyllotaxis. The staminate floral units are bipartite, with two fused stamens borne on a short pedicel. The pistillate floral units consist of two free carpels, each with a sessile ovary bearing three slender styles (McConchie et al., 1982; Tomlinson, 1982). A few days prior to dehiscence, the pedicel bearing the staminate floral units elongates, pushing the fused anthers up from between the bracts. However, the floral units (Fig. 2A) are still hidden by the leafy shoots until they abscise and float to the surface. Within the anthers, the mature tricellular pollen grains are filamentous and 3,000–5,000 μm long, with forked tails (Ducker et al., 1978). The mature pollen "noodles" lack a developed exine (Pettitt et al., 1983). Details of pollen–stigma interactions and pollen tube growth have been investigated by Pettitt et al. (1980, 1983). In pistillate plants the mature styles protrude from the shoots in a plane orthogonal to the plane of phyllotaxis.

Pollination in *Amphibolis antarctica* has been described as submarine, i.e., occurring beneath the surface of the water (Ducker et al., 1978; Pettitt et al., 1980, 1981, 1983). However, the possibility of variation is indicated by previous observations that the male flowers may be shed, releasing their pollen on the surface of the sea, with the floating pollen forming large aggregates (Ducker et al., 1978).

We studied the pollination ecology of *Amphibolis antarctica* in an intertidal population at Point Lonsdale, Victoria, Australia, attempting to verify each of the previously discussed pollination postulates. At 3:04 P.M. on December 13, 1986, during a low (0.3 m) tide, numerous staminate and pistillate plants in the population were examined and found to have mature flowers. At low tide, the tops of the plants were observed floating on the surface, with the plane of the distichous phyllotaxis coplanar with water surface. As a result, one set of stigmas from each pistillate floral unit penetrated the water surface. A few abscised staminate flowers that had already released their pollen were found along the beach, but no pollination events were observed.

Between 4:40 P.M. and 5:20 P.M. on December 15, 1986, during an even lower tide (0.2 m), several thousand staminate floral units were observed to abscise (Fig. 3A) and float to the surface (Fig. 3B). Once on the surface, the anthers dehisced longitudinally and extruded flocculent masses of floating pollen (Figs. 2A, 3C). The pollen mass from each male floral unit rapidly expanded on the water surface into large floating search vehicles (median diameter = 8,500 μm, N = 40) of fractal geometry (Fig. 3D). The tops of nearly all of the mature pistillate plants in the population were exposed during this extremely low tide so that one set of stigmas in each floral unit penetrated the water surface (Fig. 3E). Pollination was observed to occur on the water surface through the collision of the floating search vehicles with the stigmas (Figs. 2B, 3E). As the tide came back in, thousands of empty staminate floral units were washed up along the beach. Field experiments with mature and slightly immature pollen showed mature pollen to float, while slightly immature pollen proved to be neutrally buoyant.

By observing actual pollination events at the water surface, we can with confidence ascribe a two-dimensional surface pollination syndrome to *Amphibolis antarctica.* Two-dimensional surface pollination is probably characteristic of *A. amphibolis* in the intertidal zones where the stigmas have the potential to be exposed during low tides. The species can grow and flower at greater depths, however, where pollination, if it occurs at all, must of necessity be submarine. Although we believe *Amphibolis antarctica* to be primarily surface-pollinated, submarine pollination cannot be ex-

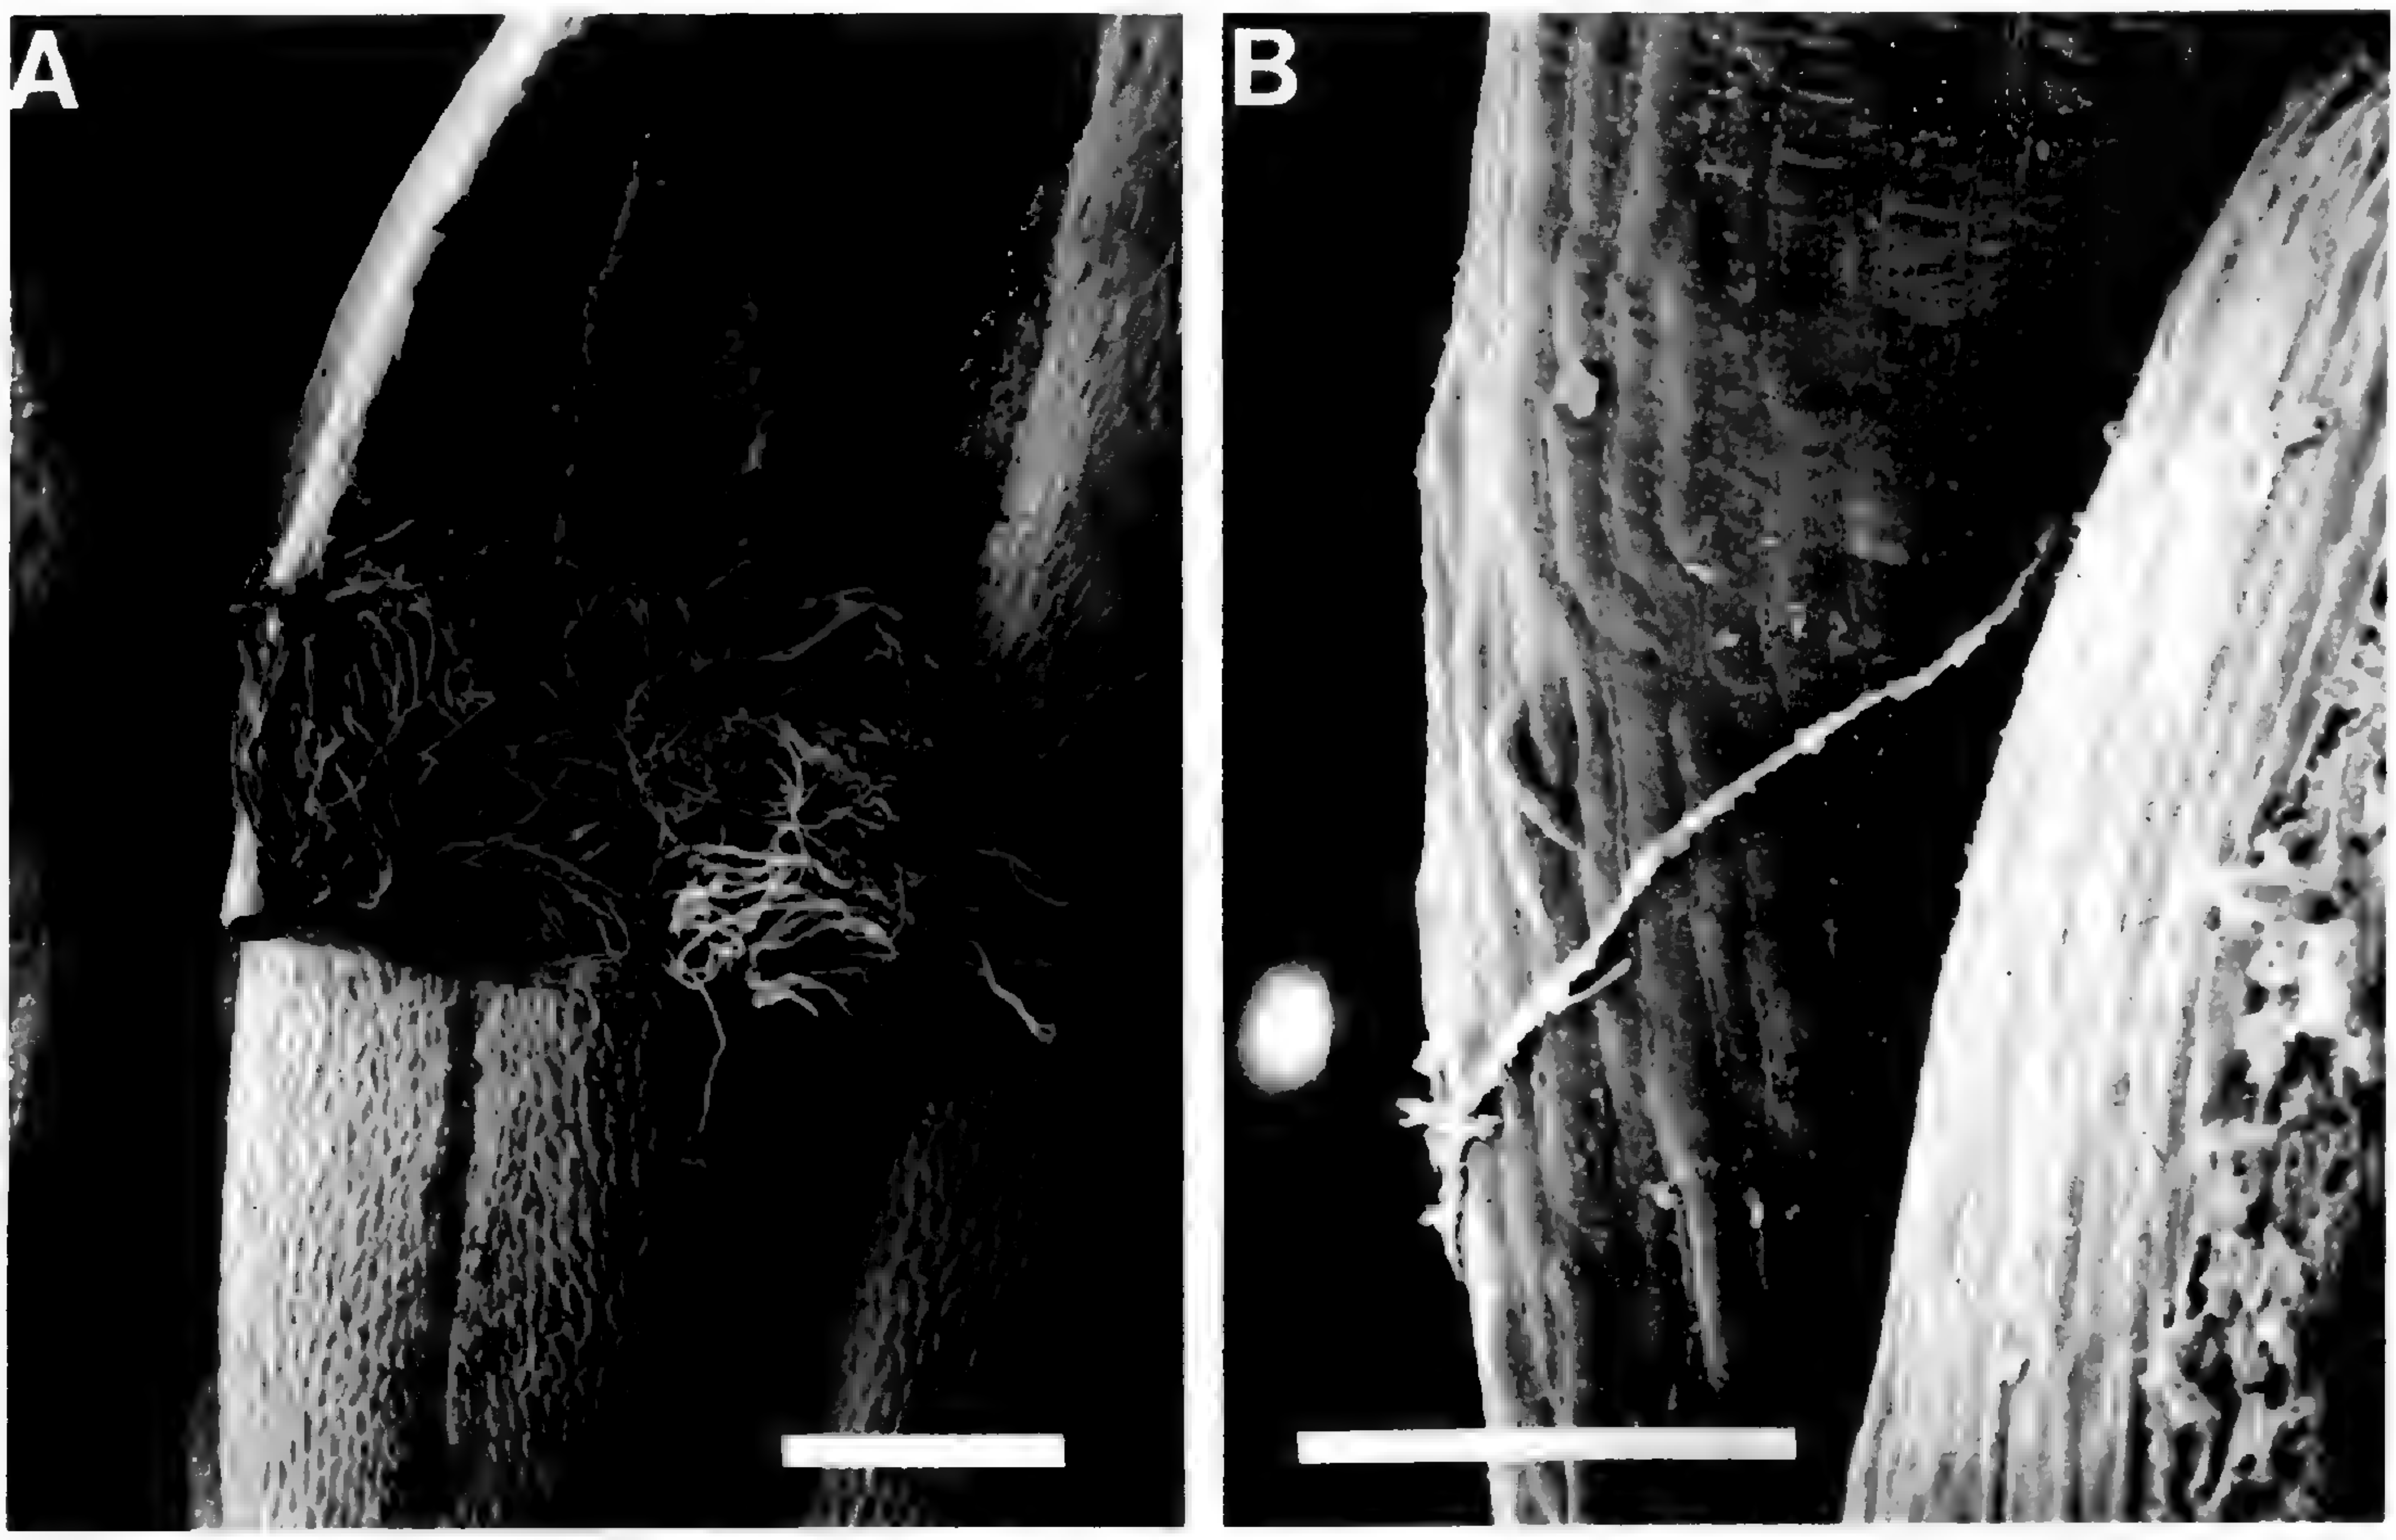

FIGURE 2. *Reproductive structures of* Amphibolis antarctica.—*A. Staminate floral unit prior to dehiscence, with the filiform pollen exposed (scale = 1 mm).*—*B. Filiform pollen grain on an* Amphibolis *stigma from a natural pollination event in the Point Lonsdale, Victoria, population (scale = 100 μm).*

cluded on the basis of our current observations and may also occur in the species.

The floral morphology of *A. antarctica* permits only one of the two sets of stigmas in each pistillate floral unit to encounter the water surface and hence be pollinated. This may relate to the fact that only one of the two ovaries develops, while the other one aborts (Tomlinson, 1982). This condition is analogous to the situation in *Ruppia*, where the inflorescence frequently floats on the surface in such a way that only one of the sets of stigmas is exposed to floating pollen while the other is submerged. Germination in *A. antarctica* is viviparous (Fig. 3F) (Black, 1913), with the mature seedling being released together with an unvascularized "grappling apparatus" (Fig. 3G) that develops as an outgrowth of the female floral unit (McConchie et al., 1982). This grappling apparatus presumably assists in attaching the seedling to a substrate.

SEARCH VEHICLE SIZE AND SUCCESS in *RUPPIA SPIRALIS*

Although two-dimensional search theory predicts that large search vehicles are much more likely to encounter stigmas than small search vehicles (Cox, 1983b), there has yet to be an empirical test of this prediction. We therefore studied pollen/stigma encounters in a *Ruppia maritima* population growing in a brackish pond near Queenscliff, Victoria. Using an immersible camera stand, we filmed natural pollination events with a video camera equipped with a macro lens. The video tape was then analyzed frame by frame with a high-resolution freeze-frame video deck attached to a Zeiss Videoplan digital imaging system. Dimensions of all search vehicles were calculated by digitizing their images on the video screen. The size distributions (largest diameters) of 1,000 such search vehicles chosen at random from the video footage were calculated and recorded. Then the video tape was analyzed again to determine the sizes of search vehicles that actually collided with stigmas. This was accomplished by finding a frame in which a search vehicle could be seen to hit the stigma, and then reversing the tape several frames so that the dimensions of the search vehicle prior to collision could be determined. This procedure was repeated for 100 such search vehicles.

The respective size distributions of successful search vehicles together with the size distributions of all search vehicles are shown in Figure 4. The median size of all search vehicles was found to be 812 μm (N = 1,000), while the median size of successful search vehicles was much larger (1,388 μm; N = 100). A *U*-test for the difference between the medians was significant at the 0.05 level. This

suggests that larger search vehicles do, in accordance with theoretical predictions, have a much greater chance of successfully encountering a stigma than small search vehicles.

Many questions, however, remain concerning two-dimensional pollination. What is the role of stigma morphology on search vehicle encounter rates? Computer simulations (P. A. Cox & J. Sethian, unpubl. data) indicate filamentous stigmas to be far more efficient in pollen capture, but the relative importance of stigmatic texture is unknown. The stigmas of the five surface-pollinated genera we studied are smooth, while the stigmas of the two-dimensional submarine-pollinated species *Thalassia testudinum* are densely papillate (Cox & Tomlinson, 1988). Major questions also remain concerning mixed modes of pollination. Is it possible that some seagrasses have both surface and submarine modes of pollination as has been suggested by Hartog (1970) for *Phyllospadix* and *Zostera* (Cock, 1980)? If so, what are the relative importances of these different modes? Another important question concerns the effect of two-dimensional pollination systems on breeding systems. If the pollen shadows are far smaller than the average clone size of the species, will there be strong selection for obligate outbreeding systems (Cox, 1988) such as dioecism? It is of interest in this regard that 75% of the seagrass genera are dioecious. Gene flow between populations mediated by pollen exchange must be exceedingly rare in seagrasses (Cox, 1983b) and even rarer in freshwater hydrophilous plants, since the pollen cannot move from one pond to another (Cook, 1987). The evolutionary ecology of such genetically isolated populations merits further investigation. Finally, convincing evolutionary explanations have yet to be made of lack of a developed exine in the pollen of many hydrophilous plants (Ducker et al., 1978). We believe that more light will be shed on these questions as further ecological studies are made of two-dimensional pollination systems.

BREEDING SYSTEMS, POPULATION STRUCTURE, AND EVOLUTION IN HYDROPHILOUS ANGIOSPERMS[1]

Donald H. Les[2]

ABSTRACT

True hydrophily occurs in 18 submersed angiosperm genera. Of these, 17 are monocots, 12 are marine, and 5 contain annuals. Three genera include hermaphroditic species, 8 have monoecious species, and 13 have dioecious species. The prevalence of dicliny in hydrophiles has led to assumptions of outcrossing and high levels of genetic variability in these plants. Many water-pollinated species, however, may often fail to meet all conditions necessary for outcrossing. In hydrophiles, decreased seed output associated with dicliny increases the probability of dispersal by vegetative propagules. The predominant role of asexual reproduction and clonal growth in many hydrophile populations may restrict outcrossing despite the high potential for xenogamy in some species. This inference is substantiated by preliminary genetic analyses which indicate very low levels of variability and high homozygosity in hydrophile populations. A shift to asexual reproduction is offered as one explanation for the slow evolutionary rates associated with this biological group of species. Exceptions to these conclusions are noted in annual species, which must reproduce sexually to survive. Annual hydrophile genera have higher species diversity and possibly greater genetic variability within and between populations.

Aquatic plants are notorious for their anatomical, morphological, and physiological peculiarities. A question relating to their unusual biological features is whether the course of evolution in aquatic plants differs fundamentally from that of terrestrial plants. This question is difficult to address because water plants are not a monophyletic group; therefore, the assessment of "peculiarities" would necessarily involve interpreting patterns of convergent evolution. Certainly, there is no reason to suspect that hydrophytes do not follow evolutionary paths dictated by the same basic factors that have influenced terrestrial plant evolution. On the other hand, there are evolutionary patterns associated with the "biological group" of submersed hydrophilous angiosperms that warrant consideration. A particularly striking feature of these species is their slow rate of evolutionary diversification, a conclusion revealed by several lines of evidence.

Data tabulated for 31 principally aquatic families (from Cook et al., 1974) furnish an average of about eight species per genus. The number of extant species in most hydrophilous angiosperm genera, however, is fewer than eight (Table 1). In comparison, some genera of nonhydrophilous submersed aquatic plants (e.g., *Potamogeton, Myriophyllum, Ranunculus*) may contain 35–100 or more species. Not all hydrophilous genera, however, have few species; *Najas* contains 35–50 species, the largest number among hydrophilous genera (Table 1). Furthermore, the fossil record indicates that at least several hydrophilous angiosperms have undergone a prolonged period of morphological "stasis." In an evolutionary study of the genus *Ceratophyllum*, Les (1986a: 32) observed: "One interesting aspect of the fossil record is that most of the extinct taxa can be associated with the extant genus *Ceratophyllum*, and often with extant species . . . ." Similar statements were made by Hartog (1970) with respect to the hydrophilous seagrasses, e.g. (p. 15): "It is noteworthy that these Tertiary [seagrass] fossils all belong to still existing genera and that at least two of them can be identified with still existing species." And (p. 30): ". . . evidence for the great age of recent species . . . is supported by the fact that fossil remains of *Cymodocea* from the European Eocene can be identified with still existing species." Hartog (1970)

attributed the slow rate of evolution in seagrasses to the relative uniformity of the marine environment, and Les (1986a) related stasis in *Ceratophyllum* to interactions of hydrophily and aspects of the breeding system.

Are the slow evolutionary rates that apparently characterize various unrelated hydrophile species a consequence of their unique pollination system? This question has prompted the present study to review not only the pollination system but the overall reproductive biology of hydrophilous angiosperms. Specifically, the intent of this paper is to hypothesize possible evolutionary implications associated with peculiarities of hydrophile reproductive biology. Establishment of a theoretical basis will provide a means for testing hypotheses empirically. Although this symposium focuses on freshwater angiosperms, consideration must also be given here to marine angiosperms, which dominate this biological group.

SALIENT FEATURES OF HYDROPHILY

True hydrophily includes hyphydrophily where pollen is transported exclusively under water, and ephydrophily where pollination occurs at the surface (Faegri & van der Pijl, 1979). Various mechanisms by which pollen is transported above the water surface (e.g., *Enhalus*, *Vallisneria*) mimic hydrophily but are not considered here.

Hydrophily is viewed as a derived condition in angiosperms and probably developed from both anemophily and entomophily (Faegri & van der Pijl, 1979); however, the immediate precursor to hydrophily in most instances appears to have been anemophily (Les, 1988b). Hydrophily is unique to submersed aquatic angiosperms and occurs only within 18 genera which represent seven families and which constitute a heterogeneous group phylogenetically. The taxonomic distribution and selected features of these genera are summarized in Table 1, from which several associations are apparent. Except for *Najas*, there are 1–12 species in hydrophilous genera. The frequency of sexual reproduction ranges from common to rare. Nearly all genera are principally perennial, and all (even annuals) possess mechanisms for vegetative reproduction. An overwhelming consistency is the diclinous sexual condition (monoecy or dioecy), with hermaphroditic flowers occurring in only three genera. Most hydrophilous genera are marine; seven genera occur in freshwater.

Like anemophily, hydrophily is an abiotic pollen-transfer mechanism and therefore inherently "wasteful" (i.e., much of the pollen produced does not contact a receptive stigma) because of nondirectionality (Faegri & van der Pijl, 1979; Cox, 1983). The three-dimensionality of hyphydrophily leads to high pollen wastage, although higher efficiency may be attained in shallow water where pollen loads may concentrate. Ephydrophily reduces pollen wastage by confining the dispersal of grains to the two-dimensional water surface (Faegri & van der Pijl, 1979). Because of the stochastic nature of hydrophily, the highest level of efficiency is probably achieved with autogamous pollinations, where the shortest transport distance is involved, and presumably decreases with the greater distances involved in geitonogamous (involving different flowers on one individual) or xenogamous (involving flowers on different individuals) pollinations. Underwater pollination in some species is enhanced by the reduction of water currents over plant beds (which assists pollen deposition) and the relatively large area of pollen influence around female flowers (Ackerman, 1983, 1986).

Hydrophile pollen exhibits structural modifications that apparently maximize transport efficiency. The surface area of most hydrophile pollen is increased variously (Table 1). In some species, globular pollen grains form filiform chains, or the grain itself is highly elongate (Pettitt & Jermy, 1975; Cox, 1983). In other species, precocious germination of the pollen tube (Fig. 1A) may increase surface area to maximize capture by the stigma (Sculthorpe, 1967; Faegri & van der Pijl, 1979; Cox, 1983; Les, 1986a). In *Ceratophyllum*, the surface area is increased further by the occasional branching of pollen tubes (Fig. 1B), and grains with precocious pollen tubes have been observed to mass together (Sehgal & Ram, 1970), thereby mimicking pollinia. Typically, the exine of hydrophilous pollen is highly reduced (Pettitt & Jermy, 1975).

Hydrophily and anemophily are the major abiotic pollination systems in plants. Understandably, the two systems share certain similarities in their floral syndromes, such as frequent dicliny, reduced perianths, high pollen/ovule ratios, reduced pollen exines, and enlarged receptive surfaces (Faegri & van der Pijl, 1979; Les, 1986a; Sculthorpe, 1967; Whitehead, 1969). Both systems lack the specificity and constancy associated with biotic pollination systems. There are, however, various differences between the two abiotic systems. Anemophily relies on the availability of wind, whereas availability of water is seldom a liability to submersed plants. Pollen dispersal distances of anemophiles are limited only by the longevity of grains and their ability to be carried aloft. Dispersal distances in hydrophiles are restricted entirely to the dimensions of the body of water they inhabit. For freshwater species, this distance may be quite small, e.g., a pond, pool, or small lake. A further consideration is that hydrophiles are generally confined to shallow depths, and pollen transported to deeper water has little chance of encountering plants. With respect to ephydrophily, Cook & Urmi-König (1985: 118) stated: "Pollen transfer on the surface of the water may well be efficient over distances best measured in centimeters, but for distances measured in meters or kilometers it will become inefficient or even ineffective."

Hydrophile pollen is not subject to desiccation, but studies are needed to determine the duration of its viability. In *Zostera*, pollen retains viability for over 48 hours (De Cock, 1980). Although pollen of hyphydrophiles frequently contains starch to promote sinking (Sculthorpe, 1967; Les, 1986a), it is conceivable that water currents may facilitate resuspension of grains (particularly in very shallow water), which may increase opportunities for contact with submerged receptive stigmas.

A Hypothesis of Outcrossing in Hydrophiles

Most angiosperms are hermaphroditic (Bawa & Beach, 1981), with dioecy (depending on the region) occurring in only 2–28% of species (Bawa, 1980) and monoecy equally rare (Grant, 1975).

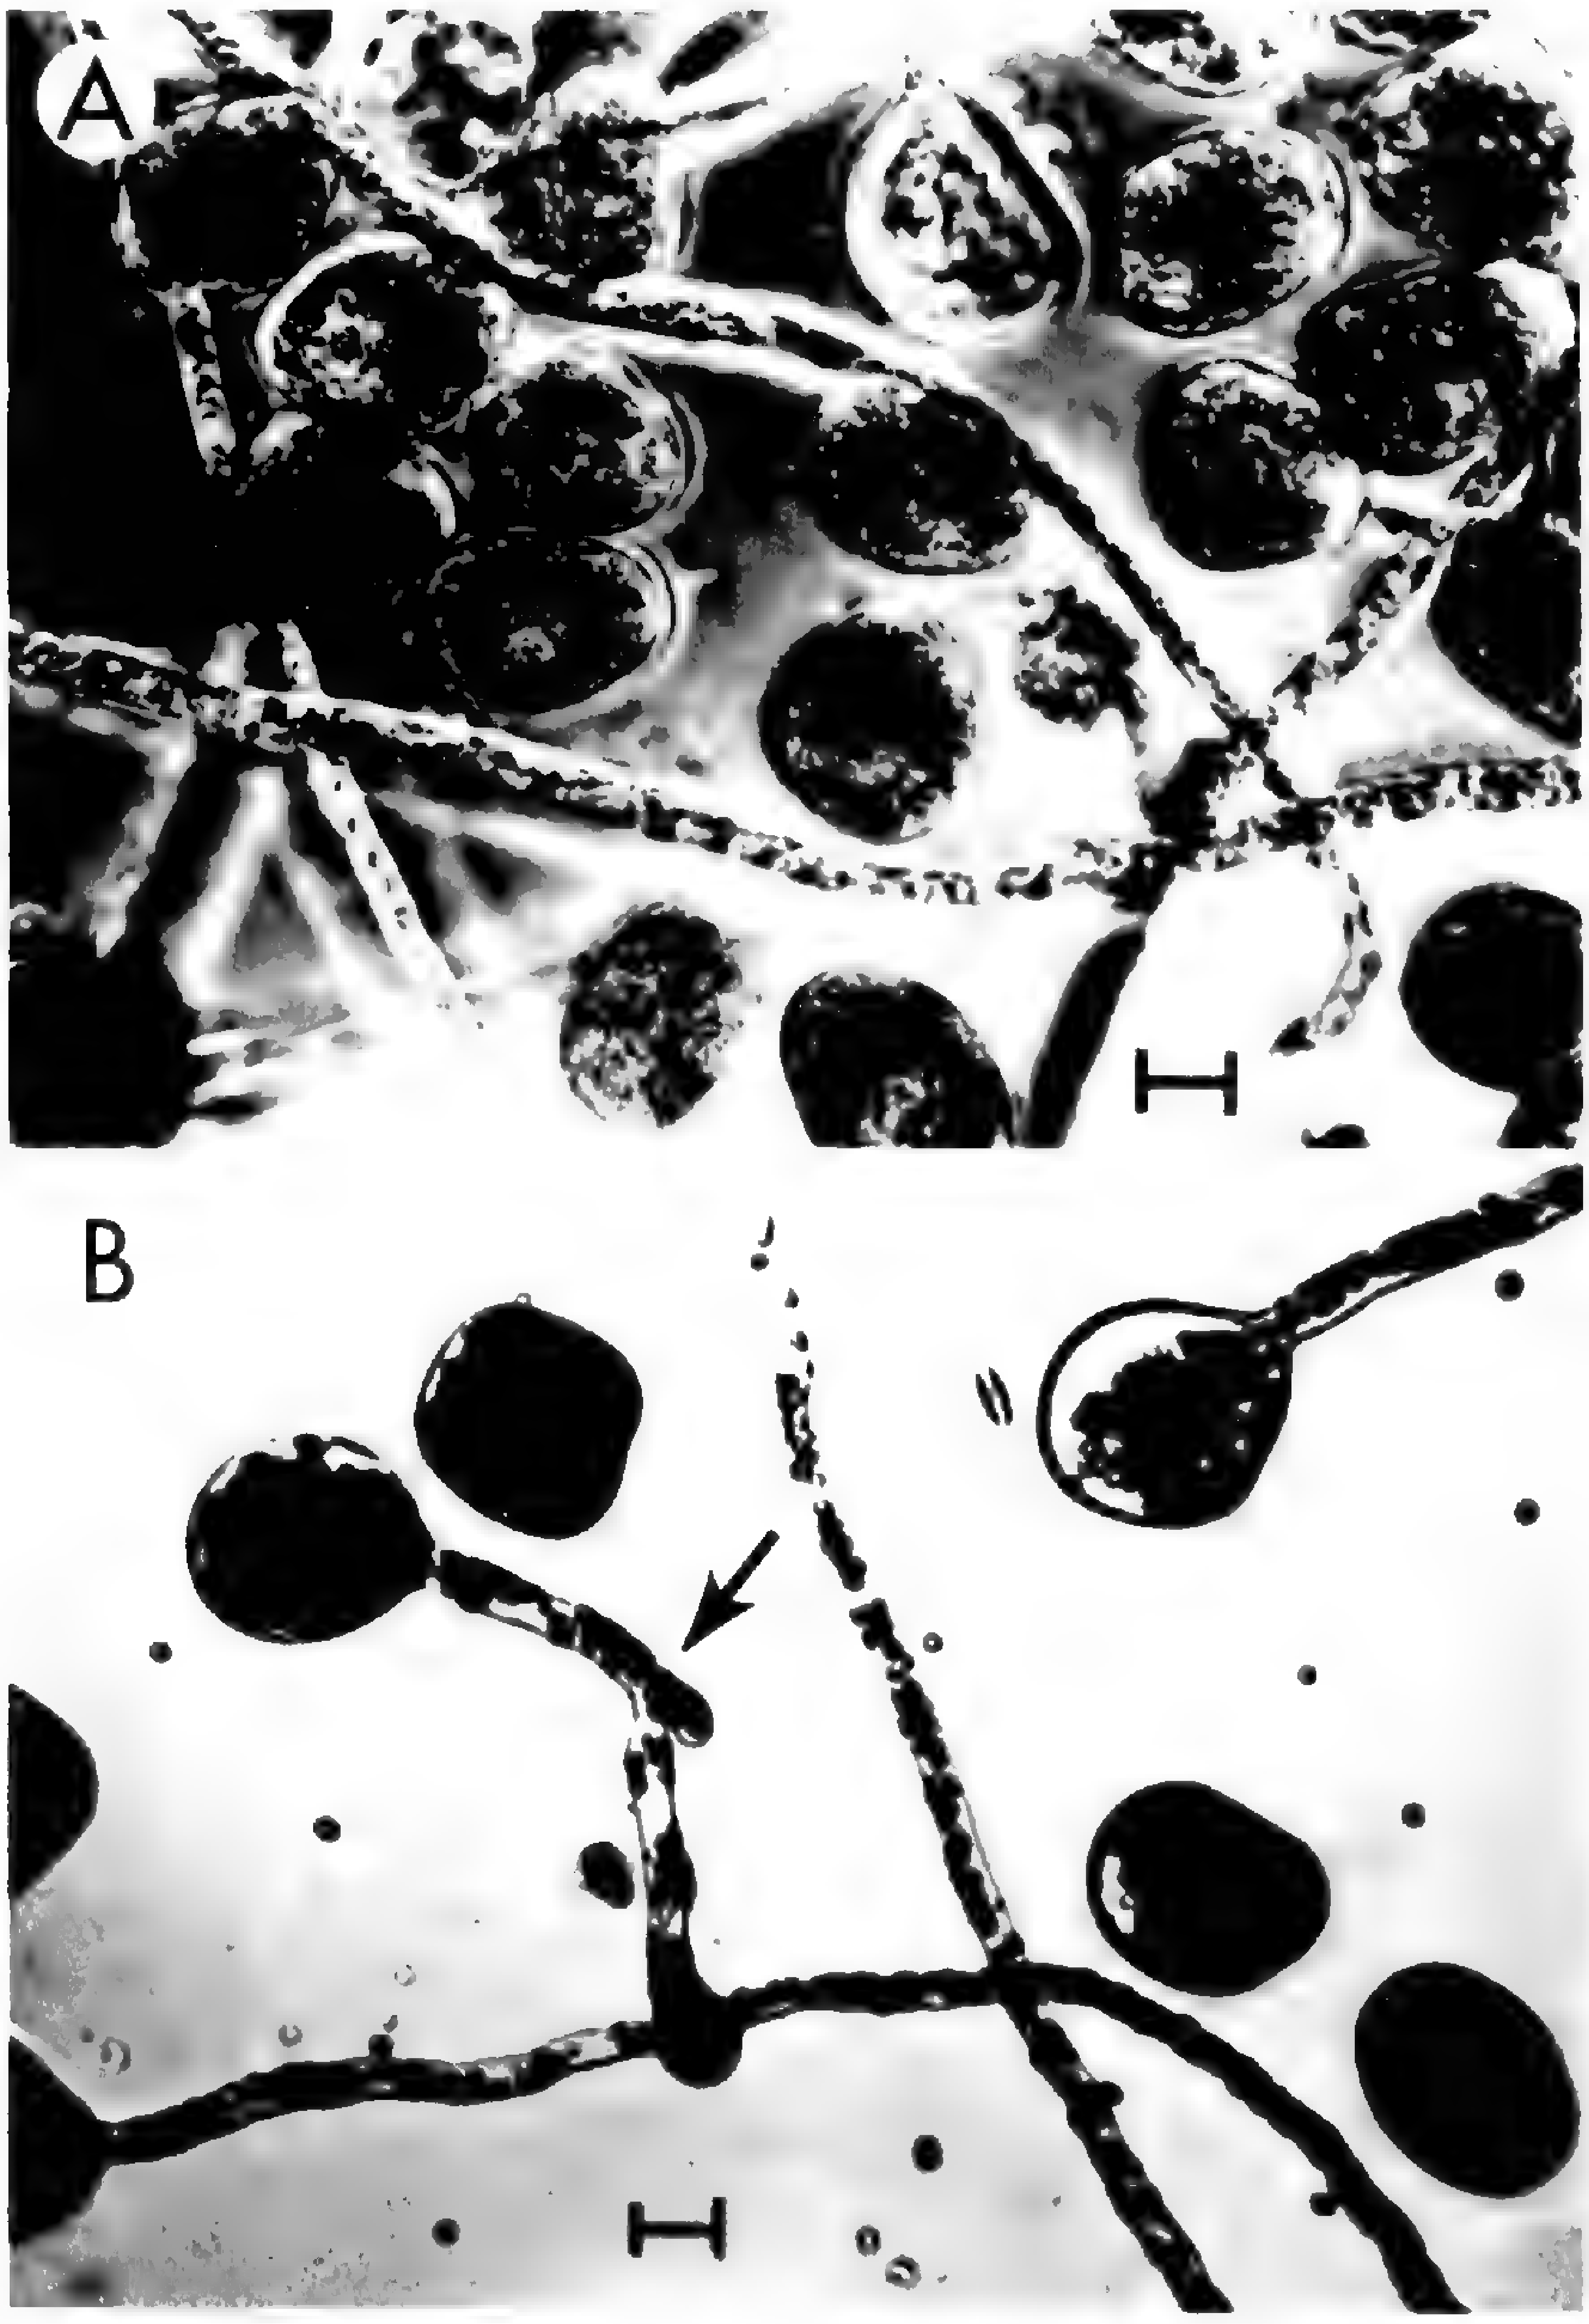

FIGURE 1. *Pollen tube modifications in* Ceratophyllum demersum.—*A. Precocious germination of grains showing elongated pollen tubes.—B. Branching of pollen tubes (at arrow). Scale bars = 5 μm.*

In contrast, 13 of the 18 genera (72%) of hydrophilous angiosperms have dioecious species; 8 genera (44%) have monoecious representatives; and only about 8.7% of hydrophile species are hermaphroditic (Table 1). The association between dioecy and hydrophily was noted by Sculthorpe (1967), who did not provide an evolutionary explanation for the co-occurrence of these traits.

Others, however, have viewed the predominance of dicliny in hydrophiles as evidence of an inevitable association with outcrossing and production of genetically variant progeny (Hartog, 1970; Pettitt et al., 1981). Although dioecy is associated with reduced prolificity because of the presence of males (Lloyd, 1980), it has been postulated (in seagrasses) that ". . . gains in survival attributable to continuous out-breeding outweigh the disadvantages of diminished seed production" (Pettitt et al., 1981: 137). These conclusions can be interpreted as a hypothesis that embraces three components: 1) hydrophiles are characterized by outcrossing, which leads to the production of genetically variable offspring; 2) the selective advantage of outcrossing in hydrophiles offsets the evolutionary costs associated with transitions to dicliny; and 3) dicliny has evolved in hydrophiles as a mechanism for promoting outcrossing. The appealing rationality of such a hypothesis belies the fact that it rests entirely on circumstantial evidence associated with sexual conditions and is not substantiated by more empirical evidence. Furthermore, it is difficult to rationalize the slow evolutionary diversification of this group with a supposed history of outcrossing and prolific genetic variability. It is possible that few species have made the transition to hydrophily in recent time, and therefore the hydrophile genera have simply not had sufficient time to diversify. This interpretation, however, is incongruent with fossil evidence that indicates a great age of many hydrophile genera. Obviously, it is necessary to consider other sources of data that may be more pertinent in assessing the extent of outcrossing in hydrophiles.

TESTING THE "OUTCROSSING HYPOTHESIS"

In hydrophiles, the possibility of outcrossing (natural crossing as defined by Grant, 1975) exists only when several conditions are satisfied. One requirement is for sexual reproduction. A second requirement is for xenogamy, which assures that sperm of one individual reach the eggs of different individuals. Thirdly, the parents contributing gametes must differ genetically and their offspring must survive. By evaluating the ability of hydrophiles to satisfy these conditions, it may be possible to assess better the role of outcrossing in these species. To interpret fully the significance of outcrossing in hydrophiles, it is also necessary to understand the relative level of inbreeding that may occur in outcrossing species.

THE EXTENT OF SEXUAL REPRODUCTION IN HYDROPHILES

There has been much discussion regarding the costs and benefits of sexuality in organisms. Using a group selection model, Lloyd (1980) argued that dioecious populations experience a cost of sex, whereas hermaphroditic populations do not. Furthermore, he pointed out that asexual reproduction results in greater prolificity than dioecy, raises the potential rate of increase, and may aid in the long-term persistence of asexual populations and species. He concluded, however, that asexuality does not appear to have been significant in group selection against dioecy because of the relatively lower evolutionary success of asexual lines. Nevertheless, hydrophyte reproduction occurs both sexually and asexually, most species have well-developed means of vegetative reproduction, and most reproduction in perennial hydrophytes is estimated to be asexual (Hutchinson, 1975).

Approximately half of hydrophile genera are characterized by rare sexual reproduction (Table 1). A quote from Hartog (1970: 34) illustrates this point: ". . . inflorescences, flowers, fruits and seeds . . . are not often found in most seagrasses, and in some species they are not known at all or only incompletely." The rarity of fruiting in the freshwater genera *Elodea* and *Ceratophyllum* is also widely recognized (Cook & Urmi-König, 1985; Les, 1986a).

One facet of sterility in dioecious hydrophiles is the low percentage of flowering in several species. The seagrasses *Halophila stipulacea, Halodule beaudettei, H. bermudensis, H. ciliata, Cymodocea rotundata, C. serrulata, C. angustata,* and some *Posidonia* species are rare-flowering according to Hartog (1970). McMillan (1976, 1979, 1980) noted that environmental conditions have wide effects on the reproductive biology of many seagrasses. Even when flowering, dioecious hydrophiles may exhibit another facet of sterility. In *Thalassia testudinum,* fewer than 1% of plants may flower simultaneously in "beds," and beds are often unisexual (Hartog, 1970; Durako & Moffler, 1987). Such conditions may result in frequent sterility of the species, such as that reported by Edwards (1976). Similarly, plants of *Thalassodendron ciliatum* and *Elodea* species typically exist in unisexual colonies with plants of both sexes rarely coexisting (Hartog, 1970; Cook & Urmi-König, 1985). Such circumstances surely contribute to low fruit production in these species. Cook & Urmi-König (1985) attributed the unisexuality of *Elodea* populations to differential competition for habitat by the sexes. Alternate explanations, however, include the possibility that unisexual populations are derived clonally, or that sex expression is affected by environmental rather than by strictly genetic factors.

A further restraint of sexuality is the rarity of seedling production in some plants with high seed output, e.g., *Zostera noltii* (Hartog, 1970).

Agamospermy is possibly mistaken at times for sexual reproduction in some hydrophiles. In *Halophila stipulacea,* cultured plants induced to flower produced no males, yet the females produced seed (McMillan, 1980), a good reason to suspect agamospermy. In *H. hawaiiana,* male and female plants are not known to coexist (Herbert, 1986). Although agamospermous reproduction is genetically equivalent to vegetative propagation, one obvious difference is production of fruits allowing for "normal" dispersal. It would be an important contribution to test experimentally for agamospermy among other hydrophilous species.

Although gene recombination via sexual reproduction is viewed as important for response to changing or heterogeneous environmental conditions, genetic uniformity enforced by vegetative reproduction may be more advantageous for a species already adapted to uniform habitat conditions (Grant, 1981; Lloyd, 1980). Therefore, the relative uniformity of freshwater and marine environments (Hartog, 1970; Tiffney, 1981) provides one explanation for the ubiquity of efficient vegetative reproduction in hydrophytes.

Demands on parental energy for reproductive effort have been implicated in compromises between sexual and asexual avenues in some plants. In many instances, the relationship is inverse, i.e., high fruit production with low vegetative propagation and vice versa (Salisbury, 1942; Harper, 1977). In hydrophiles, free-fruiting species often exhibit less vegetative development than rare-fruiting species. Of the freshwater hydrophiles, poor vegetative development occurs in the genera *Althenia, Lepilaena, Ruppia, Najas,* and *Zannichellia,* which are all typically free-fruiting (Table 1). Of these genera, *Najas, Zannichellia,* and *Lepilaena* are mainly annual. In *Ruppia,* little biomass is allocated to reproductive structures in perennial species, whereas allocation to reproductive structures in annuals is always much higher (Brock, 1982). The freshwater genus *Elodea* has coarse vegetative growth and low seed output. All species of *Ceratophyllum* are perennial, yet much higher seed output occurs in species with fine foliage than in the coarse-leaved species *C. demersum* (Les, 1986a). Sometimes in *Zannichellia* relatively robust plants have been associated with lower flower and fruit production and behave like perennials, whereas slender plants have higher flower and fruit production (Uotila et al., 1983). Similar associations are not as evident in marine hydrophiles, possibly because a well-developed vegetative system for anchoring plants against forces of tidal currents and wave action is essential for marine existence (Hartog, 1970). In the marine genus *Zostera,* however, a relationship exists between fruiting and shoot development. Arber (1920: 127) observed: "In *Zostera marina* . . . the fertile and sterile plants are readily distinguishable from one another, since in the fertile plant the stem is slender, erect, and much branched, while that of the sterile individual is thick, creeping, more luxuriantly leafy, and anchored to the soil by adventitious roots . . . ." Furthermore, annual individuals of *Zostera marina* can be distinguished readily from perennial individuals by the former's lack of vegetative shoots and rhizomes (Keddy & Patriquin, 1978). Although most species within the principally annual genus *Najas* have relatively fine foliage, the perennial species *N. marina* is characterized by very coarse leaves and has the ability to form vegetative turions (Agami et al., 1986).

Differential resource allocation to reproduction has been studied in terrestrial plants in some detail (Silvertown, 1982) and provides a convenient explanation for the association of high vegetative development with low sexual reproduction in some hydrophytes. It is possible that the development of effective perennating mechanisms in hydrophytes was accompanied by a sacrifice of sexual reproduction. It could be argued that vegetative growth and reduced reproductive effort in perennials vs. high sexuality and reproductive effort in annuals are merely adaptive life history traits. On the other hand, the shoot dimorphism described above between both fertile/sterile and annual/perennial individuals of *Zostera marina* indicates that tradeoffs in reproductive allocation do occur. In *Zostera marina,* the different reproductive strategies (annual, perennial, sexual, asexual) are employed depending upon environmental circumstances (Phillips et al., 1983). Although other factors may be involved, it is possible that the relationship between low sexual reproduction and high vegetative development noted in hydrophiles and other hydrophytes is due in part to constraints related to resource allocation.

From the above discussion, it is evident that sexual reproduction in water-pollinated plants is not commonplace. This conclusion is important because, despite any other factor, outcrossing cannot occur in hydrophile populations that reproduce only asexually.

THE EXTENT OF XENOGAMY IN HYDROPHILES

Hermaphroditic, monoecious, and dioecious sexual conditions in hydrophiles allow for three possible means of gametic exchange: autogamy, geitonogamy, and xenogamy. Although outcrossing can occur only when gametic exchange is xenogamous, xenogamy is possible with all three sexual conditions.

Autogamy in many hermaphroditic terrestrial plants is prevented or restricted by mechanisms such as dichogamy, herkogamy, heteromorphy, and self-incompatibility (Faegri & van der Pijl, 1979; Lewis, 1979). Heteromorphy is associated with biotic pollinators (Lewis, 1979) and is unknown in hydrophiles. Incompatibility mechanisms have not been reported in hydrophiles, presumably because of constraints imposed by the water-liability of recognition substances and by reduction of the exine in hydrophilous pollen (Pettitt & Jermy, 1975). Herkogamy, the spatial separation of sexes, is not characteristic of hermaphroditic hydrophiles. This leaves only the possibility of dichogamy, the temporal separation of sexes, as a means of preventing autogamy in hermaphroditic hydrophiles.

Autogamy is possible only in three genera (*Posidonia, Ruppia, Zannichellia*) which have members with hermaphroditic flowers. Sexual reproduction in these genera is common (Table 1). Aston

(1973) described fruit production as "prolific" for *Posidonia*, and the numerous fruits of *Ruppia* and *Zannichellia* taken from waterfowl stomachs (up to 4,000 and 10,000 per stomach, respectively) indicate high fruit production in these genera (McAtee, 1939). A single plant of *Zannichellia* is capable of producing more than two million seeds in six months (Yeo, 1966). Discounting apomixis, the prolific fruit production in these genera reflects their successful adaptation to hydrophily. Much of this prolificity, however, probably results from autogamy.

In hermaphroditic *Zannichellia* (Aston, 1973), autogamy is possible due to the enclosure of stamen and carpels within the cuplike perianth, although the flowers may be dichogamous. Most species of *Zannichellia*, however, are monoecious and even some dioecy has been reported (Muhlberg, 1982). In monoecious *Zannichellia*, the arrangement of flowers results in functional bisexuality. Male and female flowers are typically adjacent and appear ". . . to rise as a group in a leaf axil" (Sculthorpe, 1967: 298). Although the anther of the male flower is raised above the carpels, pollen grains have a higher specific gravity than water and ". . . sink on to the peltate or tongue-shaped stigmas . . ." (Sculthorpe, 1967: 299). Arber (1920: 71) reported a similar scenario for *Zannichellia*. She noted that, "The anther dehisces and the pollen grains fall into the open mouths of the cornucopia-shaped stigma . . . ." These accounts suggest that dichogamy does not occur in *Zannichellia* and that selfing would be commonplace. Hutchinson (1975: 232), however, presumed that local turbulence would displace the descending pollen of *Zannichellia*, ". . . so that occasional cross-pollination can occur even when . . . the male and female flowers [are] very close together." The description of pollination in *Zannichellia* by Haynes & Holm-Nielsen (1987: 264) renders Hutchinson's presumption untenable: ". . . the anther of the staminate flower arches over the funnel-shaped stigmas of the carpellate flower. Pollen transfer is entirely underwater: it is released from the anther in a gelatinous mass and falls directly into the stigma." Although monoecious *Zannichellia* cannot be categorized as autogamous, these descriptions of pollination in the genus indicate predominant geitonogamy (virtually the genetic equivalent of autogamy). Even the effects of turbulence that Hutchinson proposed would probably result in geitonogamy rather than xenogamy, as the gelatinous pollen masses would be more likely to settle than to be transported laterally. Furthermore, the floral morphology of *Zannichellia* does not appear to be adapted for xenogamy. Pollen/ovule ratios are not known specifically in *Zannichellia*; however, they are probably relatively low, with only a single stamen for every cluster of four one-ovuled female flowers. The sculptured exine of *Zannichellia* pollen is atypical of hydrophilous angiosperms (Pettitt & Jermy, 1975). The pollen shape is globular and the grains do not form chains (Table 1), an indication that it is not as well-adapted for transport over distances as that of other hydrophiles. For *Zannichellia*, the high percentage of fruiting is likely a result of autogamy in hermaphroditic plants or of geitonogamy in monoecious plants, rather than of xenogamy.

Exceptions may occur with *Zannichellia contorta* and *Z. peltata*, in which the anther filaments are much longer than those of other species, and their pistillate and staminate flowers arise at different nodes (Talavera et al., 1986; Van Vierssen & Van Wijk, 1982). With the greater spatial separation of anthers and pistillate flowers in these species, the opportunity for xenogamy is enhanced. Haynes & Holm-Nielsen (1987) concluded that generally the pollination system in *Zannichellia* limits outcrossing but is valuable for the annual habit because pollination is essentially assured.

The pollination system of *Ruppia* has been described in some detail. In *Ruppia cirrhosa*, the hermaphroditic-flowered inflorescence reaches the surface of the water but remains submersed; the anthers dehisce, are carried to the surface by air bubbles, and release pollen explosively when contacting the atmosphere. Cohering pollen grains cover the surface in chainlike strings and eventually reach the carpels, which are raised to the surface by bending of the inflorescence. In *R. maritima*, the discoid, peltate stigmas form a canopy above the anthers and trap the ascending pollen chains; the grains drift around the stigma to its surface, where some adhere and germinate. (For details see Arber, 1920; Gamerro, 1968; McCann, 1945; Sculthorpe, 1967.)

In *Ruppia* it is difficult to ascertain the extent of autogamy. Frequent fruit production can be explained either by autogamy (such as described for *R. maritima* above) or by xenogamy. The observance of spreading surface pollen masses of *Ruppia* (Faegri & van der Pijl, 1979) demonstrates the potential for xenogamy. The two-dimensional nature of the ephydrophilous mechanism "concentrates" the pollen, thereby increasing the chances for pollen capture. In aquarium studies, however, pollen of *R. megacarpa* remained mostly near the stigmas of the flower from which it was released (Van Vierssen et al., 1982), an indication that selfing may occur frequently in the species. In any case, sexual reproduction in *Ruppia* plays a large role in its propagation (Edwards, 1976).

Information on the reproductive biology of the marine *Posidonia* is too general to infer much of its breeding system. The flowers consist of three or four sessile anthers surrounding the simple carpel, which terminates in a feathery, lacerate stigma (Sculthorpe, 1967). When the anthers dehisce, clouds of filamentous pollen are released into the water (Pettitt et al., 1981). Because the carpel is surrounded by anthers, the potential for autogamy might be quite high. Without direct observations and knowledge of possible dichogamy, however, this conclusion can only be implied.

In monoecious plants, autogamy is prevented but geitonogamy is not. Hartog (1970), however, attributed cross-fertilization to all monoecious seagrasses (*Zostera, Heterozostera, Halophila decipiens*) due to their protogyny.

In the monoecious *Zostera marina*, the potential for xenogamy is indeed increased by protogyny (Arber, 1920). Pollen is shed in cloudy masses, with pollen tubes already beginning to protrude (Arber, 1920). Pollen is released either slowly under water or quickly in floating masses, which readily adhere to any object coming in contact with the grains (De Cock, 1980). Despite widespread protogyny in *Zostera* (Sculthorpe, 1967), the proximity of male and female flowers within a spathe (Aston, 1973) suggests the possibility of occasional geitonogamy among flowers within the spathe. In fact, De Cock (1980) observed that self-pollination in *Zostera* will occur in the absence of cross-pollination and takes place widely in plants cultured in aquariums. The extent of geitonogamy in natural populations of *Zostera* is not clearly known.

A similar situation exists in the related genus *Heterozostera*. Although male and female flowers occur within the same spathe, the flowers are protogynous, with the stigmas falling off prior to the opening of anthers within the same spadix (Aston, 1973; Hartog, 1970). *Halophila decipiens*, the sole monoecious species of the principally dioecious genus, is likewise protogynous, with male and female flowers occurring within the same spathe (Hartog, 1970).

In the monoecious *Ceratophyllum demersum*, xenogamy is probably infrequent. The rarity of flowering and the aggressive vegetative growth of this species greatly limit sexual reproduction (Les, 1985). When sexual reproduction occurs, the self-compatibility of the species allows for geitonogamy (Les, 1980, 1985). Although xenogamy is possible, transport of pollen tends to be within large clones (Les, 1986b).

Flowers of the monoecious *Lepilaena australis* are similar to those of *Zannichellia* but appear to be more conducive to xenogamy. Female flowers are borne on the upper parts of the plant and occur at the ends of peduncles up to 14 cm long. The male flowers are very short-stalked and occur on the lower portions of the plant (Aston, 1973). In this arrangement, geitonogamy would require the upward transport of pollen, and lateral movement of pollen would be more likely to facilitate xenogamy. In monoecious *Lepilaena preissii*, however, the male and female flowers are clustered together (Aston, 1973) and here geitonogamy is more likely. Pollination in the monoecious *Lepilaena cylindrocarpa* is ephydrophilous. Stigmas create depressions in the water surface into which floating pollen grains released from submersed anthers were drawn (Van Vierssen et al., 1982). This arrangement would facilitate geitonogamy (as pollen from the same plant would be in closest proximity to the stigmas), although xenogamy may occur as well.

The freshwater genus *Najas* is predominantly monoecious (with only one dioecious species) and annual (Haynes, 1977). The pollination biology of *Najas* is not known in detail, but several aspects have been described. Sculthorpe (1967) observed that pollen tube germination is precocious, often as the microspores are released from the floral envelope. He reasoned that the dense growth of plants would place male and female flowers together, and that liberated pollen would be (p. 301) ". . . caught haphazardly on the elongated stigmas." Aston (1973) observed that pollen is discharged apically through an opening in the floral envelope and is transported through the water to the stigmas. There is no indication that *Najas* possesses any mechanisms to prevent geitonogamy.

Dioecy is the only sexual condition that ensures xenogamy, and all dioecious hydrophiles must be regarded as possessing a high outcrossing potential. Dioecy does not guarantee outcrossing, however, which will occur only when all conditions have been satisfied.

THE EXTENT OF GENETIC VARIATION IN HYDROPHILE POPULATIONS

The genetic structure of a hydrophile population ultimately determines the extent of outcrossing. In sexual and xenogamous populations, outcrossing will occur whenever sexual reproduction is consummated between genetically different individuals. How different genetically are individuals in

hydrophile populations? Few published studies have addressed this essential question.

Dioecy and outcrossing are typically equated despite unresolved questions whether heterosexual individuals of dioecious plant species always differ genetically. Although sex in the majority of dimorphic plant species is believed to be determined solely by genetic factors (Lloyd & Bawa, 1984), diphasic responses have been reported in many dioecious plants, including species reported to have sex chromosomes (Freeman et al., 1980). If diphasic sex changes can occur in hydrophiles that reproduce extensively by vegetative growth, then there would be at least the potential for clonally derived individuals to express different sexes. Unfortunately, there is little available evidence to provide a satisfactory resolution to the question of whether such changes occur in dioecious hydrophiles or not.

In addition to direct observation of population sexuality over several seasons, Lloyd & Bawa (1984) regarded consistent sex production in widely spaced ramets or branches and sex ratios of unity as circumstantial evidence of phase stability in dioecious plants. Few studies of dioecious hydrophiles have provided direct observation of phase stability or change. Grey & Moffler (1978) reported an overall female-biased sex ratio of 3:1 for *Thalassia testudinum*, although they observed a range of ratios from 21:0 to 1:1. Durako & Moffler (1985a) determined that three out of four populations of *T. testudinum* were characterized by male-biased ratios (Table 2). Further studies of *Thalassia* demonstrated that male-biased ratios occurred only in one of three years of observation and correlated with highest seed output (Durako & Moffler, 1985b). There was no apparent relation of the ratios to flowering frequency; male bias occurred at flowering frequencies from 3–38% (Table 2). In *Thalassia testudinum*, the variation of sex ratios among populations and their deviation from unity may indicate that sex expression in this species is affected by environmental conditions. Durako & Moffler (1985a, b), however, attributed the yearly differences in the sex ratios not to sex change but to annual variation in the density of males; the female densities remained fairly constant temporally.

Biased sex ratios also occur in other dioecious hydrophile species. Estimates of flowering frequency and sex ratios computed from data published by Cook & Urmi-König (1985) and Catling & Wojtas (1986) for three dioecious and ephydrophilous species of *Elodea* indicate female-biased ratios of 1.2–1.8:1 (Table 3). In *Elodea*, the highest female bias was found in *E. bifoliata*, the most frequently flowering species (Table 3). Greater female-biased sex ratios occur in dioecious marine hydrophiles, epitomized by *Phyllospadix*, with an approximately 12:1 ratio of female to male plants (Dawson, 1966). Using specimen lists cited in Hartog (1970), flowering frequencies and sex ratios were computed for seven dioecious species of hydrophilous seagrasses (Table 4). There are some indications of stability in the sex ratios of these species. The 11:1 ratio calculated for *Phyllospadix* approximates the 12:1 ratio reported independently by Dawson (1966); both the frequency of flowering and the sex ratio are nearly equal for two species of *Syringodium*. Although sex ratios of three species of *Elodea* are similar, Cook & Urmi-König (1985) have discussed various aspects of sex instability in the genus. Sex ratios of unity were noted only in *Thalassia testudinum*, *Halodule uninervis*, and *Thalassodendron ciliatum*; most other ratios were female-biased (Tables 3, 4). An interesting trend in the data is a possible relationship between sex ratios and flowering frequency. A decrease in the frequency of flowering is associated with a lower female bias in the sex ratios; lower floral frequencies appear to be asso-

Total	346	184	—	1.9:1

ciated with equal or male-biased ratios (Table 4). This trend is also apparent in *Elodea*, but to a much lesser degree (Table 3). Sex ratios of the dioecious *Thalassodendron ciliatum* indicate a male bias at low flowering frequencies of 15–19% (Kay, 1971). *Syringodium* flowers commonly, and produces mostly female flowers (Kay, 1971). An exception to this trend occurs in the infrequently flowering genus *Cymodocea*, which has been observed to produce only female flowers (Kay, 1971). The absence of male flowers, however, was possibly due to the sampling of a single clonal population (Kay, 1971). In other populations of *Cymodocea*, however, sexes co-occur but are partitioned spatially into unisexual zones (Caye & Meinesz, 1985). It is possible that the relationship of reduced female-bias and low flowering frequency may result in part from sampling error.

Sex-ratio data must be interpreted cautiously. The different methods of assessment (e.g., plant ratios, short-shoot ratios, single population ratios, multiple population ratios) and wide variability in sample size are only two shortcomings. Furthermore, there have been no real efforts to distinguish between genets and ramets in populations where studies have been conducted. Because of the effective system of vegetative reproduction in hydrophiles, sex-ratio data may be misleading. Apomixis and other factors that can influence sex ratios have been summarized elsewhere (e.g., Opler & Bawa, 1978). Ultimately, a precise knowledge of sex expression in dioecious hydrophiles will be required before any reliable conclusions can be drawn from sex-ratio data.

Less is understood of sex ratios in monoecious hydrophiles. In *Ceratophyllum demersum*, plants fruit rarely, but fertile specimens are typically male-biased (Les, unpubl.). Sex ratios computed for a fertile population of *C. demersum* from Wisconsin, U.S.A., provide some insights into its sex ratios. The ratios were calculated by counting all flowers on 30 dissected plants. The range of sex-ratio variation in this population is extensive. Most plants are male-biased (up to 10:1); however, nearly a third of the sample is female-biased (Table 5). Although the species is monoecious, unisexual plants were observed for both sexes. The overall sex ratio was male-biased at 1.9:1. Fruiting was low (2%), and fruits were found only on plants with female-biased ratios. In species of *Ceratophyllum* where fruiting is more common, sex ratios appear to be less male-biased (Les, unpubl.). Reasons for the wide amplitude of sex distribution on *Ceratophyllum* plants are not clear, but it is apparent that sex ratios are not rigidly fixed genetically. The potential for environmental influence of sex expression in *Ceratophyllum* was demonstrated by the sole production of male flowers on plants of *C. demersum* and *C. echinatum* grown under continuous illumination (Les, 1980). Plants from the same population observed in the field were normally monoecious.

In *Zostera marina*, a consistent sex ratio of one pistil to one anther was observed from a population in France, despite wide variability in the flower number per spathe (Jacobs & Pierson, 1981). In monoecious *Zannichellia*, the close association of male and female flowers indicates a probable 1 : 1 ratio. Such consistent values may indicate tighter genetic regulation of sex expression in these species. Sex ratios of other monoecious hydrophiles have not been studied in any detail.

Although hydrophily is often equated with outcrossing, a critical point is made by Faegri & van der Pijl (1979: 41): ". . . hydrophilous mechanisms give no guarantee against autogamy. However, the gregarious habit of the plants in question will generally cause allogamy and counteract auto- and geitonogamy unless *the whole meadow represents a single clone*" [emphasis mine]. The extent of clonal growth in hydrophiles is surely an important determinant of their population structure.

Hutchinson (1975) recognized that most reproduction in hydrophytes is asexual, and as a result (p. 238) ". . . large clonal populations are likely to be very common in lacustrine angiosperms." He also observed that for perennial species (p. 233), ". . . any given specimen is much more likely to have arisen by asexual than by sexual processes."

An important difference between asexual reproduction in terrestrial plants and aquatic plants is that vegetative buds, fragments, turions, etc. in the latter can facilitate dispersal without the planting requirement necessary for fragments of most terrestrial species (Hutchinson, 1975). This feature is evidently one of the most important mechanisms for dispersal in aquatic plants, particularly those that produce small quantities of seeds. The efficiency of vegetative dispersal in hydrophilous species is exemplified by the spread of *Elodea canadensis* across Europe, which occurred within 50 years following its introduction from an uncertain North American source. This feat was accomplished entirely by vegetative means, as the species is dioecious and (with one exception) only female plants were introduced (Cook & Urmi-König, 1985; Grant, 1981). Cook & Urmi-König (1985: 118) remarked that the ". . . aggressive vegetative growth [of *Elodea*] leads to . . . the consequence that one habitat becomes fully occupied by one genotype."

Similar conclusions have been drawn for other hydrophiles. In *Cymodocea serrulata*, the "only" means of medium- or long-range dispersal is by vegetative fragments, and clonal growth patterns are typical due to the vigorous vegetative growth (Kay, 1971). In *C. nodosa*, seeds are not disseminated, and sexually derived offspring must be spatially and temporally restricted (Caye & Meinesz, 1985). Likewise, vegetative reproduction is more prevalent than sexual reproduction in the maintenance and spread of *Thalassia* (Kay, 1971; Grey & Moffler, 1978). In *Halophila*, *Thalassia*, *Cymdocea*, and *Halodule*, sexual reproduction is rare and reproduction is mostly vegetative (Edwards, 1976; Jacobs & Dicks, 1985). For *Halophila hawaiiana*, Herbert (1986: 101) stated that ". . . it is possible that the monospecific meadows of *Halophila* in the Hawaiian islands are made up of plant material from a single genetic individual." According to Obermeyer (1966), propagation of *Halophila ovalis* is mainly vegetative and may lead to the formation of "homogeneous colonies." *Zostera marina* reportedly flowers infrequently and maintains stable population sizes by vegetative reproduction (Harrison, 1979). Both *Zostera* and *Heterozostera* reproduce asexually by unusual vegetative propagules (Cambridge et al., 1983). *Ceratophyllum demersum* is rare-flowering and highly clonal (Les, 1986b). Haynes & Holm-Nielsen (1987) stated that all Zannichelliaceae "grow clonally."

Widespread vegetative growth in hydrophilous species may lead to the formation of large, genetically uniform populations in which outcrossing would be thwarted even among sexual, xenogamous individuals. Hutchinson (1975), however, noted that the few aquatic annuals such as *Najas* are exceptions to the generalization that most hydrophytes reproduce asexually. Development of an annual habit in hydrophiles, where consistently high levels of seed production are essential for survival, may have provided an escape from constraints on outcrossing imposed by dense clonal growth. Although vicinism may also occur in diclinous annuals such as *Najas*, there is at least a much higher potential for dispersal of sexually derived propagules to other sites, which betters the chances that future generations will breed with genetically different individuals.

The foregoing discussion cites only circumstan-

TABLE 6. *Summary of enzyme variability in species from 13 hydrophilous angiosperm genera. * = enzyme displaying intra- or interpopulational variability at one or more loci; all other enzymes monomorphic (compiled from A: McMillan et al., 1981; B: Les, 1986b; C: McMillan, 1981; D: McMillan & Williams, 1980; E: McMillan, 1982; F: Triest et al., 1986; G: McMillan & Phillips, 1981; H: Gagnon et al., 1980).*

tial evidence for assessing the degree of genetic variation in hydrophile populations; however, there is some empirical evidence that can be brought to bear on this issue. The use of enzyme gel electrophoresis has allowed for the direct estimation of genetic variation in plant populations (Gottlieb, 1981; Brown, 1979; Hamrick et al., 1979). Fortuitously, most electrophoretic studies on aquatic plants have been carried out with seagrasses (Wain et al., 1985), all of which are hydrophilous.

Approximately 30 species representing 12 genera of seagrasses have been studied electrophoretically (Wain et al., 1985). These analyses consistently report genetic uniformity and provide little evidence of electrophoretically detectable genetic variation in hydrophile populations (Table 6). According to Wain et al. (1985: 43), "In most species [of seagrasses] there exists no intraspecific variation in banding patterns, even across large geographic distances." Furthermore, the level of heterozygosity in seagrasses is apparently extremely low (Wain et al., 1985; McMillan, 1982). Of the 32 hydrophile species studied, enzyme variability has been reported only in *Zostera marina*, *Halodule uninervis*, *Phyllospadix scouleri*, and *Najas marina* (Table 6). As Crawford (1983) discussed, enzyme uniformity of this sort is more characteristic of self-pollinating plants than of outcrossers.

Preliminary studies of *Ceratophyllum* have given similar results. Populations of the rare-flowering *C. demersum* are relatively uniform both morphologically and genetically, and are probably clonal (Les, 1988b). Populations of the more sexual species *C. echinatum* are more variable morphologically and display patterns of intrapopulational variability that are quite representative of the species as a whole (Les, 1988a). An electrophoretic study of populations of both species is under way in hopes of providing further insight into the genetic structure of populations of the predominantly sexual vs. asexual species of *Ceratophyllum*.

Enzyme polymorphisms have been reported in electrophoretic studies of the annual species *Najas marina* (Triest et al., 1986), a possible indication of greater genetic diversity in this genus. Further electrophoretic surveys are necessary to determine the extent of intrapopulational genetic variation in other *Najas* species and annual hydrophiles in general. An informative study would be to compare populations of *Najas* and *Zannichellia* electrophoretically. Although both genera are annual, *Zannichellia* has few species compared with *Najas*, a possible outcome of the predominantly geitonogamous/autogamous breeding system of *Zannichellia*.

Despite the large number of electrophoretic studies carried out on hydrophiles, an adequate understanding of population structure in this group is far from being reached. A major difficulty has been that most studies have reported genetic data qualitatively rather than quantitatively (Table 6). Because data have not been presented in allelic form, it is not possible to compute appropriate quantitative measurements of population structure such as fixation indices, average heterozygosity, proportion of loci polymorphic, number of alleles/locus, and gene diversities (Nei, 1987). Furthermore, no study has measured outcrossing rates quantitatively in any hydrophilous species. Because models for estimating outcrossing rates should be evaluated in terms of the pollination system of a species (Shea, 1987), it may first be necessary to develop a specific model for hydrophilous plants. Electrophoretic approaches provide a powerful means of estimating population structure and outcrossing rates. The scarce amount of genetic variation detected in hydrophiles thus far is an impetus for continuing investigations in this area.

A satisfactory resolution to the question of population structure in hydrophiles will not come until rigorous genetic analyses have been carried out. On the other hand, it is important to emphasize that the widely held assumption of extensive genetic variability in hydrophile populations is not supported by available data. The high degree of clonal growth attributed to hydrophiles may result in genetically uniform populations. Even in instances where sex expression of dioecious hydrophiles may be under strict genetic control, clonal growth allows for the possibility of the establishment of extensive unisexual populations. Because of these factors, clonal growth may thwart outcrossing in many hydrophiles. In support of this conclusion are preliminary electrophoretic data which indicate little detectable genetic variation in hydrophile populations.

Assumptions that hydrophiles are outcrossing and produce genetically variable offspring should not be taken for granted. The inefficiency of hydrophily, reduced sexuality, of autogamy and geitonogamy, and widespread clonal growth have the potential to restrict outcrossing greatly in this group. Because no studies have characterized genetically the actual level of inbreeding vs. outcrossing in any particular hydrophyte species, however, it is premature to argue too strongly either for or against the first component of the outcrossing hypothesis.

COSTS VS. BENEFITS OF DICLINY IN HYDROPHILES

The second component of the outcrossing hypothesis, that outcrossing in hydrophiles offsets evolutionary costs associated with transitions to dicliny, is even more difficult to assess. One difficulty with pursuing this possibility is that it remains to be proven conclusively that hydrophiles are highly outcrossing.

Plant breeding systems involve three general mechanisms: inbreeding, outcrossing, and apomixis (Briggs & Walters, 1984). Historically, outcrossing has been associated with enhanced genetic variability and heterozygosity, whereas inbreeding and obligate apomixis are related to low genetic variability (Faegri & van der Pijl, 1979; Briggs & Walters, 1984). With adapted gene complexes preserved by well-developed asexual reproduction systems, it is reasonable to assume that it would be advantageous for sexual reproduction in hydrophiles to provide a means of outcrossing that could respond facultatively to changing environmental conditions. Because dicliny may promote or enforce xenogamy, the prevalence of the unisexual condition in hydrophiles has been linked to outcrossing and widespread genetic variability. Presumably, a rich gene pool would facilitate adaptation and response to environmental changes. Therefore, enhanced genetic variation is interpreted as a major possible benefit of dicliny.

Grant (1975) pointed out the liability of inefficient sexual reproduction in diclinous plants, a cost related to reduced seed output in populations. If sex ratios are equal, half of the flowers would not bear seeds in either monoecious or dioecious species. This outcome could have serious consequences in hydrophiles in which seed output is suppressed by other factors such as infrequent sexual reproduction and extensive vegetative growth. Female-biased or equal sex ratios, however, may maximize seed production in dioecious species (Grant, 1975; Opler & Bawa, 1978). As discussed above, female-biased sex ratios have been noted in *Elodea*, *Phyllospadix*, *Syringodium*, and *Thalassia*, and ratios of unity have been found in *Halodule* and *Thalassodendron*. It is important to emphasize that female-biased sex ratios do not always alleviate problems of low seed production. A surplus of females in a population (in favor of reduced males) may also result in low seed output because of inadequate pollination (Grant, 1975). This limitation may have been responsible for a 28% loss in seed set observed in a population of the monoecious *Zostera marina* (Churchill & Riner, 1978). A compromise between seed output and adequate pollination may be reflected in male-biased sex ratios reported in *Ceratophyllum*, *Cymodocea*, and *Thalassia*.

Low seed output in hydrophiles may be specially implicated in their dispersal mode. Dispersal has been described as the physical basis of gene flow and in most plants occurs via transport of pollen or fruits (Grant, 1981). In aquatic plants, dispersal of vegetative propagules is also of great importance. In hydrophiles, reduced seed output may result in a greater dependence on the transport of pollen and vegetative propagules as avenues of dispersal and gene flow. This relationship may be quite significant for freshwater hydrophiles where pollen gene flow is restricted to the single body of water in which the population occurs. In such instances, interpopulational gene flow may be entirely by transport of vegetative propagules. In contrast to perennial species, seed output of diclinous annual hydrophiles is extremely high, reaching levels of 100 seeds/m^2 in *Lepilaena* (Vollebergh & Congdon, 1986). Evidently, adaptation to the annual habit has overcome seed limit costs of dicliny. In some diclinous annuals, such as monoecious *Zannichellia*, however, seed set is ensured by geitonogamy (Haynes & Holm-Nielsen, 1987), thereby negating any possible advantages of outcrossing associated with monoecy.

These circumstantial data provide no satisfying resolution to the question of whether or not the costs of dicliny are outweighed by its selective advantages. Better insight into this matter may be gained by studying the relative fitness of closely related species in genera such as *Zannichellia* that possess monoecious, dioecious, and hermaphroditic sexual conditions.

EXPLANATIONS FOR THE EVOLUTION OF DICLINY IN HYDROPHILES

The third component of the outcrossing hypothesis is that dicliny evolved in hydrophiles principally as a mechanism of promoting outcrossing. This element of the hypothesis can be challenged outright because dicliny does not always guarantee outcrossing. Lewis (1979: 4) emphasized that ". . . separation of sexes . . . offers no protection against sib-mating, because pollen from a male plant is equally effective on a female whether it be a sib or non-sib," and that ". . . separation of sexes has a limited value as an outbreeding device in static plants." It is also important to realize that inbreeding is not restricted to hermaphroditic species but can also result in diclinous species as a result of geitonogamy, and possibly even from xenogamy due to vicinism (Grant, 1981). Furthermore, anomalies such as geitonogamy in monoecious *Zannichellia* make it difficult to accept outcrossing as the compelling force in the evolution of dicliny.

Some consideration has been given to other factors influencing sexual conditions in plants such as relative resource allocation to maternal and paternal function, and constraints imposed by the dynamics of the pollination system (Bawa & Beach, 1981). Unfortunately, these discussions have not considered water-pollinated plants.

If outcrossing has been important in the evolution of hydrophiles, then why are so many species characterized by infrequent sexual reproduction? On the other hand, if outcrossing has not been evolutionarily important in this group, then why has dicliny been conserved? This dilemma may be resolved by taking into account the early evolution of hydrophilous plants. Kimura & Ohta (1971) observed that the extent of genetic variability derived from sexual recombination could be attained by mutation alone given sufficient time, and they emphasized that gene recombinations are broken up by sexual recombination as quickly as they are made. They believed that the greatest advantage of sexual reproduction is to enhance the rate of evolution.

Although the process of adaptation accompanying the transition to hydrophily may have occurred slowly by mutation alone, the combination of sexual recombination and an outcrossing breeding system would have facilitated the process by generating pools of genetic variability more rapidly. In this way, the ancestors of modern hydrophiles may have benefited greatly from sexuality and the outcrossing potential conferred by dicliny, especially if their progenitors lacked other mechanisms to prevent autogamy. In species where hydrophily was derived mainly from lines of self-compatible anemophilous plants, dicliny may have preceded hydrophily.

Once species had become well adapted to hydrophily and a submersed existence, greater fitness may have resulted from maintaining genetically uniform rather than highly variable offspring. Because aquatic environments are relatively constant, vegetative growth would maintain adaptive gene complexes and prevent their breakup by sexual reproduction. The phasing out of sexual reproduction may have been accompanied by greater resource allocation to vegetative growth. A shift to asexual reproduction would likely result in slow evolutionary rates and low species diversity in the group, precisely the pattern that we see in the fossil record of several modern species. By this scenario, dicliny in extant hydrophiles is essentially a relictual condition of uncertain consequence to their present reproductive biology. There are additional appealing aspects of this interpretation. Because dispersal in rare-flowering perennial hydrophiles is likely to be predominantly by vegetative propagules, many populations would be expected to be clonal and genetically uniform. The available data show that these patterns commonly occur in water-pollinated plants. The maintenance of sexuality in extant annual hydrophiles may account for their higher species diversity, the result of accelerated evolutionary rates associated with sexual recombination and outcrossing.

SUMMARY

Because of the prevalence of dicliny in hydrophiles, it is widely believed that water pollination in aquatic plants is linked to an outcrossing breeding system. Actually, there is little evidence that three necessary conditions for outcrossing (sexuality, xenogamy, genetically variable populations) are met by many extant species. Interrelationships of inefficient pollen transfer, reduced sexuality, widespread clonal growth, and diminished seed production in hydrophiles may reflect a major adaptive shift towards asexuality as a means of preserving adaptive gene complexes in stable aquatic environments. This hypothesis explains the apparent slow evolutionary rates and low species diversity of some hydrophilous species noted in the fossil record, as well as the greater species diversity observed in sexual, annual, potentially outcrossing species. If this interpretation is correct, then dicliny persists in modern perennial hydrophiles as a relictual condition associated with their early evolution.

Although the course of evolution in water-pollinated plants does not appear to differ fundamentally from that of other plants, the complex interactions of hydrophily and other aspects of their reproductive biology are likely to have profoundly influenced the patterns of their present diversity. As we improve our methods of evaluating the breeding systems and population structure of hydrophilous species, so will our understanding of evolution in this unusual group of plants be expanded.

EVOLUTION OF UNDERWATER OUTCROSSING FROM AERIAL POLLINATION SYSTEMS: A HYPOTHESIS[1]

C. Thomas Philbrick[2]

ABSTRACT

It is evident that underwater outcrossing (hypohydrophily) arose from aerial pollination systems. However, no mechanism to explain this transition has been proposed. Herein I suggest a system involving bubble pollination, similar to hydroautogamy in Potamogeton, *as an intermediate in the transition from aerial to submerged pollination systems. Such an intermediate would provide the opportunity for the gradual evolution of characters that are needed for underwater outcrossing without sacrificing seed production during the transition.*

There is general agreement that water pollination (hydrophily) is derived from aerial pollination, for the aquatic habit itself is derived in angiosperms (Arber, 1920; Daumann, 1963; Sculthorpe, 1967). Although we have some understanding of the mechanisms of pollen transfer in hydrophiles, there has been little published to explain the origin and subsequent radiation of hydrophilous systems. Hydrophily has been most widely investigated in marine angiosperms (e.g., Ducker & Knox, 1976; Ducker et al., 1978; Cock, 1980; Pettitt, 1984; Pettitt et al., 1980, 1981). Our understanding of the floral biology of freshwater hydrophiles is narrower than in marine groups, even though the unusual mechanisms of pollen transfer in some, e.g., the Hydrocharitaceae, have received considerable attention (e.g., Cook, 1982; McConchie, 1982; Wylie, 1917).

Arber (1920) and Sculthorpe (1967) proposed that marine angiosperms arose from freshwater stock (Hartog, 1970, presents a contrasting view), hence hydrophily likely arose in freshwater systems. Thus, study of hydrophily in freshwater groups could be central to understanding the origin of and selective pressures behind hydrophily, matters that remain to be adequately addressed. Herein I propose a mechanism by which underwater outcrossing evolved from aerial pollination systems. This hypothesis could serve to reorient investigations of the evolution of hydrophily and its role in diversification of aquatic angiosperms.

BACKGROUND

Over 90% of aquatic angiosperms bear aerial flowers and have the same manner of pollination as their terrestrial ancestors (Arber, 1920; Sculthorpe, 1967). Far fewer exhibit a system whereby water is the vector for pollen transfer, i.e., hydrophily. Currently two classes of hydrophily are recognized: 1) epihydrophily; pollination at the water surface, i.e., in two dimensions, and 2) hypohydrophily; pollination below the water surface, i.e., in three dimensions. However, it is evident that epihydrophily embraces at least two rather dissimilar subtypes. In one, the flowers undergo anthesis above the water surface and the reproductive structures (e.g., stigmata, pollen) remain dry: dry-epihydrophily. *Vallisneria* represents the best-known example of dry-epihydrophily (Cook, 1982, and references therein). In contrast, many seagrasses exhibit wet-epihydrophily, where the reproductive structures are wet at anthesis but in close association with the water surface, e.g., the pollen floats just below the water surface but not upon it. Hypohydrophily is more similar to wet- than dry-

epihydrophily. In fact, wet-epihydrophily may be but an evolutionary "refinement" of the more general hypohydrophily.

It is clear that wet-epihydrophily and hypohydrophily require greater modification and adaptation of reproductive structures than does dry-epihydrophily. Many of these modifications no doubt reflect specialization to facilitate pollen release and capture in water, a medium that in addition to being wet is significantly more viscous than air. Features that are associated with wet-epihydrophily and hypohydrophily are summarized in Table 1.

Hypohydrophily occurs in relatively few angiosperm families (Arber, 1920; Cox, 1983; Daumann, 1963; McConchie, 1982; Sculthorpe, 1967); most are monocotyledons. The Ceratophyllaceae are the only dicotyledonous exception. From its taxonomic distribution it is evident that hypohydrophily is polyphyletic, with convergence toward a similar overall morphology.

The Najadales (sensu Cronquist, 1981) exhibit a complete range of pollination systems (aerial, epihydrophily, hypohydrophily) and thus are an ideal group in which to search for clues to the evolution of hypohydrophily. This order comprises 10 families and nearly 200 species (Cronquist, 1981). Phylogenetic relationships in this and related orders are largely unclear, but the families are believed to be closely related (Cronquist, 1981; Dahlgren & Clifford, 1982; Tomlinson, 1982). Eight of the 10 families are made up of freshwater or marine aquatic taxa. The species in the remaining two families grow as emergents in marshy habitats. Aerial pollination characterizes most species of Potamogetonaceae, Aponogetonaceae, Scheuchzeriaceae, and Juncaginaceae. Dry-epihydrophily is found in *Ruppia* (Ruppiaceae) (Verhoeven, 1979) and *Lepilaena* (Zannichelliaceae) (Vierssen et al., 1982). Wet-epihydrophily occurs in a number of seagrasses. Hypohydrophily is found in the largely freshwater *Najas* (Najadaceae) (Sculthorpe, 1967) and *Zannichellia* (Zannichelliaceae) (Vierssen et al., 1982) in addition to some seagrasses. Given our limited understanding of the distinctions between wet-epihydrophily and hypohydrophily, no attempt will be made to distinguish them. For brevity, the term hypohydrophily will be used in the following discussions to include both wet-epihydrophily and hypohydrophily.

It is generally believed that floral biology has played an important part in the evolution of angiosperms (Baker, 1963; Crepet, 1983, 1984; Grant, 1949, 1963; Grant & Grant, 1965; Stebbins, 1970; and others). Therefore, it is not unreasonable to propose that diversification of hypohydrophilous systems has played an integral role in speciation, e.g., *Najas* (ca. 40 species) (Haynes, 1977).

Mechanisms that ensure pollination during evolutionary transitions in floral structure have been proposed as being primary in the evolution of pollination systems (Baker, 1963; Stebbins, 1970, 1974). Given the almost universal occurrence of aerial flowers among angiosperms, adaptations for an aerial floral biology are undoubtedly well fixed in the angiosperm genome. An impediment to the formulation of hypotheses regarding the evolution of hypohydrophily has been a lack of obvious intermediate pollination systems. Hypohydrophily requires the abandonment or modification of a suite of characters that are intimately tied to the dry, aerial flowering condition. The mechanical and biochemical ramifications entailed in adapting to un-

derwater release, transport, and capture of pollen raise significant adaptive obstacles.

The fact that flowers of hypohydrophiles are wet when anthesis occurs makes them unique. The rapid decrease in viability of pollen when wetted (Daumann, 1963; Jones, 1967) illustrates the sensitivity of aerial flowers to the influence of water. Means by which selection for wettability could act upon an aerial flower and yield a "half-wet" intermediate while retaining seed production and sexuality are not evident.

Strong selective pressure to retain aerial flowers, or at least perhaps to avoid flowering under water, is evidenced by the retention of aerial flowers in a clear majority of aquatic angiosperms. This phenomenon is particularly well illustrated in species that exhibit pronounced modification of submerged vegetative structure yet exhibit aerial flower production, e.g., *Utricularia* and *Myriophyllum* (Arber, 1920; Sculthorpe, 1967). Nonetheless, some aquatics have essentially abandoned aerial flowers. These can be organized into two general groups: 1) those that produce submerged, aerial-type flowers that self-pollinate, and 2) those that have apparently dispensed with flower production or with sexual reproduction altogether, and reproduce by a variety of asexual means. Of course many species combine asexual and sexual reproduction. The abundance of species in these two classes underscores the evolutionary importance of alternatives to aerial flower production. The occurrence of hypohydrophilous groups in the extant flora reveals an additional evolutionary pathway, where modification has taken place to allow the employment of the aquatic medium as a pollen vector.

Given that hypohydrophily evolved from aerial-flowered systems, there can be little argument that its evolution would require the submergence of aerial flowers. When typical aerial flowers become submerged, closing of the perianth usually serves to trap and maintain a small bubble of air around the reproductive structures. Therefore, pollination within such flowers is equivalent to selfing in a functionally dry flower (Arber, 1920; Hutchinson, 1975; Sculthorpe, 1967). Thus, little selection for wettability would occur, for during anthesis there is no contact between the reproductive structures and the water. It appears that the evolutionary submergence of flowers *per se* would not necessarily provide the circumstances under which selection leading to hypohydrophily would proceed. The flowers of a progenitor of hypohydrophily would have to have been somehow predisposed such that selection could act on flowers that are open underwater, while the ability to produce seed is retained. That is, an intermediate pollination system ("bridging" of Baker, 1961, 1963) was likely important during the transition.

HYDROAUTOGAMY IN *POTAMOGETON*

I propose that a reproductive system similar to hydroautogamy in *Potamogeton* occupied a key intermediate stage between aerial systems and hypohydrophily. Numerous species of *Potamogeton* exhibit underwater flowering and seed production,

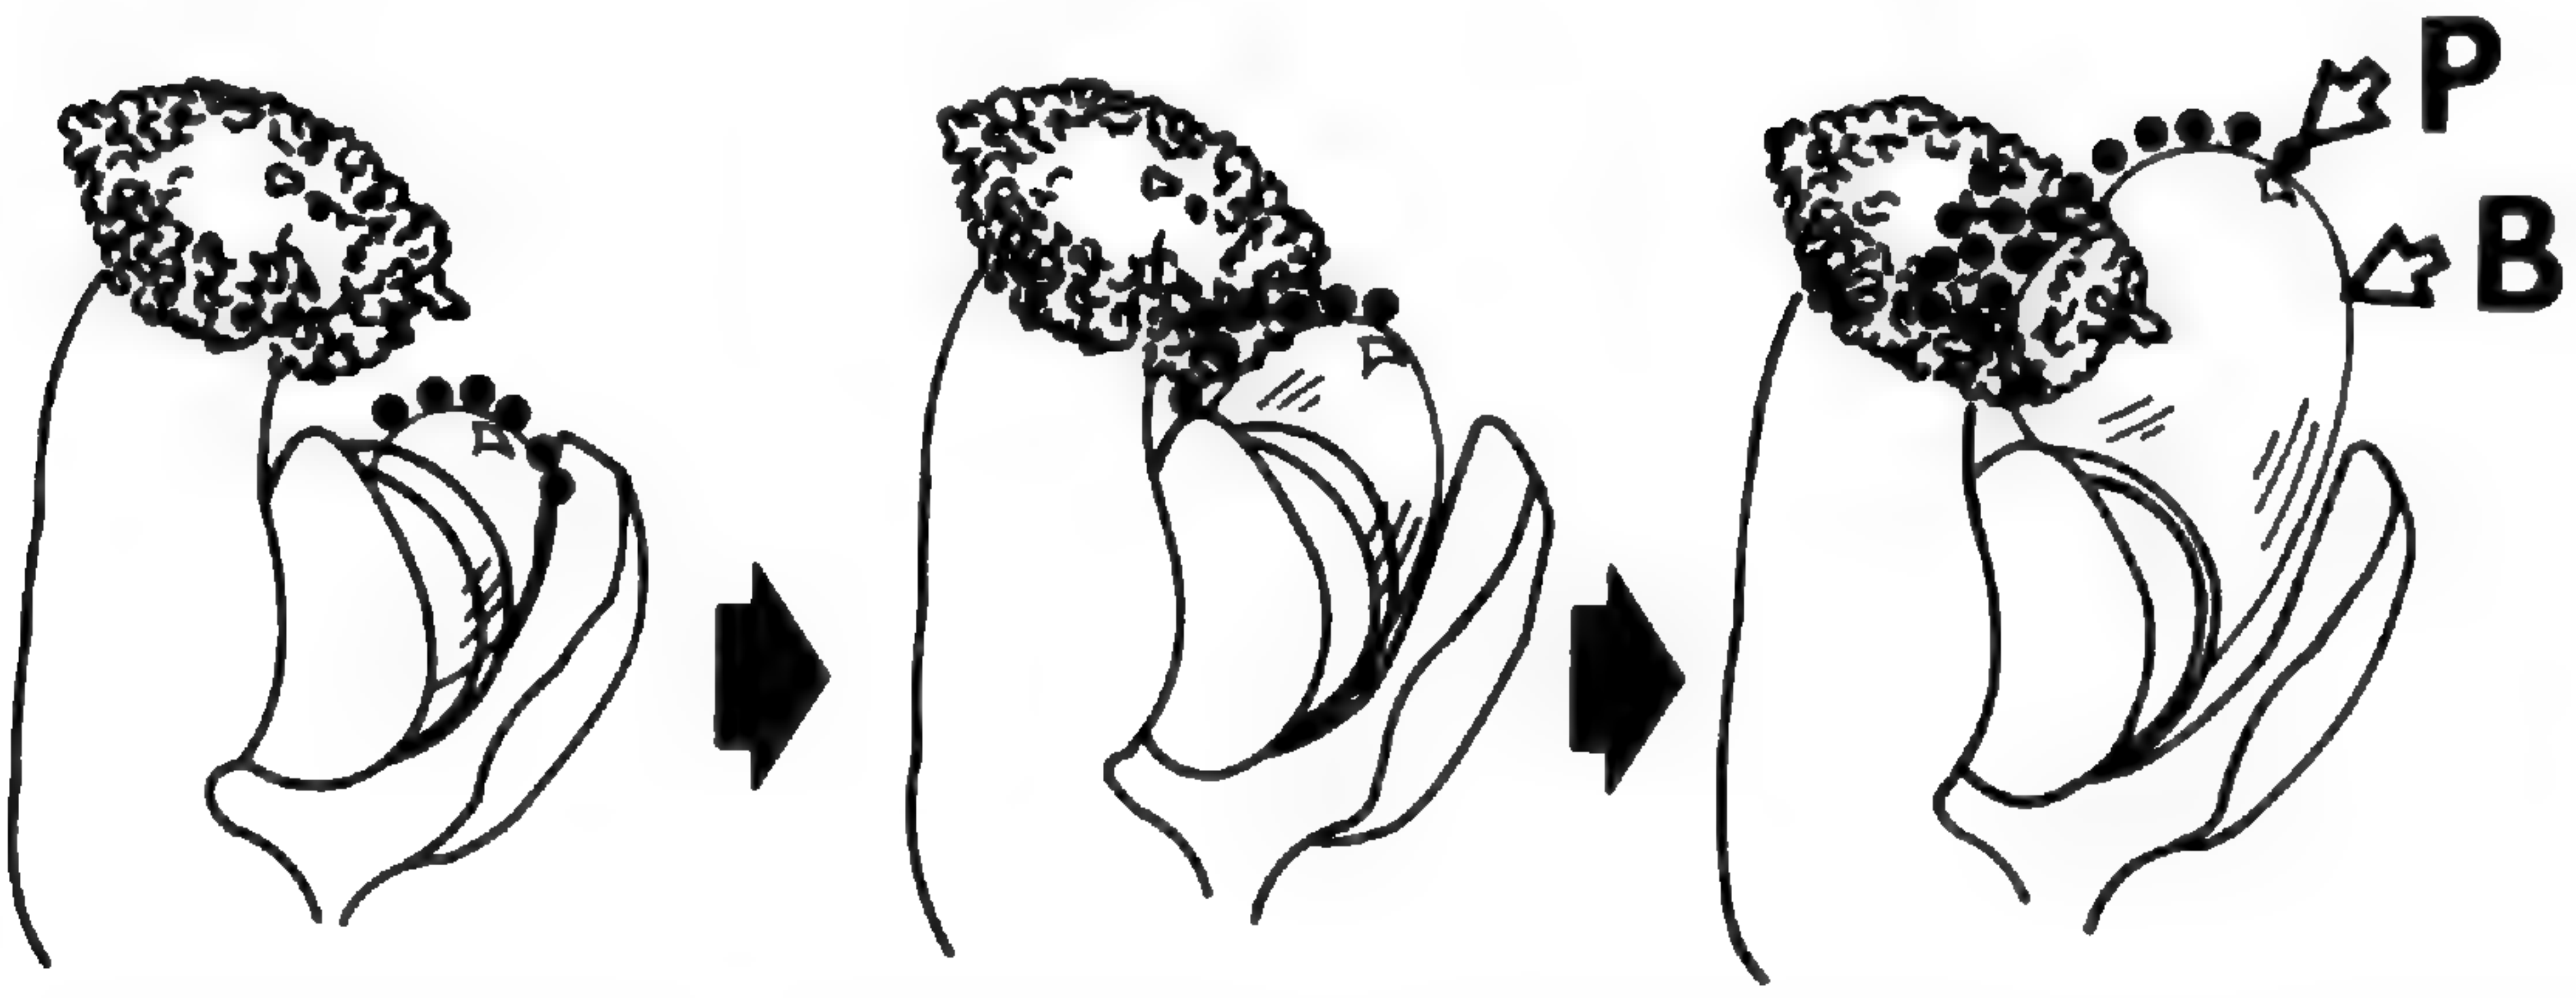

FIGURE 2. *Idealized diagrams of a portion of a* Potamogeton pusillus *flower that illustrate the progressive enlargement of a bubble (B) during anthesis and the deposition of pollen (P) onto the stigma from the bubble surface.*

a derived condition in the genus (Philbrick & Anderson, 1987, and references therein). Flowers of *Potamogeton* open while submerged; thus pollen and stigmata are exposed to water during anthesis. Self-pollination via hydroautogamy (the movement of bubble-borne pollen from anther to stigma within an open flower) rather than hypohydrophily seems to be the principal mechanism of pollination in submerged flowers (Philbrick & Anderson, 1987). During anthesis, bubbles are produced as gas is released from the dehiscing anthers (Figs. 1, 2). Preliminary study with T. Taigen suggests the gas is carbon dioxide. Pollen travels from the anther onto the outer surface of the bubble (Fig. 2). The bubble increases in size until it extends from the anther to the stigma. Pollen is then deposited onto the stigma from the bubble surface (Fig. 2) and self-pollination and subsequent fertilization results. The bubble continues to enlarge until it breaks free from the flower and rises to the surface. Additional bubbles are formed as each anther opens. An important consequence of this system of self-pollination is that the pollen and stigmata are wet during anthesis. In addition, close inspection reveals that individual pollen grains often drift off the bubble surfaces.

In systems where transition is occurring within a pollination-vector category, e.g., one insect species to another, relatively minor changes in floral structure that accommodate a new vector would be more probable than when the shift is from one broad category of pollen vector to another. The hypothesis of "fortunate accidents" formulated by Baker (1963), which suggests a chance preadaptation to an available vector, is more likely to hold when the gross structure of the flower remains unchanged. In contrast, floral modification that allows a change from one type of pollination vector to another, e.g., wind (dry) to water (wet), is less likely to be sudden because of the numerous modifications involved (Table 1). A hydroautogamous system would provide an opportunity for the operation of selective pressures leading to the gradual accumulation of hypohydrophilous features while maintaining seed production.

Lacunae systems such as those in the plant body of *Potamogeton* may have played an important role in the acquisition of hypohydrophily. Lacunae are common in submerged hydrophytes and allow movement of gases within the plant body (Arber, 1920; Hutchinson, 1975; Sculthorpe, 1967). Lacunae are also evident in the inflorescence and floral structures of *Potamogeton* (U. Posluszny, pers. comm.). Gases that are transported via the lacunae build up within the anther and seem to play a role in its dehiscence.

It is reasonable to propose that early in the acquisition of a hydroautogamous-like system the contents of the anther were dry at dehiscence. In such a case, the pollen would be shed dry and presumably remain on the inside surface of the bubble. This is little different from the behavior of airborne pollen when it becomes trapped upon the surface film of water. The water/atmosphere interface is similar in both instances. Similarly, the stigmata remain within the bubble during pollination. However, the surface of the bubble is important because it provides an opportunity for selection to operate. Although the pollen is virtually dry when inside the bubble, humidity levels there would be high, favoring pollen that could withstand the effects of increased humidity, i.e., increased wetting. Similarly, stigmata that could withstand wetting would be favored. Thus, the gradual selection of two major characters that distinguish hypohydrophily from aerial systems would result: wettable pollen and wettable stigmata. The bubble system provides a setting wherein major obstacles in the evolution of hypohydrophily could be surmounted.

Stebbins (1970, 1974) discussed the importance of character syndromes, i.e., correlations between characters, in the evolution of pollination systems. Selective modification of one feature is often manifested in a change in related features. Thus, selection for wetting might have affected pollen and stigmata simultaneously. Selection for wettability would result in the pollen no longer being limited to the inside of the bubble. The pollen could then move to the outside surface of the bubble, as in the extant species. Pollen on the outside of the bubble would be subject to continued selection, as well as "loss" by drifting away; the stage would then be set for the initiation of outcrossing.

Unisexual flowers characterize all of the documented cases of hypohydrophily. Arguments for the evolution of unisexual flowers in terrestrial plants (e.g., Anderson & Stebbins, 1984; Bawa, 1984; Charnov, 1982; Lloyd, 1982) would be equally applicable to hypohydrophilous aquatics. I propose that unisexuality was acquired not before, but after the initial submergence of a bisexual flower and initial selection toward hypohydrophily was on a bisexual flower. Evolution of hypohydrophilous characters from aerial, unisexual flowers seems less likely due to the requirement for simultaneous and somewhat independent acquisition of hypohydrophilous features in both staminate and pistillate flowers (Table 1). Further, seed production via sexual means would be more difficult to maintain.

High pollen production (pollen/ovule ratios) characterizes abiotic pollination systems (e.g., Cruden, 1977; Philbrick & Anderson, 1987; Whitehead, 1969). Lower pollen/ovule ratios are a general feature of predominantly self-pollination systems (Cruden, 1977). Aerial-flowered species of *Potamogeton* exhibit high pollen production and are believed to be anemophilous (Philbrick & Anderson, 1987). Hydroautogamous potamogetons exhibit lower pollen production than aerial taxa but not as low as would be expected for selfers (Philbrick & Anderson, 1987). The maintenance of relatively high pollen production in largely autogamous lineages may be due either to genetic constraints, the relatively recent acquisition of selfing, or the fact that hydroautogamy itself is a somewhat stochastic system. The propensity for continued high pollen production in hydroautogamous taxa may have been instrumental as a preadaptation in subsequent selection for hypohydrophily, a stochastic system that relies, as does anemophily, on high pollen/ovule ratios.

CONCLUSION

There is general agreement that hydrophily evolved from aerial pollination systems. In contrast with some previous ideas, I consider hypohydrophily to be significantly different from dry-epihydrophily, where pollination is effectively aerial. Hypohydrophilous taxa exhibit many more specializations to the aquatic medium in reproductive features.

A major obstacle to the evolution of hypohydrophily is the accumulation of characters that allow for seed set with wetted pollen and stigmata. I suggest that such characters were acquired gradually, and offer a hypothesis where a system that utilizes bubble pollination, similar to hydroautogamy in *Potamogeton*, could serve as an intermediate between aerial pollination systems and hypohydrophily. Hydroautogamy could provide an opportunity for the gradual selection of hypohydrophilous characters without sacrificing seed production.

This hypothesis is the first to address explicitly the issue of the evolution of hypohydrophily from aerial systems. Corollaries of this hypothesis are testable via studies of hydroautogamy in *Potamogeton* (e.g., viability of pollen that is released from the bubble, ability of submerged stigmata to capture water-borne pollen). Further investigation of the mechanisms of hypohydrophily and phylogenetic relationships among hydrophilous and nonhydrophilous taxa will provide information that can be used to evaluate this hypothesis.

INSECT FORAGERS ON *SOLANUM* FLOWERS IN AUSTRALIA[1]

Gregory J. Anderson[2] *and David Symon*[3]

ABSTRACT

Eighteen native insect species were found on flowers of 18 Solanum *species in a field study in Australia. All of the* Solanum *species studied are endemic to Australia, and about one-half of them are andromonoecious or dioecious. Fifteen of the insect species and 93% of total floral visitors were bees. New records of activity on* Solanum *flowers in Australia are reported for* Braunsapis *and* Xylocopa *(Anthophoridae)*, Leioproctus *(Colletidae)*, *and* Trigona *(Apidae). Two species each of the pollen-collecting bees* Amegilla *(Anthophoridae)*, Nomia *(Halictidae), and* Trigona *are considered the most significant floral visitors. This conclusion is based on the distribution, abundance, and behavior of the bees, and on the high percentage of* Solanum *pollen in pollen loads.* Amegilla *and* Nomia *extract pollen by "buzzing" it out of the anthers;* Trigona *species do not. Species of* Amegilla *are hypothesized to effect interpopulation outcrosses.* Trigona *species are considered important primarily in self-pollination, and species of* Nomia *transmit pollen both within and between plants. This pollinator assemblage is postulated to have been associated with the evolution of dioecy in Australian* Solanum.

Solanum flowers are of the "dish-bowl" type of Faegri & van der Pijl (1979) and as a consequence do not physically exclude floral visitors. However, these wide-open flowers do not represent the cornucopia to bees and other floral visitors that some other dish-bowl species do (e.g., *Tilia*, Anderson, 1976) because floral rewards are limited and there are specialized requirements for pollen extraction. Although extrafloral nectaries have been described in *Solanum*, floral nectar is absent (Anderson & Symon, 1985); and pollen, the only reward offered, is not easily accessible to all floral visitors. *Solanum* is the exemplar of the more than 540 genera whose anthers open by terminal pores rather than by longitudinal slits (Vogel, 1978; Buchmann, 1983). *Solanum* pollen is typical for species with poricidal flowers (Buchmann, 1983) in that it is relatively dry (not sticky) and has a smooth, granulate tectate exine (Anderson & Gensel, 1976). To remove pollen, floral visitors can either "milk" the anthers by stroking them from base to apex with their mandibles (e.g., Thorp & Estes, 1975), dig it out of the terminal pores, steal pollen by biting holes in the sides of the anthers (Buchmann, 1983), or buzz the pollen out of the terminal pores. Thorp & Estes (1975) described buzz or vibratile pollination succinctly as "shivering the indirect flight muscles of the thorax while the wings [are] in repose." Buchmann (1983) estimated that about 60% of angiosperm species with poricidal anthers, including *Solanum*, are buzz pollinated.

The general syndrome of *Solanum* pollination, as described above, is well known. However, there is little known about specific pollinators and pollination. This is particularly true for Australia, where even some of the floral visitors are unknown (see below). Michener's (1965) major study of the bees of Australia reported collections of only three species from three genera on a single species of *Solanum* in southern Queensland. Symon's (1979) review of *Solanum* pollinators includes reports of seven taxa of bees. Armstrong's (1979) thorough overview of biotic pollination in Australia includes only one citation beyond Michener's and Symon's studies. Thus, we present information that expands the data base on *Solanum* pollinators. Also included is an analysis of insect pollen loads and relative abundance of insects on flowers to address the question of their importance as effective pollinators of *Solanum*. Finally, we speculate on the role of pollinators

---

[1] *We are especially grateful to Terry Houston of the Western Australian Museum (Perth) for identifying the vast majority of the insects mentioned herein. We thank Mary Jane Spring for drawing the figure, Rose Karosi for typing the Appendix, and M. Anderson, P. Bernhardt, K. Holsinger, T. Houston, C. T. Philbrick, R. W. Thorp, and G. L. Webster for comments on the manuscript. R. W. Thorp also generously contributed observations of bees on* Solanum *flowers. We gratefully acknowledge research support from the Waite Agricultural Research Institute, the Australian National University, the Botany Department of the University of California–Davis, and the Systematic Biology and International Programs of the National Science Foundation.*

in the evolution of nonhermaphroditic breeding systems.

METHODS

Insects were collected only from open *Solanum* flowers (i.e., not from the extrafloral nectaries) primarily from natural populations in 1979–1980. The study was centered on andromonoecious or dioecious solanums, the distribution and biology of which are given by Symon (1981). The species studied are as follows. The five-letter abbreviations are those used in Appendix I; the single letters indicate whether the species bears only hermaphroditic flowers (H), or whether it is andromonoecious (A) or dioecious (D): *Solanum asymmetriphyllum* Specht (asymm) (D), *S. beaugleholei* Symon (beaug) (A), *S. cinereum* R. Br. (ciner) (A), *S. cunninghamii* Bentham (cunni) (D), *S. dioicum* W. Fitzg. (dioic) (D), *S. diversiflorum* F. Muell. (diver) (A), *S. eburneum* Symon (eburn) (A), *S. ellipticum* R. Br. (ellip) (H), *S. esuriale* Lindley (esuri) (H), *S. hoplopetalum* Bitter & Summerh. (hoplo) (H), *S. leopoldense* Symon (leopo) (D), *S. lucani* F. Muell. (lucan) (H), *S. parvifolium* R. Br. (parvi) (H), *S. petrophilum* F. Muell. (petro) (H), *S. quadriloculatum* F. Muell. (quadr) (H), *S. sturtianum* F. Muell. (sturt) (H), *S. tudununggae* (tudun) (D).

Because these *Solanum* species occur primarily in northern Western Australia and the Northern Territory, fieldwork was concentrated there. The study in this region ranged over some 5,000 km. Collections were also made in South Australia, including a small sample taken from garden-grown native plants in Adelaide, and from Western Australia (by R. Thorp). Flowers were open, and collections and observations were made throughout the daylight hours. Thousands of individuals were observed, but not all floral visitors were taken. After vouchers were taken within a given area, only observations of behavior were recorded. Specimens netted from flowers were stored with cotton in separate vials to prevent contamination of pollen loads. The plant species, time of day, and notes on insect behavior were recorded at each site. Pollen loads removed from insects were mounted on slides in aniline blue in lactophenol and analyzed for the percentage of *Solanum* pollen and the num-

ber of other pollenomorphs. The fidelity to *Solanum* flowers was estimated from these calculations. Plant vouchers are in AD and insect vouchers in the collections of the Western Australian Museum in Perth.

RESULTS

INSECT DIVERSITY AND DISTRIBUTION

Specific data on time and place of collection and on pollen loads carried are presented in Appendix I, and the locations of the collection sites given there are plotted in Figure 1. The data from the Appendix are summarized in Table 1.

More that 150 insects, 93% of which were bees, were collected, representing at least 18 species in two orders (Appendix I). All of the bees were females except one *Amegilla pulchra* taken from *S. ellipticum* in South Australia. In addition to collections from Western Australia and the Northern Territory, a few individuals of *Nomia* and *Amegilla* were taken in South Australia. The following four bee genera are reported here for the first time from *Solanum* flowers in Australia: *Braunsapis*, *Leioproctus*, *Trigona*, and *Xylocopa*. The emphasis in the following analyses centers on the three most frequently collected genera: *Amegilla*, *Nomia*, and *Trigona*.

The collection sites (Fig. 1) of the three primary bee genera correspond to the general range of the solanums in the study area (Symon, 1981). As Table 1 shows, individuals of *Nomia* and *Trigona* were found at nearly twice as many sites as *Amegilla*, and individuals of *Amegilla* were less abundant than either *Nomia* or *Trigona*. The two species of *Amegilla* were equally abundant and widespread; one species was more widely distributed and was locally abundant in *Nomia* (*N. flavoviridis*) and in *Trigona* (undescribed species "B"). While these data accurately reflect the rank-order of occurrence of the genera as we observed them in the field, the frequency figures are biased against *Nomia* and *Trigona*, which were much more abundant than reflected in the collections. *Trigona* was particularly abundant, with sometimes tens of individuals foraging over the flowers of a single plant.

FORAGING BEHAVIOR

As indicated in Table 1, *Amegilla*, *Nomia*, and *Xylocopa* were observed to vibrate or "buzz" the pollen out of the flowers; the remaining five bee genera were not. *Lasioglossum*, however, has been observed to buzz flowers in other studies (e.g., Bernhardt, 1986; Buchmann, 1983). Of the five genera not observed to utilize vibratile extraction, only *Trigona* was found on more than three occasions (Table 1); thus, the other four are not considered primary pollinators. Individuals of *Trigona* collect pollen from the anthers by digging it out of the terminal pores and by scavenging for it on floral parts such as the corolla and stigma (Fig. 2). No obvious differences in behavior were noted for insect visitors to hermaphroditic flowers, to staminate flowers of the andromonoecious species, or to the staminate or pistillate flowers of the dioecious species.

FIGURE 2. *A* Trigona *(within circle) foraging on the stigma of a hermaphroditic flower of the andromonoecious* Solanum beaugleholei. *The flower is about 30 mm in diameter.*

The length of time individual bees stay on flowers is correlated with their size and capability to buzz flowers. The bees that vibrate pollen out of the flowers are generally larger (*Amegilla*—about 13 mm; *Nomia*—8–10 mm) and stay for only a short time (one to a few seconds) on each flower (Table 1). On the other hand, individuals of *Trigona* (smallest of the three species, about 5 mm) spent up to one minute on each flower. Individuals of *Trigona* frequently visited several flowers in the same inflorescence. This is in contrast with *Amegilla*, where an individual usually visits only a single flower per plant and then flies some distance, often away from the population under study. Individuals of *Nomia* most often foraged within and/or among inflorescences of the same population.

Most *Amegilla* visits take place before 10 A.M. (Table 1; Appendix I, column 5). The majority of visits by *Nomia* and *Trigona* also occur during this period, but significant proportions of the individuals of these two genera are also active after noon.

INSECT FIDELITY

The average fidelity for all six major insect visitors (two species each from *Amegilla*, *Nomia*, and *Trigona*) is high (Table 1; Appendix I, column 3). For the genera overall, however, the fidelity estimate for *Trigona* is 20% higher than for either *Nomia* or *Amegilla*. These figures are, as one would expect, paralleled by the estimates of the number of other species visited (Table 1; Appendix I, column 4): *Nomia* and *Amegilla* pollen loads include about seven times as many other species as found in pollen loads of *Trigona*.

The pollen loads from the scopae or corbiculae respectively of the *Nomia* and *Trigona* were somewhat more sticky than those carried by *Amegilla*.

Amegilla scopae are covered with long hairs, among which the drier pollen loads were packed.

DISCUSSION

Solanum flowers present a relatively rich pollen resource for the bees that can exploit them. Although they lack nectar and restrict access to pollen (having only terminal anther pores), they are heavily visited by at least a few species. This is likely a tribute to their local abundance and the relatively large quantity of pollen available per flower (more than one million grains in some species, Anderson & Symon, in press). Although a range of insects was observed to visit the flowers, not all were considered significant pollinators (Table 1). Based on distribution and abundance over the range of the solanums, five of the bee genera and other insect groups are considered relatively insignificant pollinators, but these cannot be ruled out as occasional pollinators (see below). Two species each in *Amegilla*, *Nomia*, and *Trigona* are the primary floral visitors, and, as a consequence of this and their behavior, we propose that they are the major pollinators of the *Solanum* species studied.

Michener (1965) suggested that a large percentage of the Australian bees are oligolectic on the Myrtaceae but proposed that this is due largely to the overwhelming abundance of species in this family. In addition, he listed several genera, including *Nomia*, *Trigona*, and *Amegilla*, as examples of bees visiting a wide variety of species. In fact, some of the same genera of pollen-collecting bees (*Nomia*, *Trigona*, *Braunsapis*, *Xylocopa*) are reported as pollinators of another species from nearby Indonesia that is dioecious and offers only pollen as a reward, *Decaspermum parviflorum* (Myrtaceae) (Kevan & Lack, 1985). Although Michener (1965) did not treat the bee species we studied, this generalist behavior also likely applies to them. On the other hand, the proportion of *Solanum* pollen in pollen loads (79–99%) implies fidelity high enough to consider these polylectic genera to be important pollinators and to be temporally and spatially specialized on *Solanum*. This supports the contention by Thorp (1979) and Armstrong (1979) that most pollen-collecting bees show a high degree of diurnal or temporal constancy. Prance (1985) made a similar suggestion for polylectic bees from the Amazon rain forest.

Although the sticky pollen masses carried by individuals of *Nomia* and *Trigona* might indicate collection of nectar from other species (Thorp, 1979; Buchmann, 1983), the nearly monotypic nature of the loads (especially of the *Trigona*) suggests that some other substance could be involved (perhaps stigmatic exudate, see below). Alternatively, the *Trigona* species could be moistening pollen loads with honey carried in their crops. Obviously nectar or honey from some source other than the *Solanum* flowers provides the carbohydrate resource to subsidize the pollen-collecting activities of the bees.

Nomia and *Amegilla* are ground-nesting, solitary, larger bees and are well represented in Australia (85 and 69 species, respectively; T. Houston, pers. comm.). These genera also share the ability to vibrate pollen out of the anthers. Michener (1965) indicated that the highly social, tree-nesting *Trigona*, although not as diverse in Australia (only about 14 species, T. Houston, pers. comm.), visits a wide range of monocots and dicots. However, this mostly tropical genus (Bernhardt, 1987) does not vibrate pollen out of the anthers and is too small to simultaneously contact stigmata while working anthers of a few of the large-flowered diclinous solanums.

Are species of *Trigona* then simply pollen thieves removing the reward without effecting pollination? In this instance, that conclusion does not seem warranted. We never observed them biting holes in anther bases to steal pollen, and anthers of dried voucher specimens do not have holes. Some individuals of *Trigona* opportunistically collect pollen spread over the flower, taking advantage of the activities of the vibratile pollinators. However, others are active on flowers not visited previously; we regularly observed them digging pollen out of the terminal pores of anthers. Members of *Trigona* were also observed foraging on stigmatic surfaces (Fig. 2). They may have been gathering pollen, but it is also possible that they were collecting stigmatic fluid to cement pollen grains together, as Baker et al. (1973) reported for other angiosperms. In either case, with such behavior they could effectively transmit pollen from anthers to stigmata in even the large-flowered species. Given this, and that *Trigona* species were omnipresent diurnally, were more abundant on *Solanum* flowers than all the other species combined, and showed 99% fidelity, we propose that these little bees are significant pollinators.

In view of the fact that representatives of *Trigona* tended to visit flowers in the same inflorescence, those on the same plant, or those within a population, we suggest that most often they effect self-pollination. This is reinforced by the colony behavior of social bees like *Trigona*, where individuals in various parts of a colony tend not to sample widely but continue to visit one area or population repeatedly (T. Seeley, pers. comm.). Two features of the plants are relevant to this hypothesis as well. First, it is possible to self because most species of *Solanum* that have been studied (outside of the tuberous solanums and their relatives), including those from Australia, are self-compatible (Anderson & Symon, in press; Whalen & Anderson, 1981). Secondly, we observed that populations of most of the *Solanum* species studied are small in size and are widely separated from each other. These populations are even smaller (genetically) when one takes into account that most of the species reproduce vegetatively and form large clones, thus most of what appear to be genets in an area are actually ramets (Symon, 1981; Anderson & Stebbins, 1984; Anderson & Symon, in press). As a result, even many foraging visits between "plants" simply constitute visits to different ramets.

The largest but least abundant bees (*Amegilla*) visit flowers for only a very short time, supporting Buchmann's (1983) suggestion that the length of buzzing time is inversely correlated with bee size. These bees behave like "trap liners" (e.g., Janzen, 1971); that is, most visited only a single flower in an area and then flew off and out of sight, presumably to another *Solanum* flower (based on the nearly 80% purity of pollen loads). Such behavior supports the contention that *Amegilla* species are outcrossing agents transmitting pollen among genets. The bees in the first section of Table 1 were not abundant within any population at any site studied. Thus, if they are significant pollinators, they are also likely to effect outcrossing.

The *Nomia* species are intermediate between the small *Trigona* and large *Amegilla* in temporal pattern, abundance, size, visitation times, and behavior (Table 1). Individuals of *Nomia* visited more than one flower per plant and often visited other plants within the population before flying out of sight. As a consequence, we predict that these species generally effect inbreeding.

It seems that most flowers are visited, and observations of fruit set from the previous season showed a high seed set. Thus, we conclude that seed set is likely not pollen limited. Snow (1986) implied this is often the case for insect-pollinated species.

The nectarless flowers of *Solanum* may promote interplant or interpopulation foraging as suggested by Bernhardt (1987) for Australian *Acacia* (which also has no floral nectar). Bees collecting pollen have to find other species as nectar sources; this interruption raises the possibility of returning to a different plant or population of *Solanum*, thereby increasing the chance of effecting outcrossing. On the other hand, given the population structure of the solanums and the pattern of visitation (especially that of *Trigona*), it is likely that more than three-fourths of interfloral visits result in self crosses. This strong likelihood lends strength to the arguments (Anderson & Stebbins, 1984; Anderson & Symon, in press) that dioecy, which promotes genetically wider crossing, may have been selected in response to several features of the hermaphroditic-flowered progenitors of the andromonoecious and dioecious species. These features include self-compatibility, vegetative reproduction, scattered population distribution, and the behavior of the pollinator assemblage as described herein.

This exclusive pollen-collecting behavior of insects on *Solanum* flowers has been accommodated in the Australian diclinous species. In both andromonoecious and dioecious species, all flowers are morphologically hermaphroditic (Anderson & Symon, in press). In staminate flowers of the andromonoecious and dioecious species the gynoecia are present but reduced. This reduction is presumably of little consequence to the pollen-collecting foragers. Of more importance is the fact that in the dioecious species the pistillate flowers bear anthers with pollen. This pollen reward differs from the usual tricolporate pollen of *Solanum* in that it is inaperturate (Anderson & Gensel, 1976). The inaperturate pollen is fully viable but incapable of germination (Levine & Anderson, 1986). Thus, the Australian dioecious species have a reward system that maintains pollinator visitation, but one that also disallows the self-pollination promoted by the plant biology and pollinator behavior.

TWO NEW SPECIES OF *CALYPTROCARYA* (CYPERACEAE: SCLERIEAE) FROM VENEZUELA AND OBSERVATIONS ON THE INFLORESCENCE MORPHOLOGY OF THE GENUS[1]

Gerrit Davidse[2] *and Robert Kral*[3]

ABSTRACT

Two new species, C. montesii *and* C. delascioi, *are described from Guárico, Venezuela. Both species have multiple, sessile, headlike inflorescences.* Calyptrocarya delascioi *is the first species in the genus with elongated rhizomes.* Calyptrocarya montesii *is the second species in the genus with three stigmas. A detailed discussion of inflorescence morphology is presented, demonstrating that compound male and female spikelets are borne in separate inflorescence units in all species of the genus.*

A recent review of specimens of *Calyptrocarya* for a treatment in the *Flora of the Venezuelan Guayana* has brought to light two distinctive gatherings of *Calyptrocarya* from a region just north of the flora area.

This tropical American genus has been revised by Koyama (1967, 1969b), who recognized six species. The presence of two undescribed endemic taxa from a small region in the state of Guárico may seem suspicious, yet seems to be justified by their distinctive morphologies. The low mesas of Parque Nacional Aguaro-Guariquito that rise out of the llanos harbor a number of distinctive endemic elements. One of these is *Rhynchospora papillosa* W. Thomas (1984), a species recently described from Montaña de Guardahumo, in Parque Nacional Aguaro-Guariquito. Ironically, the type of *C. montesii* was collected as a mixture in the type gathering (*Delascio, Montes & Davidse 11342*) of *R. papillosa.*

DESCRIPTION OF NEW SPECIES

Calyptrocarya montesii Davidse & Kral, sp. nov. TYPE: Venezuela. Guárico: Distrito Miranda, Parque Nacional Aguaro-Guariquito, Montaña de Guardahumo, ca. 8°88′–8°92′N, 67°44′W, 40–60 m, Dec. 1981, *F. Delascio, R. Montes & G. Davidse 11342A* (holotype, MO). Figure 1.

Species affinis *C. delascioi* a qua habitu caespitoso, culmis capitulis 2, bracteis capitulis longioribus et stigmatibus 3 differt.

Cespitose annual with lax culms and leaves. Roots fibrous, slender. Lowermost leaves mostly sheaths, short, keeled, multinerved, dull brown, friable and soon lost; principal leaves well overtopping the inflorescence, the largest lowest and more approximate with short, dull brown sheaths; blades 10–30 cm long, 3–5 mm wide, linear, thin, flat, glabrous, 3-costate, the midrib projected on the lower surface, the lateral costae projected on the upper surface, the apex abruptly acute, the margins scabro-ciliate only distally, otherwise smooth; upper leaves gradually reduced and more distant, with all but the uppermost blades elongate and overtopping the inflorescence. Culms 6–16 cm long, ca. 0.5 mm wide, all fertile, centrally borne, trigonous; nodes usually 3, the upper 2 usually bearing inflorescences; internodes glabrous with scaberulous culm angles. Inflorescence a congested head

---

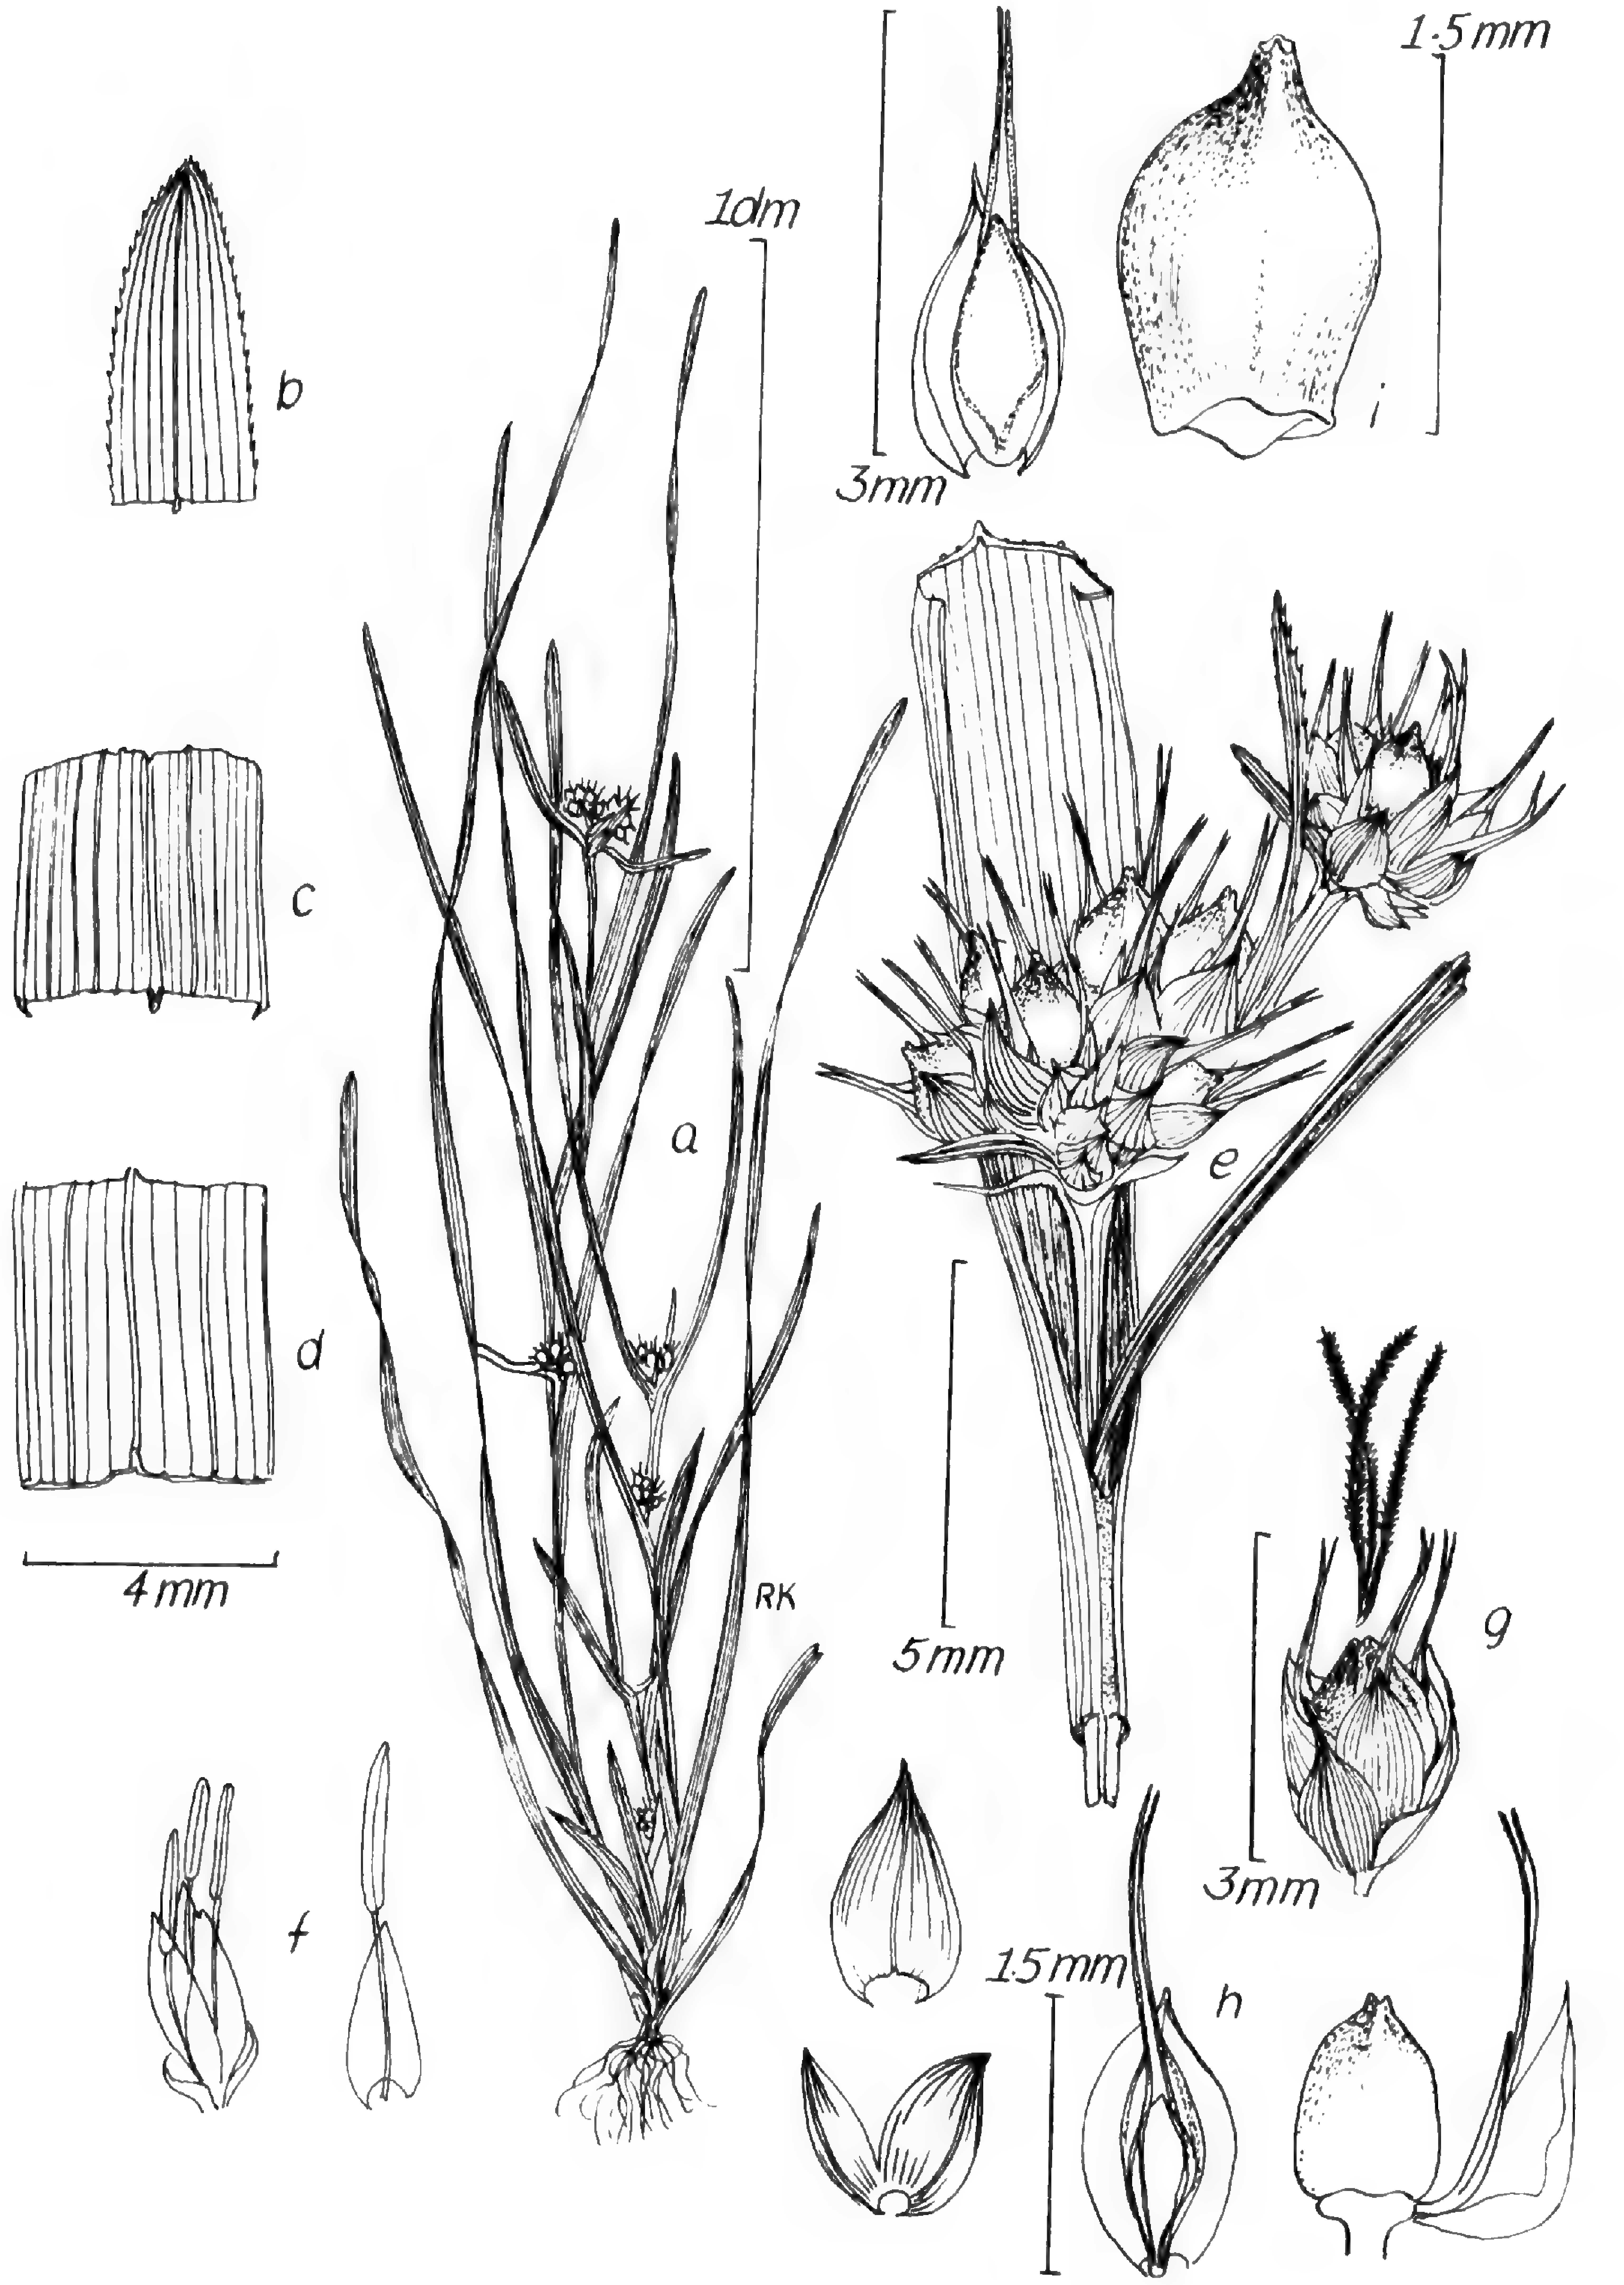

FIGURE 1. Calyptrocarya montesii *Davidse & Kral (from holotype).—a. Habit sketch.—b. Upper surface of leaf blade tip.—c. Upper surface of mid blade.—d. Lower surface of mid blade.—e. Portion of inflorescence showing two heads composed of globose clusters of compound spikelets.—f. Staminate spikelet.—g. Young female compound spikelet.—h. Dissection of female compound spikelet, from left: lowest female spikelet bract; intermediate bract (prophyll); adaxial view of upper bract and sterile spikelet; young fruit with attached upper bract and its sterile spikelet.—i. Left, upper bract complex; right, mature fruit.*

5–8 mm long and wide, composed of smaller globose clusters of compound spikelets; globose clusters sessile or nearly so; involucral bracts 1–3, leaflike, 0.5–8 cm long; lower 1–3 compound spikelets in a globose cluster male, the upper 4–8 compound spikelets female. Male compound spikelets 1.3–2.2 mm long, usually unbranched; lowest bract 1.8–2.2(–8) mm long, membranous or in the lowest spikelet of the head sometimes herbaceous and leaflike, several-nerved; prophyll 1.3–1.6 mm long, 2-keeled, membranous, truncate, inconspicuously many-nerved; bracts subtending the solitary stamens 5–7, the uppermost usually reduced and rudimentary and not subtending a stamen; male flowers solitary stamens, the filaments as long as or slightly longer than the subtending bracts at anthesis, the anthers 0.7–1.2 mm long, linear. Female compound spikelets 3.1–4.2 mm long, composed of 5 primary bracts; lowest bract 1.8–4.2 mm long, ovate, 9–15-nerved, acute or awned to 1 mm; prophyll 1–1.1 mm long, often split into 2 parts, 2-keeled, many-nerved; upper bracts 3, 1.6–2 mm long, 1.4–1.7 mm wide, herbaceous, broadly ovate, 15–19-nerved, prominently apiculate, each subtending 1 sterile, axillary spikelet and surrounding a central, terminal female spikelet; sterile spikelets 2.9–4 mm long including the pedicel, much exceeding the achene, long attenuate, the lowest bract 1.4–2.1 mm long, 2-keeled and clasping at the base, membranous, inconspicuously many-nerved, the upper bract 2.4–3 mm long, 0.4–0.5 mm wide at the base, lanceolate-linear, strongly 2-keeled, the tip of the keels free as awn points 0.1–0.3 mm long, the lateral nerves 2–4; female spikelet a solitary female flower; achenes 1.5–1.6 mm long, ellipsoid; utricle with the base triangular in outline, somewhat thickened and forming a low 3-lobed annulus, the upper part a hyaline, pale brown, smooth to minutely puberulent sac closely appressed to the achene; beak ca. 0.2 mm long; stigmas 3, ca. 1 mm long.

Calyptrocarya montesii is known only from the type collection. It is named in honor of Dr. Rubén A. Montes, a co-collector of this new species.

This species is most clearly characterized by its lax foliage, sessile, multiple inflorescences, and three stigmas. The species appears to be annual, which would be unique in the genus. However, the available specimens are too few to be certain of this interpretation.

The only other species in the genus with three stigmas is *C. luzuliformis* T. Koyama, from which *C. montesii* differs by having relatively broader, laxer leaves, sessile heads, and minutely puberulent rather than pubescent utricles.

Two other species have sessile headlike inflorescences, *C. monocephala* Hochst. ex Steud. and *C. delascioi*. *Calyptrocarya montesii* differs from *C. monocephala* in its multiple rather than solitary inflorescences, broader and laxer leaves, and three versus two stigmas. *Calyptrocarya montesii* differs from *C. delascioi* in the lack of rhizomes, less numerous inflorescences per culm, much longer involucral bracts, smaller achenes, and three rather than two stigmas.

Calyptrocarya delascioi Davidse & Kral, sp. nov. TYPE: Venezuela. Guárico: Distrito Miranda, Parque Nacional Aguaro-Guariquito, Montaña de Guardahumo, ca. 8°88′–8°92′N, 67°44′W, 40–60 m, Dec. 1981, *F. Delascio, R. Montes & G. Davidse 11336* (holotype, MO; isotype, VEN). Figures 2, 3.

Species rhizomatibus productis gracilibus a congeneribus diversa; folia laxa, culmi capitulis 3–8 sessilibus; stigmata 2.

Rhizomatous perennial with lax culms and leaves; aerial shoots up to 7 clumped together, all fertile; roots fibrous, slender. Rhizomes 1–10 cm long, ca. 1.5 mm thick, scaly, slender; scales 6–10 mm long, purple, multinerved, slightly dilated and open distally at the acute, sometimes bifid apex, usually slightly overlapping, passing into scalelike basal leaves. Principal leaves longest and most crowded toward the culm base, there with short, red to purple loose sheaths to 3 cm long, these ventrally scarious, brownish, nearly open, passing at the orifice into strongly folded dull-green blades; blades 30–60 cm long, 3.5–7 mm wide, well overtopping the inflorescence, linear, very lax, thin, flat, glabrous, 3-costate, the midrib projecting on the lower surface, the lateral costae projecting on both surfaces, the tip obtuse, the margin scabro-ciliate distally, otherwise a smooth nerve; upper leaves gradually shortening, but even the upper ones overtopping the inflorescences. Culms to 35 cm long, ca. 1 mm wide, lax, centrally borne, glabrous, trigonous, each angle with a strong costa, each concave face with several low ribs, nodes 3–9 (–10), all usually bearing inflorescences. Inflorescence a congested head 3.5–7 mm long, 3.5–9 mm wide, composed of globose clusters of compound spikelets; globose clusters sessile or with rays to 5 mm long; involucral bracts inconspicuous, 1–3 mm long, linear-lanceolate; lowest 2–3 compound spikelets in a globose cluster male, the upper 5–8 compound spikelets female, larger and firmer than the male compound spikelets. Male compound spikelets 1.5–2.1 mm long, usually unbranched; lowest bract 1.9–2.1 mm long, 7–11-nerved, lan-

ceolate, acute; prophyll 1.1–1.3 mm long, membranous, 2-keeled, 5–7-nerved; bracts subtending the solitary stamens 6–8, 1–1.6 mm long, lanceolate to linear-lanceolate, membranous, especially the inner, the uppermost 2–3 reduced or rudimentary and not subtending a stamen; male flowers solitary stamens, the filaments flattened, slightly longer than the subtending bracts at anthesis, the anthers 0.5–0.8 mm long, oblong-linear. Female compound spikelets 2.5–4 mm long, composed of 5 or rarely 6 primary bracts, the tips and/or upper margins conspicuously purple, otherwise pale green; lowest bract 1.9–2.3 mm long, ovate, herbaceous, 15–19-nerved, acute; prophyll 1–1.2 mm long, usually split into 2 parts, 2-keeled, many-nerved; upper bracts 3 or rarely 4, 2–2.3 mm long, 1.2–1.6 mm wide, herbaceous, ovate, acute, 9–11-nerved, acute, each subtending an axillary spikelet and surrounding a central, terminal female spikelet; axillary spikelets sterile or female, 2–3.2 mm long including the pedicel, when sterile composed of a 2-keeled prophyll and 1–3 bracts, when fertile, bearing 3 bracts above the prophyll, each bract subtending a solitary, axillary spikelet, and surrounding a central, terminal female spikelet; female spikelet a solitary female flower; achenes 1–1.2 mm long, 0.8–1 mm wide, lenticular; utricle with the base elliptic in outline, slightly thickened and forming a low, trilobed collar around the achene, the upper part a hyaline, pale brown, puberulent sac closely appressed to the smooth stramineous achene; beak 0.1 mm long; stigmas 2.

Calyptrocarya delascioi is known only from the type collection. It grew in shallow water of a small stream in the shade of a low gallery forest through the *Trachypogon* savanna that covers most of the mesa top. At the time of the collection, the leaves and culms were mostly floating on the surface of the water.

This species is named for Mr. Francisco Delascio Chitty, a co-collector of the type collection.

Calyptrocarya delascioi differs from all other species in the genus in the development of long, slender rhizomes; all other species are cespitose. In *C. irwiniana* Koyama, however, lateral culms are produced that eventually arch and bend toward the ground. Spikelets often become proliferated and produce new shoots that take root (Koyama, 1969b). This species is thus functionally stoloniferous. The central culms of *C. glomerulata* (Brongn.) Urban also occasionally reproduce plantlets in the inflorescence through proliferation of spikelets.

Calyptrocarya delascioi may be most closely related to *C. montesii*. See the discussion of that species for a comparison.

INFLORESCENCE MORPHOLOGY

The inflorescence morphology of *Calyptrocarya* has been consistently misinterpreted in recent years (Eiten, 1976; Koyama, 1967, 1969a, b, 1971). For example, Koyama (1967) described the spikelets as "compound, sessile or short-peduncled; glumes 6 (including a prophyll); prophyll and the lower 2 empty; the upper 3 bearing an axillary staminate floret; fructification solitary, terminal." A similar interpretation was accepted by Eiten (1976).

The typical compound spikelet, such as in *Calyptrocarya glomerulata*, that is borne toward the tip of a globose head and that matures an achene bears, in fact, 5 bracts (Fig. 4). The lowest bract subtends a reduced axillary branch system that bears a 2-keeled prophyll as its first foliar bract. Both the lowest bract and prophyll do not subtend flowers. Three multinerved bracts are borne successively above the prophyll, each subtending an axillary sterile spikelet. Koyama (1967) considered these axillary spikelets to be staminate spikelets but, after examining spikelets of all species except *C. irwiniana*, of which we have not seen authentic material, we have never observed any stamens or even the remains of filaments in these spikelets. Even *C. irwiniana*, judging from the published illustration (Koyama, 1969b), appears to conform to the general pattern in the other species. The sterile axillary spikelets consist of a pedicel bearing a basal two-keeled prophyll, usually followed by two or three bracts. These two or three bracts are clearly separate in some species (e.g., some specimens of *C. poeppigiana* Kunth, *C. delascioi*, and *C. bicolor* (Pfeiffer) Koyama, and many specimens of *C. luzuliformis* and *C. monocephala*); however, in certain species (e.g., *C. montesii*, *C. glomerulata*) and some specimens of most other species, the upper two bracts appear to have their margins

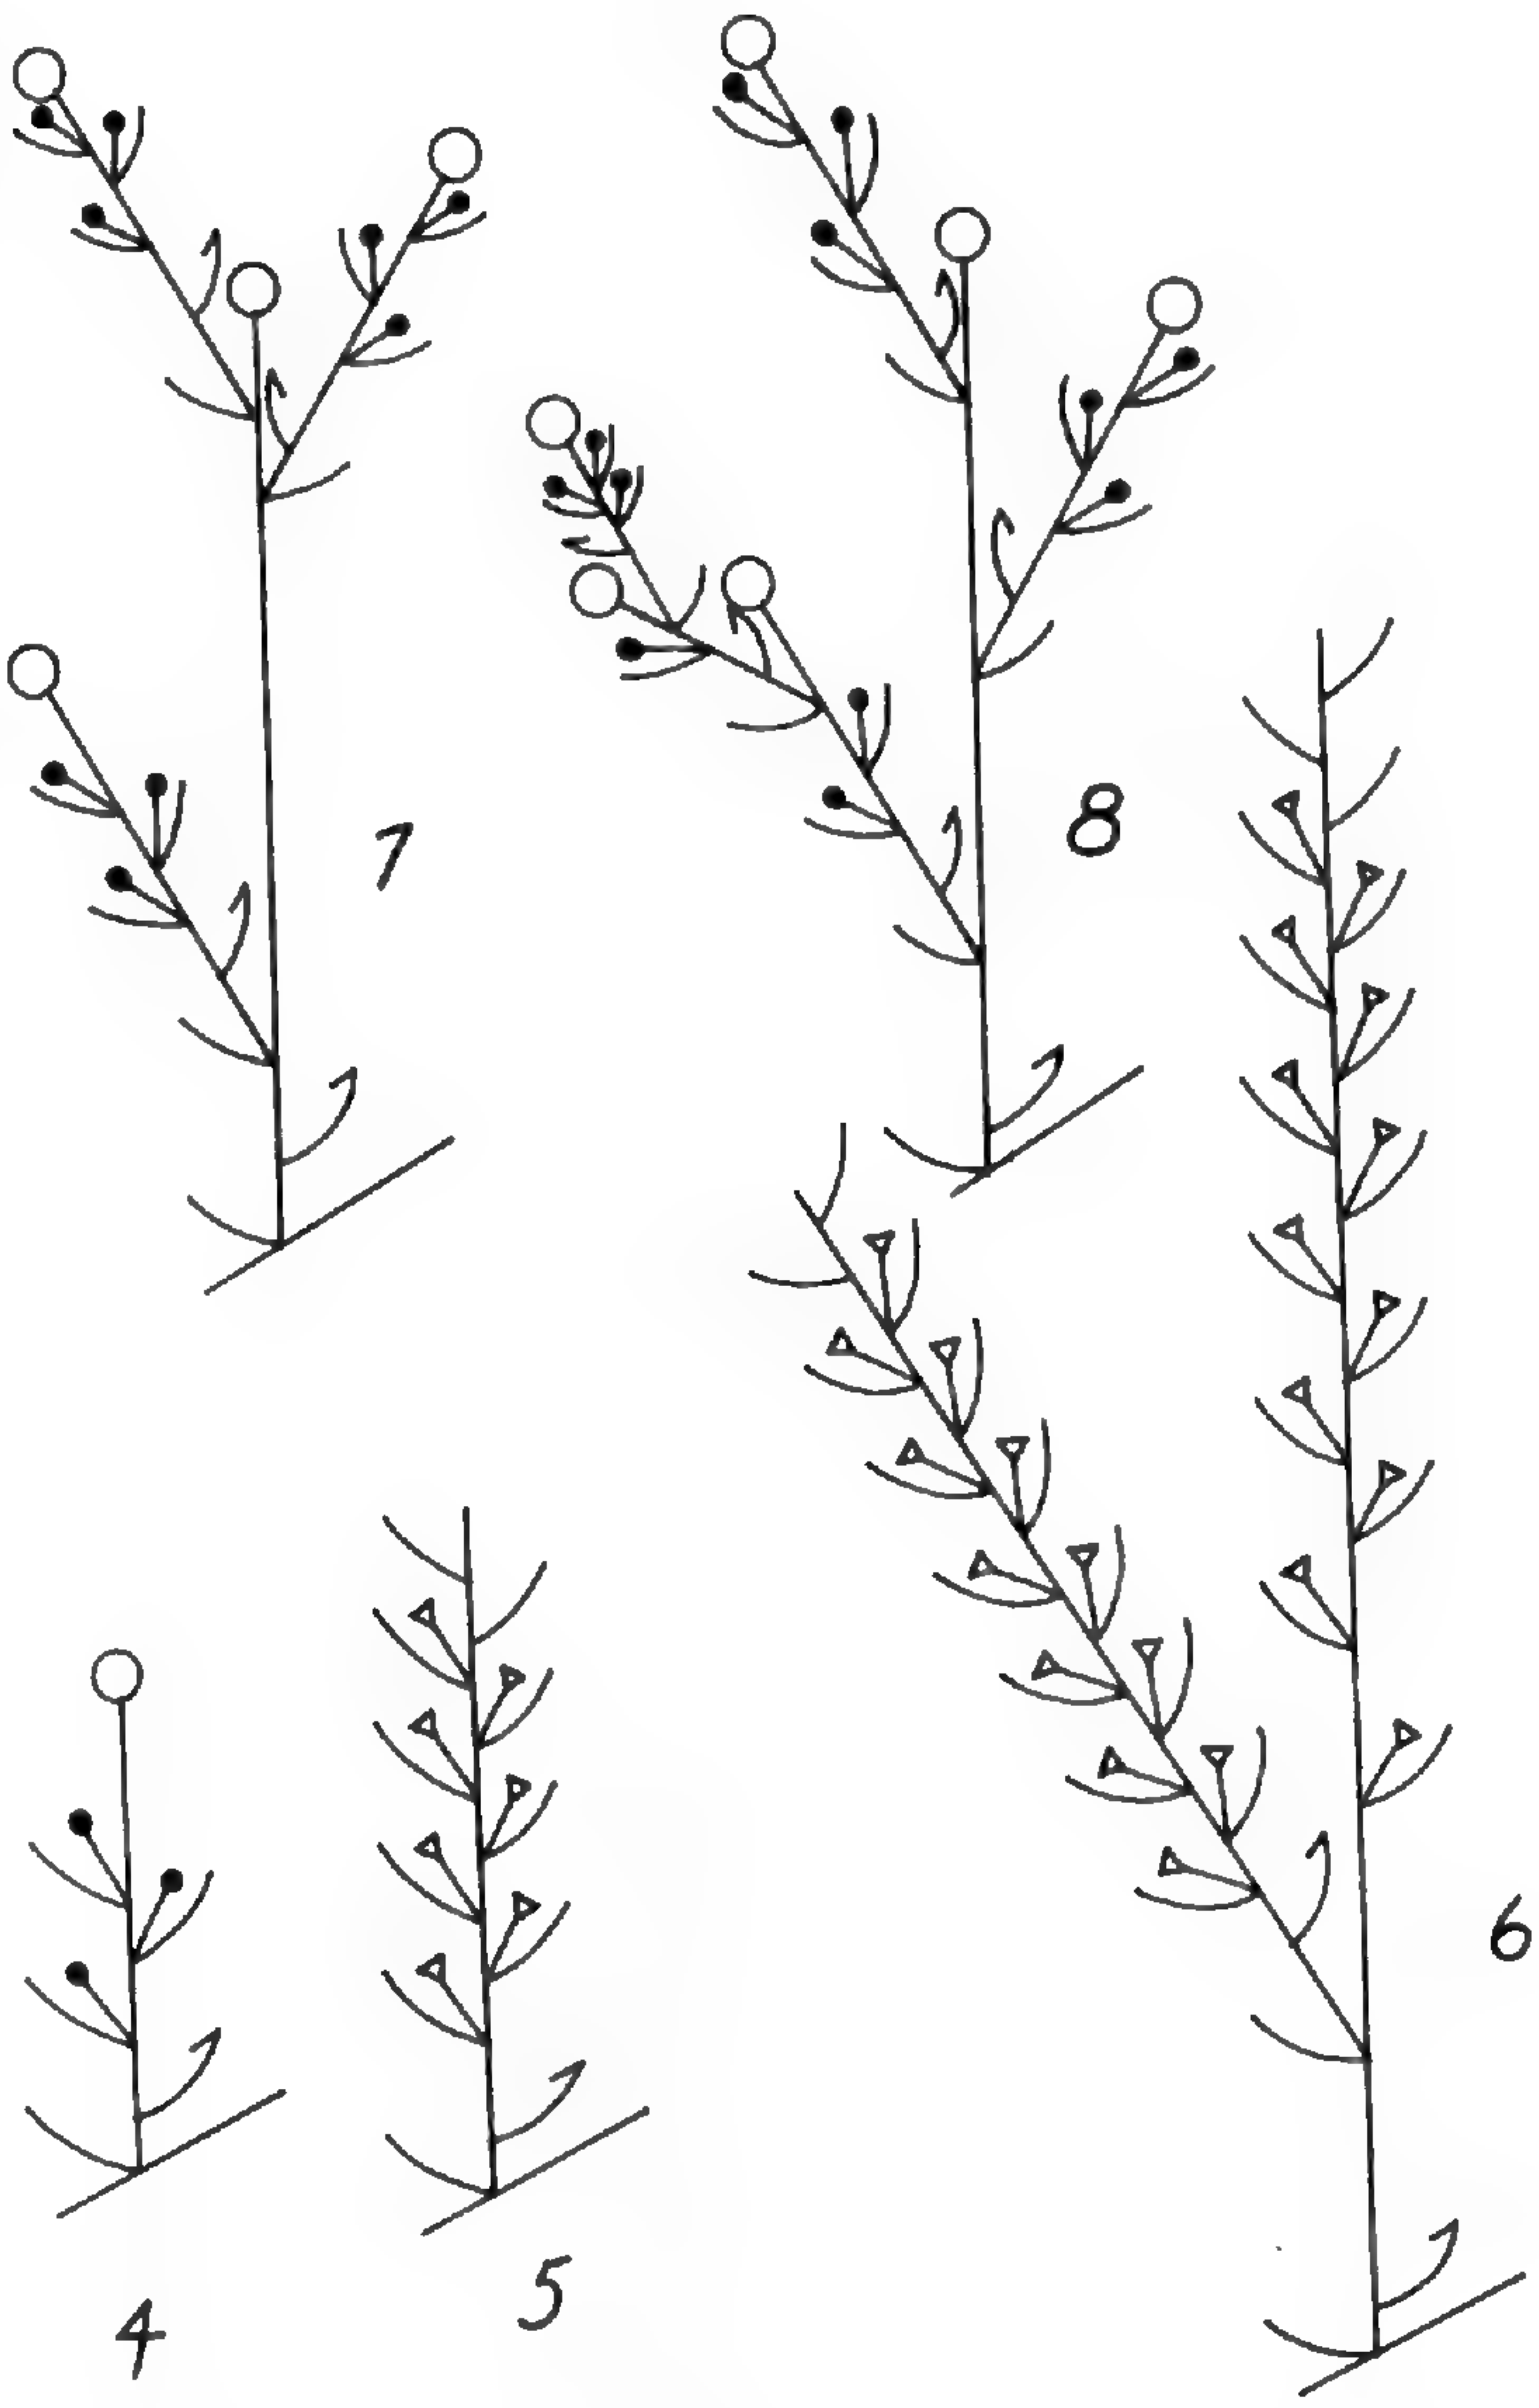
fused, thus appearing to be a single two-keeled structure. In any case, the compound spikelets near the tip of the globose heads are functionally female with never any evidence of stamens.

The functionally male compound spikelets are borne separately at the base of each inflorescence head and often also near the tip of each head, depending on the species. The number of parts is much more variable in the male compound spikelets than in their female counterparts. As in the female compound spikelets, the typical male compound spikelet is borne in the axil of a bract and the first bract on the axis is a two-keeled prophyll. The axis beyond the prophyll may be branched or not. When it is unbranched (Fig. 5), the bracts are spirally arranged, and each subtends a solitary stamen which represents the male flower. Typically, the uppermost one to six bracts in a male compound spikelet are reduced or rudimentary. There is no morphological evidence of a pistil in any of the male compound spikelets that we have observed.

In branched male compound spikelets (Fig. 6), the branch within the spikelet is borne in the axil of a bract, and the first bract on the branch is a two-keeled prophyll. All subsequent bracts except the uppermost subtend solitary stamens. In some male spikelets of *C. poeppigiana* that are branched once again, the distinction between the lowest basal bract and prophyll from the bracts subtending stamens is difficult to observe, because the bracts become smaller and narrower towards the tip of each compound spikelet. An additional difficulty is that either the lowest basal bract or prophyll may sometimes be absent.

It is unlikely, as maintained by Eiten (1976) and Koyama (1967, 1969a, b, 1971), that the axillary spikelets borne below the terminal pistil in the female compound spikelet of *Calyptrocarya* (Fig. 4) are staminate or rudimentary staminate spikelets. Rather, it seems certain that these sterile axillary spikelets represent rudimentary female spikelets of a branched female compound spikelet. This interpretation is based on three observations: (1) We have not been able to confirm the presence of stamens in such spikelets, contrary to the assertions of Koyama (1967, 1969a, b, 1971) and Eiten (1976). (2) The branched male compound spikelets are morphologically equivalent to the branched female compound spikelets. The main difference is that almost all female compound spikelets uniformly contain three branches, whereas the male compound spikelets are commonly two-branched, less uncommonly unbranched, and least commonly more than two-branched. (3) Comparison of a gradation series of female compound spikelets in different *Calyptrocarya* species shows that the axillary spikelets represent female spikelets. That the relatively simple structure of the female compound spikelet in *C. glomerulata* (Fig. 4) and *C. montesii* (Fig. 1g) represents a reduction may be seen by comparing them with the female compound spikelets of *C. bicolor*, *C. delascioi*, *C. monocephala*, and *C. luzuliformis*. In *C. bicolor* and *C. delascioi*, the axillary spikelets commonly bear larger and additional bracts compared with those of *C. glomerulata*. Such axillary spikelets in *C. bicolor* are still nonfunctional and usually do not bear a pistil. In *C. delascioi*, *C. luzuliformis*, and *C. monocephala*, on the other hand, the ax-



FIGURES 4–8. *Schematic diagrams of compound spikelets of* Calyptrocarya *species.—4. Simple female compound spikelet of* C. glomerulata.—*5. Simple male compound spikelet of* C. montesii.—*6. Branched male compound spikelet of* C. monocephala.—*7, 8. Branched female compound spikelets of* C. luzuliformis. *Symbols: large open circles = fertile female flowers; small closed circles = sterile female spikelets; open triangles = fertile male flowers; curved lines = bracts; hooked curved lines = prophylls.*

illary spikelets that surround the solitary terminal pistil are frequently fully developed, each in turn bearing a fully developed functional terminal pistil surrounded by three lateral bracts, and each of these bearing a solitary axillary sterile spikelet (Fig. 7). Instances in which these third-order axillary spikelets are functional may also be observed in *C. luzuliformis* (Fig. 8). However, in such cases of third-order branching, the number of branches is often less than three, as in Figure 8 where there are two third-order branches with one of them fertile.

From these three lines of evidence, but especially the last where we have demonstrated intergrading series of axillary spikelets in female compound spikelets from rudimentary to fully developed, the conclusion is inescapable that the axillary spikelets borne below the terminal pistil always represent female spikelets. This means that the female and male compound spikelets of *Calyptrocarya* are always borne on completely separate units of the inflorescence, exactly as in many species of *Scleria* Bergius, a closely related genus in the tribe Sclerieae.

The major feature of this interpretation, namely, that the male and female spikelets of *Calyptrocarya* are borne on separate inflorescence units, is not new, since Nees (1842) had already correctly described and illustrated the genus as having separate male and female partial inflorescences. His characterization seems to have been misinterpreted by many subsequent students of the genus, probably through false analogy with other sclerioid and mapanioid genera.

Eiten's diagnosis of *Calyptrocarya* was slightly different from Koyama's interpretation in that she noted and, in fact, illustrated (Eiten, 1976, fig. 14) axillary spikelets lacking male flowers. However, she also indicated that these axillary spikelets usually bear male flowers composed of one stamen.

At anthesis, prophylls in male and female spikelets are often torn and sometimes appear to be two distinct structures. However, this seems to result from the expansion and growth of spikelets at anthesis, and in the female spikelets especially from expansion of the achene. This commonly torn prophyll seems to be responsible for the assertion by Nees (1842), Koyama (1967, 1969a, 1971), and Eiten (1976) that the ultimate unit of the *Calyptrocarya* inflorescence is composed of six bracts. In fact, the intact prophyll can be observed readily in very young spikelets of all species and is even easily visible intact in the narrow, postanthesis male compound spikelets of *C. luzuliformis* and *C. monocephala*. It is true, as in an unusual spikelet of *C. delascioi* that we observed, that four rather than three bracts may rarely subtend the central, terminal pistil. But such cases are clearly anomalous and do not affect our interpretation of the structure of the prophyll.

KEY TO THE SPECIES OF *CALYPTROCARYA*

1a. Inflorescence composed of headlike, sessile, or nearly sessile clusters of spikelets.
    2a. Heads solitary per culm .... *C. monocephala*
    2b. Heads several per culm.
        3a. Stigmas 3; plants cespitose; involucral bracts conspicuous, longer than the head; heads usually 2 per culm .... *C. montesii*
        3b. Stigmas 2; plants rhizomatous with elongated rhizomes; involucral bracts inconspicuous, shorter than the head; heads 3–8 per culm .... *C. delascioi*
1b. Inflorescence composed of some peduncled globose clusters of spikelets arranged in a cymose panicle.
    4a. Stigmas 3; leaf blades less than 5 mm wide; utricle pubescent .... *C. luzuliformis*
    4b. Stigmas 2; leaf blades sometimes wider than 5 mm; utricle puberulent.
        5a. Culms lateral .... *C. irwininana*
        5b. Culms central.
            6a. Achenes 1.2–1.5 mm wide, 1–1.5 mm long .... *C. glomerulata*
            6b. Achenes 1.6–2.2 mm wide, 1.7–2.2 mm long.
                7a. Upper basal leaves 5–9(–12) mm wide, attenuate at the apex, mostly longer than 25 cm .... *C. poeppigiana*
                7b. Upper basal leaves (8–)10–28 mm wide, abruptly acute at the apex, mostly shorter than 25 cm .... *C. bicolor*

NIGERIAN *SOLANUM* SPECIES OF ECONOMIC IMPORTANCE

Z. O. Gbile[1] *and S. K. Adesina*[2]

Abstract

Many Solanum *species that occur in Nigeria are sources of food and medicinal products. The domesticated species especially serve as sources of edible fruits and vegetables. Many of the species remain good sources of diosgenin and solasodine, chemicals of great importance in the steroid industry.*

The genus *Solanum* is represented by some 25 species in Nigeria, including five introductions: *S. mammosum, S. tuberosum, S. melongena, S. wrightii,* and *S. seaforthianum* var. *disjunctum* (Gbile, 1987). *Solanum macrocarpon, S. aethiopicum, S. scabrum, S. melongena, S. gilo, S. indicum, S. anomalum, S. americanum, S. nigrum,* and others are domesticated, and their leaves or fruits or both are eaten as vegetables and used in traditional medicine. Many other *Solanum* species grow wild and are less known or used.

Chemical information on the Nigerian *Solanum* species is scanty and it is difficult to assess the values of these species in this regard.

The present article reports on the protein content of some domesticated *Solanum* species and also reviews the economic importance of the Nigerian *Solanum*.

SOLANUM SPECIES AS FOOD PLANTS

The common *Solanum* species that are used for food include *S. tuberosum*, "Irish potato," which grows well in the highlands; *S. melongena*, "aubergine" or "eggplant," which flourishes in the lowlands; *S. americanum*; *S. nigrum*; and the additional species listed in Table 1. *Solanum anomalum, S. gilo,* and *S. melongena* provide edible fruits. Fruits and leaves of *S. aethiopicum* and *S. macrocarpon* are edible, and only the leaves of *S. scabrum, S. nigrum, S. americanum* are eaten as vegetables. While the fruits of *S. aethiopicum* and *S. gilo* are usually eaten raw or are steamed before eating, the leaves of *S. aethiopicum, S. americanum, S. macrocarpon, S. nigrum,* and *S. scabrum* are usually boiled. The relative bitterness of the leaves and fruits dictates to a great extent which is edible vs. poisonous. Bitterness has been attributed to steroidal alkaloids in these plant parts.

DETERMINATION OF PROTEIN AND ASH (MG, P) IN *SOLANUM* EDIBLE SPECIES

MATERIALS AND METHODS

The *Solanum* species were interplanted in the same experimental plot behind the Forestry Research Herbarium, in Ibadan. After fruiting, each species was sampled and separated into edible leaves and fruits. Plant materials were dried in an oven to constant weight at 60°–70° C and ground to pass through a 1-mm sieve in a Thomas-Wiley meal in preparation for chemical analyses. All determinations were prepared in duplicates.

Nitrogen was determined by the semi-micro Kjeldahl procedure using selenium as catalyst. Percentage of crude protein content was obtained by multiplying N_2 content by 6.25. In the determination of phosphorus and magnesium, samples of 0.5 g were digested using a mixture of nitric acid and perchloric acid. Phosphorus was determined by colorimetry using vanadomolybdate yellow color development, while magnesium was also determined colorimetrically by the titan-yellow method. The results are detailed in Table 1.

SOLANUM SPECIES AS MEDICINAL AGENTS

Many *Solanum* species are used in indigenous medicine to counter ailments as listed in Table 2.

Many of these species are employed as tonics, antirheumatics, remedies for colds, fevers, and dizziness, and are eaten as vegetables for their high nutritive values or as potherb as mild anticonvulsants. Modern research has shown that some *Sola-*

TABLE 1. *Protein and ash content of some edible* Solanum *species.*

Species	Organ	% Crude Protein	% P	% Mg
Solanum macrocarpon L.	fruit	1.4	0.25	0.12
S. macrocarpon	leaf	2.4	0.44	0.40
S. aethiopicum L.	fruit	1.6	0.38	0.26
S. aethiopicum	leaf	3.2	0.37	0.38
S. scabrum Miller	fruit	1.8	0.36	0.16
S. scabrum	leaf	2.9	0.40	0.44
S. melongena L.	fruit	1.6	0.25	0.08
S. gilo Raddi	conical fruit	1.2	0.47	0.17
S. gilo	spherical fruit	1.3	0.45	0.22
S. indicum L. subsp. *distichum* Thonn.	fruit	1.4	0.46	0.27

num species have antiviral, anticancer, anticonvulsant, and anti-infective agents.

Antiviral activity has been demonstrated in extracts of *Solanum melongena*, *S. nigrum*, and *S. tuberosum* (Roychoudhury, 1980). Weak anticonvulsant activity has also been demonstrated in extracts of *S. dasyphyllum* fruit (Adesina, 1985), *S. aethiopicum* leaf, *S. americanum* leaf and unripe fruit, *S. melongena* root, and *S. scabrum* leaf and fruit (Adesina et al., 1985). Besides, all the extracts examined for anticonvulsant activity exhibited an interference on the functions of the CNS to varying degrees. Anticonvulsant activity has been related to the presence and concentration of scopoletin and related coumarins found present in most *Solanum* species examined (Adesina et al., 1985). The anticonvulsant, sedative, hypotensive, and antipyretic properties of scopoletin and scoparone have been reported before by many workers (Jamwal et al., 1972; Adesina et al., 1981; Ojewole & Adesina, 1983a, b; Adesina et al., 1985).

Chemical and biological work on immature berries of *Solanum nigrum* showed that the berries possess anticancer activity. 3-O-β-lyco-tetraoside, desgalactotigonin, and solamargine isolated from the berries showed inhibitory activity against JTC-26 (100, 97.9, 100%, respectively in concentration of 15 μg/ml) (Saijo et al., 1982). It has also been shown that the crude alkaloid fraction isolated from the leaves of *Solanum melongena* exhibited significant analgesic effect and some CNS depression in mice but no anticonvulsant action (Vohora et al., 1984). This effect was also noted for *S. scabrum* alkaloidal fraction (Adesina & Gbile, 1984).

Molluscicidal activity was examined in some *Solanum* species. All the parts of *S. americanum* were found toxic to *Biomphalaria glabrata* and *B. globosus* used as test snails and could possibly be used to check schistosomiasis.

SOLANUM SPECIES AS SOURCES OF PHARMACEUTICALLY IMPORTANT CHEMICALS

Some *Solanum* species have recently assumed great importance as rich sources of precursors of steroid drugs. Steroidal raw materials have been found useful in cardiovascular therapy, as human abortifacients, as anti-inflammatory agents, and as menopause regulants and are now known to influence the CNS. Many researchers have investigated *Solanum* species for their steroidal sapogenin and alkaloid content with a view to determining the quantities of these compounds.

Indrayanto et al. (1985) recently examined the fruit of *Solanum wrightii* chemically for its solasodine content.

Pharmaceutically important compounds diosgenin and solasodine were isolated from the tissue samples of *Solanum verbascifolium* in appreciable amounts (Jain & Sahoo, 1981a, b). The leaf was found to contain solasodine (0.26%), tomatidine (0.05%), solaverbascine (0.01%), progesterone (0.001%), 16-pregnenolone, and other compounds (Adam et al., 1979, 1980). Telek (1979) found a very good yield of crude solasodine, suitable for the commercial synthesis of 3β-acetoxy-5, 16-pregnadiene-20-one, in *S. mammosum*.

Studies on *Solanum nigrum* berries by Bose & Ghosh (1980) revealed that solasodine content of the berries varies from 5–6% in ripe berries to 4–5% in unripe berries and that this could be exploited for commercial synthesis of new drugs. Tigogenin and diosgenin have also been reported from the plant. The unripe fruit of *S. incanum*, on examination by Segal et al. (1977), led to the identifi-

TABLE 2. *Some medicinal and food uses of* Solanum *species.*

Species	Medicinal and Food Values
Solanum aculeatissimum Jacq.	Fruit used in enema, constipation
S. aethiopicum	Ripe fruits edible raw or when cooked, fruits remedy for colic and flatulence; potherb
S. americanum (L.) Jacq.	Fruit and leaf used as digestive tonic, diuretic, depurative, and antiparasitic; plant has high nutritive values and eaten as vegetable or in soup after cooking; whole plant used to remove dizziness due to epilepsy and other disorders
S. anomalum Thonn.	Serves as vegetable, laxative, and treatment of ear sores and infections
S. erianthum G. Don	Roots and fruits deliriant, purge, diuretic, and cholagogue
S. gilo	Restorative, fruit eaten raw as vegetable, has high nutritive values; remedy for fevers and dizziness, weak anticonvulsant
S. incanum L.	Used to treat syphillis, fruit for patients with high blood pressure
S. macrocarpon	Bitter fruit edible when cooked; plant cultivated as potherb, fruit and leaf eaten in soups and sauces
S. melongena	Root and boiled fruit used as antirheumatic, digestive tonic, and for veterinary purposes; all three varieties of fruit with high nutritive values as vegetable when cooked; plant used for various skin diseases and infections and to relieve excitement in nervous diseases
S. nigrum L.	Anticonvulsant, African remedy for malaria, fever, dysentery; antispasmodic, diaphoretic, and sedative; ripe fruit and leaf eaten after cooking as digestive tonic; whole plant used as medicine for eye, heart, and liver
S. scabrum L.	Anticonvulsant, digestive tonic, leaf boiled and eaten as vegetable; has high nutritive values. Whole plant sedative, depressant, anticonvulsant and antiparasitic
S. torvum Sw.	Ripe fruits edible (eaten in India) and used medicinally for liver and spleen complaints; fruits expectorant and sedative

cation of diosgenin and yamogenin in fairly large concentrations suitable for chemical development. *Solanum macrocarpon* furnished solasodine, tomatidine, diosgenin, and sitosterol on chemical hydrolysis. Recent chemical examination of some other Nigerian *Solanum* by Adesina & Gbile (1984) and Adesina (1985) revealed large amounts of solasodine, diosgenin, and tomatidenol in *S. scabrum* and *S. dasyphyllum* fruits.

CONCLUSION

From Table 1, it can be seen that the edible tissues examined contain a high percentage of protein and remain a good source of ash for use as vegetables.

Wild *Solanum* species are less studied than domesticated species. Despite this, the Nigerian *Solanum* remains a good source of pharmaceutically important chemicals and of vegetable for the teeming population.

CHROMOSOME NUMBERS OF GRASSES (POACEAE) FROM SOUTHERN AFRICA. I.[1]

Takuji Hoshino[2] *and Gerrit Davidse*[3]

ABSTRACT

Chromosome numbers and meiotic behavior are reported for 8 Namibian and 55 South African grass collections representing 30 genera and 45 species. First chromosome counts are reported for the following 13 species: Andropogon amethystinus, n = *ca. 30;* Anthephora argentea, n = *9;* Brachiaria chusqueoides, n = *9;* B. glomerata, n = *9;* Centropodia glauca, n = *24;* Danthoniopsis parva, n = *12;* Digitaria diversinervis, n = *18;* Ehrharta longigluma, n = *12;* Miscanthidium capense, n = *15;* Panicum monticolum, n = *27;* P. schinzii, n = *9;* Triraphis fleckii, n = *10;* T. ramosissima, n = *10. Chromosome counts differing from any previously reported numbers were obtained for six species. Of the 45 species, 57% are polyploid and 43% are diploid.*

This paper is part of a series contributing to a broader knowledge of chromosome numbers of African grasses. In the first we reported new chromosome counts for Zimbabwean grasses (Davidse et al., 1986). In this report we present chromosome counts for 63 collections representing 45 species and 30 genera of South African and Namibian grasses.

The major studies dealing with chromosome numbers of South African grasses are those of Moffett & Hurcombe (1949), Pienaar (1955), De Wet (1954a, b, 1958, 1960), De Wet & Anderson (1956), Spies & Du Plessis (1986a, b, 1987a, b, 1988), and Spies & Jonker (1987), although other smaller scattered reports, mostly dealing with individual genera, have also been made.

MATERIALS AND METHODS

All cytological samples studied were collected and fixed in the field January to March 1974. The methodology is the same as explained in Davidse et al. (1986). Voucher specimens (Table 1) are deposited at MO and PRE. The suprageneric classification used in this paper follows the one of Clayton & Renvoize (1986) except that we recognize the tribe Brachypodieae.

RESULTS AND DISCUSSION

A complete list of the species studied, their chromosome numbers, the generic base number derived from the determined number, and the voucher specimens is given in Table 1, where totally new counts and counts differing from any previous count for the same taxon are also identified. We illustrate only new counts (Figs. 1–4, 7, 9, 10, 15–20) and counts different from any other for a given taxon (Figs. 5, 6, 8, 11, 13, 14). Unless otherwise indicated, meiosis was regular for all taxa listed in Table 1. Comments on chromosome or base numbers without reference to original sources are based on the indices of Fedorov (1969), Moore (1973, 1974, 1975), and Goldblatt (1981, 1984, 1985).

TRIBE ANDROPOGONEAE

Diheteropogon amplectens was previously reported to be tetraploid $2n = 40$ from a Zimbabwean population (Moffett & Hurcombe, 1949). We found two collections from the Transvaal to be diploid with $n = 10$ (Fig. 13).

Heteropogon melanocarpus was previously known only as an aneuploid ($2n = 22$) from Zimbabwe (Moffett & Hurcombe, 1949). Our count establishes the existence of a eudiploid population ($n = 10$; Fig. 14) in the Transvaal.

We determined both *Miscanthidium capense* (Fig. 15) and *M. junceum* to have $n = 15$. This confirms earlier counts for *M. junceum* (De Wet & Anderson, 1956; De Wet, 1958; De Wet, 1960, as *M. teretifolium*). In addition, Brett (1954) reported *M. violaceum* to have $2n = 28$. This strong-

ly indicates that the genus has a base number of $x = 15$, which itself was probably derived by polyploidization from $x = 5$, the base number for the tribe (Clayton & Renvoize, 1986). The number in *M. violaceum*, if it can be confirmed, was probably derived by secondary aneuploidy from $n = 15$. It also gives support for the continued recognition of this genus from the related *Miscanthus*, which has $x = 19$ (Clayton & Renvoize, 1986).

TRIBE ARUNDINEAE

The $n = 24$ (Fig. 2) count for one population of *Centropodia glauca* is consistent with the $2n = 24$ reported by De Wet (1954a) and Sokolovskaya & Probatova (1978) for *C. forskalii* (Vahl) Trin., as well as with the prevalent base number $x = 6$ for the tribe (Davidse, 1988).

TRIBE AVENEAE

De Wet (1958) reported a Transvaal population of *Agrostis lachnantha* to be tetraploid with $2n = 28$, but our sample had $n = 21$ (Fig. 5) and is thus hexaploid. Meiosis in *Helictotrichon turgidulum* ($n = 14$) was slightly irregular with the common occurrence of a single quadrivalent. All other chromosomes paired as bivalents.

TRIBE PANICEAE

Brachiaria nigropedata has been reported as diploid from South Africa (De Wet, 1954b; De Wet & Anderson, 1956) and tetraploid from Zimbabwe (Moffett & Hurcombe, 1949). We now add an octoploid count ($n = 36$) based on our analysis of a Transvaal population (Fig. 6).

Echinochloa haploclada has up to now been known as a diploid with $2n = 18$ from Tanzania (Tateoka, 1965) and as diploid (Malik & Tripathi, 1969) and tetraploid ($2n = 36$) from Kenya (Yabuno, 1966). We confirmed the diploid number for a Transvaal population and also found two nearby populations to be hexaploid ($n = 27$; Fig. 8). As presently circumscribed, *E. haploclada* is morphologically variable, and broadly based cytotaxonomic studies may help interpret this variation. Since diploids have never been found outside Africa in *Echinochloa*, Yabuno (1973) considered Africa to be one of the centers of origin for the genus. Our results strengthen this interpretation.

Spies & Du Plessis (1988) reported *Panicum stapfianum* as tetraploid ($n = 18$) from a population in the southern Cape Province, whereas we determined a northern population to be diploid ($n = 9$; Fig. 11).

Pennisetum villosum, a native of northern Africa, now widely naturalized in the tropics and subtropics, has been reported as a eudiploid to euhexaploid. Bridges and fragments were observed at anaphase I in the hexaploid ($n = 27$) plant that we examined. The occurrence of triploids, pentaploids, and hexaploids with irregular meiosis suggests the likelihood of apomixis in this species.

CONCLUSIONS

The basic chromosome numbers calculated for all the genera sampled in this study agree with those previously reported. Aneuploid numbers turned up in seven species.

Based on this report and chromosome numbers previously published for South African grasses, ploidy levels were determined for all the species included in this study from any part of their distributional range. On this basis 24 species (53%) of the 45 are polyploid in some part of their range. This is somewhat on the low side for grasses in general since most estimates for polyploidy among grasses are higher than 60% (Davidse et al., 1986). Analyzing this further, 47% of the species we studied are known only as diploids, 24% only as polyploids, and 29% as both diploids and polyploids. Although this sample is small (7% of the 895 species listed by Gibbs Russell et al., 1985) and may therefore not be very representative of the southern African grass flora, the percentages of species only known as diploids and only as polyploids are the reverse of that found in the Zimbabwean grass flora (Davidse et al., 1986). Whether this represents a real geographical trend or is random variation awaits further intensive sampling of the rich African grass flora.

A PRELIMINARY LIST OF THE MOIST FOREST ANGIOSPERM FLORA OF MWANIHANA FOREST RESERVE, TANZANIA[1]

Jon C. Lovett,[2] Diane M. Bridson,[3] and Duncan W. Thomas[4]

ABSTRACT

A preliminary survey of the Mwanihana Forest Reserve, Tanzania, has yielded 440 angiosperm species. These are listed systematically, and by habitat and habit. The forests are rich in species of restricted distribution, and have affinities to the Guineo-Congolian forests of western Africa.

The Mwanihana Forest Reserve has been the focus of biological study since the discovery of a new taxon of the primate *Cercocebus galeritus* there in 1979 (Homewood & Rodgers, 1981), which prompted a proposal for the area to be given national park status (Rodgers & Homewood, 1982a). In the course of further study, a new species of sunbird (*Nectarinia rufipennis*) has been recorded from the forest (Jensen, 1983), and more than 40 new species of plants have been found. These include *Seychellaria africana*, which represents the first record of the family Triuridaceae from East Africa, and new species in the genera *Uvariopsis* and *Omphalocarpum*, which were not previously known from eastern Africa.

The following account is the result of botanical exploration of the forest in 1984 as part of a National Geographic Society expedition to the area in collaboration with the World Wildlife Fund Tanzania Forest Habitat Evaluation Project. Other aspects of the botany of the forest have been treated elsewhere (Lovett & Thomas, 1986).

The main area of study was the forest on the steep east-facing escarpment slopes above Sanje village at latitude 7°50′S and longitude 36°55′E. These slopes are the eastern edge of the Gologolo Mountains, which are the northern end of the Uzungwa range. In the study area the continuous altitudinal range of the forest is from 450 m to 1,760 m, but it is greater elsewhere on the escarpment. The rainfall is approximately 2,000–2,500 mm a year, with one wet season from November to May, when on average more than 100 mm of rain a month is received. There is a four-month dry season from July to October, when each month receives 50 mm of rain on average, and months of no rain are frequent. At higher altitudes there is a rich epiphytic bryophyte cover, indicating that a mist effect may be important in the water balance. The escarpment is dissected by steep-sided valleys separated by sharp ridge tops. The ridge tops are exposed, and so species normally occurring outside the forest habitat can be found within it. Some of the valley bottoms are flat, though nowhere particularly broad, and it is here that the forest is best developed. Elephant damage is common in the higher altitudes, and buffaloes are also present. Timber is being extracted by pit sawing, and in some areas there is considerable disturbance.

The angiosperm species recorded in the forest are arranged below according to habitat, habit, and in a systematic list. The habitat is divided into four types. The first three—Zanzibar–Inhambane Lowland Forest, Zanzibar–Inhambane Transitional Forest, and Afromontane Rain Forest—correspond to White's (1983) phytogeographic vegetation classification. The fourth division, Ridge Top Forest, is a specific vegetation type of restricted extent,

---

[1] *We gratefully acknowledge the assistance of the staff at the Royal Botanic Gardens, Kew, in naming the collections. The Tanzanian National Scientific Research Council and Ministry of Natural Resources and Tourism very kindly gave us permission to work in the Mwanihana Forest Reserve. Fieldwork was supported by the National Geographic Society and World Wildlife Fund. Langson Kusoma and Henry assisted in the field.*

being the highest ridge investigated in this study. This habitat is treated separately, as there are a number of species found only there, and it indicates which species of the Afromontane Rain Forest tend towards areas of greater exposure. The systematic list is divided into dicotyledons and monocotyledons, with families arranged alphabetically. Species and genera are arranged alphabetically within the families.

The list of species is far from complete, particularly for herbaceous and shrubby species. Many of the large trees were identified from sterile material gathered during the course of a quantitative ecological survey, and the determinations are included here because the canopy species are not often collected.

SPECIES ARRANGED ACCORDING TO HABITAT AND HABIT

The habitats follow the phytogeographical definitions given by White (1983) with the exception of Ridge Top Forest. Each habitat is given an altitudinal range and a short description of forest structure. The habit of each species is self-explanatory, except that it should be noted that a tree is a single-stemmed woody plant 10 m tall or at least 20 cm in diameter at breast height. The species are arranged alphabetically.

ZANZIBAR–INHAMBANE LOWLAND FOREST

Altitudinal range 450–750 m, canopy height 25–30 m with emergents to 40 m tall. Middle and shrub layer well developed. Herb layer sparse except in disturbed areas, where it is dominated by *Olyra latifolia.*

AFROMONTANE RAIN FOREST

For ease of data presentation, Afromontane Rain Forest is taken here to include the forest type defined as Afromontane Undifferentiated Forest by White (1983). Altitudinal range 1,200–1,700 m. In valleys and sheltered areas canopy height 25–30 m with emergents to 35 m tall. On ridges and exposed sites canopy height 15–25 m. Middle and shrub layers well developed in tall forest, middle layer not pronounced in exposed forest. Herb layer sparse in tall forest, dominated by Acanthaceae and Gramineae in more open areas.

TREES: *Agauria salicifolia* var. *pyrifolia, Albizia gummifera, Allanblackia stuhlmannii, A. ulugurensis, Alsodeiopsis schumannii, Aphloia theiformis, Beilschmiedia kweo, Bequaertiodendron magalismontanum, Bersama abyssinica, Brachylaena huillensis, Bridelia brideliifolia, Caloncoba welwitschii, Canthium captum, Casearia battiscombei, Cassipourea gummiflua, C. malosana, Chrysophyllum gorungosanum, Cleistanthus polystachyus, Coffea mongensis, Cola greenwayi, Craibia brevicaudata* subsp. *brevicaudata, Craterispermum longipedunculatum, Cryptocarya liebertiana, Diospyros amaniensis, Drypetes* cf. *arguta, Faurea saligna, Ficalhoa laurifolia, Garcinia kingaensis, G. volkensii, Heinsenia diervilleoides, Hirtella megacarpa, Isoberlinia scheffleri, Isolona hexaloba, Ixora scheffleri* subsp. *scheffleri, Lasiodiscus usambarensis* var. *usambarensis, Macaranga capensis* var. *kilimandscharica, Maesa lanceolata, Maranthes goetziana, Maytenus acuminata, Memecylon ?brenanii, M.* aff. *semsei, Myrianthus holstii, Myrica salicifolia, Mystroxylon aethiopicum, Newtonia buchananii, Ochna holstii, O. kenyensis, Ocotea usambarensis, Olea capensis, Olinia rochetiana, Ouratea schusteri, Parinari excelsa, Pauridiantha paucinervis* subsp. *holstii, Phoenix reclinata, Polyceratocarpus scheffleri, Polyscias fulva, Psychotria* aff. *trichoclada, Psydrax parviflora* subsp. *rubrocostata, Rapanea melanophloeos, Rawsonia reticulata, Schrebera alata, Strombosia scheffleri, Strychnos mellodora, S. mitis, Syzygium cordatum, S. guineense* subsp. *afromontanum, S. masukuense, Trichocladus goetzei, Trichoscyphya ulugurensis, Uvariodendron* sp. nov., *Uvariopsis bisexualis, Vepris stolzii, Xylopia aethiopica, Xymalos monospora, Zanha golungensis, Zanthoxylum* sp.

SMALL TREES AND SHRUBS: *Acanthopale pubescens, Aidia micrantha* var. *msonju, Allophylus macrobotrys, Apodytes dimidiata* subsp. *acutifolia, Bertiera pauloi, Brillantaisia nyanzarum, Casearia gladiiformis, Chassalia parvifolia, Clutia abyssinica* var. *abyssinica, Coffea mufindiensis, Craterispermum longipedunculatum, Crotalaria unicella, Crotonogynopsis usambarica, Dissotis princeps* var. *princeps, Erythrococca sanjensis, E. ulugurensis, Garcinia volkensii, Isoglossa bracteosa, Lasianthus kilimandscharicus* subsp. *kilimandscharicus, L. peduncularis, Lasiodiscus usambarensis* var. *usambarensis, Leptonychia usambarensis, Maytenus mossambicensis* subsp. *mossambicensis, M. undata, Memecylon* aff. *amaniense, Memecylon* sp. nov., *Micrococca* cf. *holstii, Mimulopsis arborescens, M. kilimandscharica, Pauridiantha paucinervis* subsp. *holstii, P.* sp. nov., *Pavetta lynesii, P. mshigeniana, P. nitidissima, P. stenosepala* subsp. *kisarawensis, Peddiea polyantha, Pseuderanthemum campylosiphon, Psychotria cryptogrammata, P. faucicola, P. goetzei, P. megalopus, P. zombamontana, P.* sp. nov., *Rauvolfia mannii, Rinorea arborea, Rytigynia caudatissima, R. hirsutiflora, R. lichenoxenos* subsp. *glabrituba, Sclerochiton obtusisepalus, Sericanthe odoratissima* var. *ulugurensis, Solanum* aff. *schumannianum, Strychnos myrtoides, Tarenna uzungwaensis, Teclea nobilis, Tricalysia pallens, Trichilia* sp. nov., *Turrea holstii, Uvariopsis* sp. ?nov., *Xymalos monospora.*

DISCUSSION

The moist forests of eastern Tanzania and southeastern Kenya are well known for the high number of species that are found only in that area (Lovett, 1988; Rodgers & Homewood, 1982b). The Mwanihana Forest Reserve is no exception, and a number of new species have been described recently from the locality (Table 1). Many other species are inadequately known and more material is needed (Table 2). Undoubtedly further exploration will reveal still more novelties.

The occurrence of species in the Mwanihana Reserve that are only found on other similar mountains demonstrates that the forests of the ancient crystalline mountains of eastern Tanzania form a distinct floristic unit. Examples include *Anglyocalyx braunii, Aningeria pseudoracemosa, Anisophyllea obtusifolia, Cephalosphaera usambarensis, Allanblackia stuhlmannii, Beilschmiedia kweo, Isoberlinia scheffleri, Newtonia pau-*

cijuga, *Polyceratocarpus scheffleri*, and *Saintpaulia ionantha*.

The forests also have links with west and central Africa. For example, the species *Cincinnobotrys oreophila*, *Crotonogynopsis usambarica*, *Isolona hexaloba*, *Olax gambecola*, *Puelia olyriformis*, *Rinorea subintegrifolia*, *Saintpauliopsis lebrunii*, *Schefflerodendron usambarense*, and *Uapaca paludosa* are also found west of the arid corridor that separates the moist forests of eastern Tanzania from the Guineo-Congolian region. At a generic level *Enantia kummeriae*, *Uvariopsis bisexualis*, *Octoknema orientalis*, and *Polyceratocarpus scheffleri* are all restricted to eastern Tanzania but are of predominantly Guineo-Congolian genera.

Links to forests in the south are found in species such as *Diospyros whyteana* and *Syzygium masukuense*, while affinities with Madagascar and the Indian Ocean islands are found in the genera *Aphloia*, *Ludia*, and *Seychellaria*.

The reason for the high level of endemism in the eastern Tanzanian moist forests on ancient crystalline mountains is not difficult to explain. The mountains have probably been in existence since the Cretaceous (Sowerbutts, 1972), and Africa reached its present latitudinal position by the Oligocene (Axelrod & Raven, 1978). The area would therefore have been under the influence of a moist tropical climate for at least 40 million years. During the last 500,000 years there have been periods of pronounced aridity in continental Africa that correspond to glacial maxima (Imbrie & Imbrie, 1980; Pokras & Mix, 1987). During the last glacial maximum (18,000 years B.P.), the temperature of the equatorial Atlantic dropped 4–5°C (van Zinderen Bakker, 1982), whereas that of the Indian Ocean in the area of eastern Tanzania was similar to that at present (Prell et al., 1980). This suggests that during the last glacial maximum the climate of eastern Tanzania was similar to that at present, whereas west and central Africa went through a period of pronounced aridity with a corresponding reduction of forest area (Hamilton, 1982). If this situation reflects that of earlier glacial maxima, then the forests of eastern Tanzania have been remarkably stable in comparison with most of the Guineo-Congolian forests.

Consequently the high level of endemism can be explained by either the extinction of species over much of their range during periods of aridity but their survival in the eastern Tanzanian forests, or by evolution by isolation in the climatically stable eastern forests.

More difficult to explain are the affinities of the eastern Tanzanian forests with the Guineo-Congolian region and Madagascar. It is unclear how far these are the results of long-distance dispersal or relicts of continuous forest links.

EXPERIMENTAL STUDIES ON SPECIES RELATIONSHIPS IN *ERYTHRINA* (LEGUMINOSAE: PAPILIONOIDEAE)[1]

David A. Neill[2]

ABSTRACT

Erythrina *L. comprises about 112 species distributed throughout the tropics and subtropics. Most species are trees or shrubs, and most are diploids with* n = *21. All are adapted to bird pollination, some by passerine birds and others by hummingbirds.* Erythrina *is subdivided into five subgenera and 27 sections. Research concentrated on sect.* Erythrina, *with 36 species centered in Mexico and Central America; selected species in other sections were also studied. Experimental interspecific hybridizations and self-compatibility trials were conducted using cultivated trees at several botanical gardens in Hawaii. Comparative morphological analyses were made of the hybrids and their parents. Studies of population structure and natural hybridization were carried out in natural populations of hummingbird-pollinated sect.* Erythrina. Erythrina *species are self-compatible, but some inbreeding depression is associated with selfing. Within sect.* Erythrina, *interspecific hybrids are obtained just as readily as are progeny from within-species outcrosses. The hybrids are vigorous, fertile, and by several measures exhibit interspecific heterosis. At greater taxonomic distances between the parental species (between sections and subgenera), crossability, viability, and fertility of the hybrid progeny are generally lower than in intrasectional hybridizations. Some hybrids were obtained between species of different subgenera indigenous to different continents. There are probably no absolute internal barriers to hybridization among all the diploid species of* Erythrina. *The genus may be characterized taxogenetically as a homogamic complex. Interspecific hybrids are intermediate between their parental species in morphological traits, including macroscopic features of the inflorescence and flower and microscopic features of the leaf epidermis. The inheritance of particular features of the male parent in the progeny allows for confirmation of hybridity. Species of sect.* Erythrina *are generally allopatric, but field studies of natural populations in southern Mexico revealed several localities where two species do occur sympatrically and where natural hybrids are found. Traplining hummingbirds, the pollinators of sect.* Erythrina, *are implicated as the agents of interspecific hybridization among sympatric species. The results of experimental hybridization, together with studies of comparative morphology and distribution patterns, suggest that some species of* Erythrina *are stabilized hybrid derivatives.*

Experimental hybridization studies have been a cornerstone of research in plant biosystematics since the emergence of this synthetic field. Much of the work of early biosystematists was directed toward efforts to define taxa and taxonomic categories on the basis of reproductive barriers as revealed by experiment, an approach exemplified by the studies of Clausen et al. (1939, 1940) and their proposal

---

[1] *This study was undertaken as part of a doctoral dissertation at Washington University, St. Louis, Missouri. Peter Raven first suggested the research on* Erythrina *biosystematics as a dissertation topic and helped in innumerable ways during the research. His ideas on plant evolution and the role of hybridization in the evolutionary process provided the conceptual framework upon which this study is based. Rupert Barneby and the late B. A. Krukoff introduced me to the the systematics of* Erythrina *and suggested relationships among the taxa of particular interest for the experimental studies. This work was made possible by the generous support of the three Hawaiian botanical gardens, and especially by the efforts of their respective directors and chief horticulturists: William Theobald and Scott Lucas at Pacific Tropical Botanical Garden; Keith Woolliams and Cecilia Ufano at Waimea Arboretum; and Paul Weissich and Daniel McGuire at Ho'omaluhia Botanic Garden. Gerald Carr at the University of Hawaii provided use of his cytological laboratory and excellent advice on the handling of chromosomes. Michael Veith provided assistance and advice with the scanning electron microscope at Washington University. Hiroshi Tobe prepared the leaf sections illustrated in Figures 19, 21, and 23. Conversations with and comments by Héctor Hernández and Peter Hoch helped to improve the manuscript. Alina Chacón and Mary Merello assisted in the preparation of the manuscript and figures. As a graduate student I was supported by fellowships from the Danforth Foundation, Washington University Division of Biology and Biomedical Sciences, and Missouri Botanical Garden. The research was funded by grants from the National Science Foundation (DEB 81-20386) and Elizabeth Neill.*

ANN. MISSOURI BOT. GARD. 75: 886–969. 1988.

to establish ecotypes, ecospecies, coenospecies, and comparia as universal units of classification to replace the traditional ones. The criteria used to define taxa on the basis of fertility relationships and the enormous labor required to obtain the experimental results on a broad scale proved impractical for a general-purpose classification system, and most present-day biosystematists have rightly abandoned the earlier efforts to "meddle" with the traditional taxonomic hierarchy.

Experimental hybridization studies continue to play a central role in research on the nature of species relationships, however, and their usefulness extends far beyond the requirements of formal taxonomy. They provide the material for a broad spectrum of integrated studies in the genetics of evolutionary divergence. Research on long-lived perennials, although it requires patience and a long-term commitment of labor and resources, is particularly amenable to hybridization programs because the parentals and several generations of offspring can be grown side-by-side, and many comparative studies can be carried out with the living plants.

This paper describes the results of experimental investigations into the biosystematics and reproductive biology of *Erythrina* (Phaseoleae), a widespread genus comprising more than 110 species, most of them tropical trees. The research was concentrated on species of sect. *Erythrina*, a complex of 36 species centered in southern Mexico and Central America (Mesoamerica), but other taxa of *Erythrina* were included in some phases of the investigation. The results of the research are used to establish a series of hypotheses regarding species relationships and evolutionary history of *Erythrina*. The hypotheses are presented here in sequence: each is dependent on the validity of the previous hypotheses.

Hypothesis 1. The species of sect. *Erythrina* can all hybridize freely with each other, and the resulting hybrids are as fertile as the parents. The section is a homogamic complex, and internal, post-mating isolating barriers between the species are absent.

Hypothesis 2. The interfertile homogamic complex encompassing sect. *Erythrina* extends, to a greater or lesser degree, to species in other sections and other subgenera of the genus. Any diploid *Erythrina* species can mate with any other to form a viable F_1 hybrid, but hybrids between widely divergent species may exhibit varying degrees of sterility. The genus as a whole may be characterized taxogenetically as a series of interfertile homogamic complexes with weak to moderate reproductive barriers between the complexes.

Hypothesis 3. The widely foraging hummingbirds that pollinate trees in sect. *Erythrina* ensure effective outcrossing even in the isolated populations of small neighborhood size and low density characteristic of these species. Self-compatibility and occasional autogamy allow establishment of a population from a single founder individual. When two species of sect. *Erythrina* are sympatric, the pollinating birds do not discriminate between them, and interspecific pollen transfer is likely.

Hypothesis 4. The species in sect. *Erythrina* are mostly restricted in geographic range and are usually allopatric, separated by habitat differences. For the most part, these factors are effective barriers to interspecific gene flow. However, sometimes different species do come into contact in nature, and then fertile hybrids are formed.

Hypothesis 5. Patterns of distribution and phenetic variation in sect. *Erythrina* indicate that some distinct forms recognized as species are stabilized derivatives resulting from hybridization of two parental species. In the changing climates and dynamic geomorphologic landscape that have characterized Mesoamerica since the Miocene, and with the consequent migration of vegetation types and mixing of floristic elements, formerly allopatric species may have come into contact a number of times. With the temporary breakdown of external isolating barriers, the interfertile species hybridized, and the subsequent segregation and stabilization of hybrid derivatives has contributed to the proliferation of *Erythrina* species in Mesoamerica.

The first two hypotheses can be tested directly by experimental hybridization programs. The third and fourth can be substantially confirmed by observations of mating behavior and patterns of variation in natural populations. The fifth hypothesis is historical and can only be inferred by drawing on information obtained by testing the first four. The "level of confidence" (Gottlieb, 1972) in the final hypothesis of hybrid speciation in *Erythrina* is dependent upon the strength of the evidence presented in this paper in support of the four antecedent hypotheses.

This research was made possible by the existence of the extensive living collections of *Erythrina* at three botanical gardens in Hawaii: Pacific Tropical Botanical Garden in Lawai, Kauai; Waimea Arboretum in Haleiwa, Oahu; and Ho'omaluhia Botanic Garden in Kanehohe, Oahu. The cultivated *Erythrina* collections were assembled, beginning in the early 1970s, through the efforts of the *Erythrina* monographer B. A. Krukoff. The gardens collectively now have in cultivation more than 90 of the 112 recognized species in the genus, and the remaining species are gradually being obtained through requests to botanists around the world for seed.

SECTION 1. EVOLUTION IN HOMOGAMIC COMPLEXES: A REVIEW

The following section provides an overview of the conceptual framework of the experimental work on *Erythrina* and a literature review of the role of hybridization in the evolution of homogamic complexes.

Grant (1953) coined the term "hybrid complex" for groups of related species linked by occasional or frequent hybridization, and he classified different types of hybrid complex based on their reproductive mode and the means of stabilization of the hybrids. In two of these complexes the hybrid derivatives are mostly or entirely apomictic: in a clonal complex the hybrids are sterile and reproduce vegetatively, and in an agamic complex they reproduce by agamospermy. In the remaining three types of hybrid complexes, the hybrid derivatives reproduce sexually: (1) in a heterogamic complex they are permanent structural heterozygotes or permanent odd polyploids; (2) in a polyploid complex they are amphiploid with respect to the parental species; and (3) in a homogamic complex the hybrid derivatives exhibit normal meiosis and are sexual diploids, homoploid with respect to the parental species.

In some groups forming homogamic complexes, internal reproductive barriers may be present and the hybrid derivatives may be partially intersterile with the parents and with each other, as revealed by Grant's studies of annual *Gilia* (summarized in Grant, 1981). More frequently, though, particularly in complexes of perennials and woody plants, the derivatives are highly interfertile with the parents, with each other, and with all the other species in the complex: the only barriers to gametic exchange between any populations or any pair of taxa in the group are external.

Grant (1953) and Gottlieb (1972) pointed out a paradox inherent in the recombinational system of the homogamic complex that sets it apart from the other types of hybrid complex. In clonal, agamic, heterogamic, and polyploid complexes, the cytogenetic features or reproductive systems of the hybrid derivatives are important criteria of hybridity and distinguish them from the parents. In homogamic complexes the derivatives are fertile and cytogenetically homogeneous with the parents, so these criteria cannot be used as a test of hybridity. Consequently, homogamic complexes are more difficult to analyze and may pass undetected.

Grant (1953) contended that in the long term the "evolutionary potential" of homogamic complexes is much greater than in other types of hybrid complex. In the clonal, agamic, and heterogamic complexes, and to a lesser extent in polyploid complexes, favorable gene combinations are stabilized in the hybrid derivatives at the cost of a severe restriction in recombination. When environmental conditions change, the derivatives are less flexible in their capacity for genetic adaptation than are sexual diploids. Should the progenitors of the complex, the original sexual diploids, become extinct, an important source of new variation in the complex is lost.

These restrictions do not apply to homogamic complexes, however. Since the derivatives are sexual diploids, recombination is unrestricted. They are able to backcross freely with the parentals, and the original species may become extinct without jeopardizing the evolutionary potential and flexibility of the complex. Relative to the other types of hybrid complex, the homogamic complex is, in the words of Grant, an "open-ended genetic system."

The maintenance of the ability to hybridize gains importance because it extends the pool of natural variation available for recombination and selection far beyond that present in any single species. In environments undergoing climatic and/or geologic change, that "extra" genetic pool may be crucial for adaptive adjustment of the organisms, and hybrid recombinants from two or more species may have greater fitness in the newly created habitats than either of the parental species. Evolution in an open-ended homogamic complex may follow a reticulate pattern, with cycles of divergence and differentiation alternating with hybridization and recombination as environmental conditions change (Raven & Raven, 1976; Raven, 1980).

The paradox is that while hybridization is most difficult to detect and analyze in homogamic complexes, on a broad scale homogamic complexes may be much more important in plant evolution than other types of hybrid complex. Grant (1953) even speculated that hybridization in homogamic complexes may account for much of the diversity of the angiosperms, and for the reticulate nature of variation and lack of clear discontinuities between the major phyletic lines of flowering plants. Grant concluded that "the ancestral stocks may have been hybridizing on the diploid (or diploidized) level since the earliest stages of angiosperm evolution."

Whether or not homogamic complexes have played such an important role in the evolutionary history of flowering plants, it is now well accepted that they are characteristic of the genetic structure of many large and ecologically dominant genera of trees and shrubs, at least in temperate regions. The only really thorough biosystematic study of a homogamic complex in a genus of woody plants, combining fossil evidence, experimental hybridizations, and careful field studies, is Nobs's (1963) exemplary work on *Ceanothus* in California. Many species of *Ceanothus* are dominant shrubs in the chaparral vegetation of that region, and all are diploid with $n = 12$. Nobs showed that since the Miocene, certain wide-ranging species in *Ceanothus* sect. *Cerastes* have formed hybrid swarms in areas where they have intermixed. In novel habitats created by an increasingly arid climate and by the exposure of new substrates such as serpentine outcrops, some of the hybrid derivatives have become stabilized as new self-perpetuating species.

Numerous studies have also been carried out on natural hybridization in *Quercus*, and this enormous homoploid genus ($n = 12$), which dominates the forests of much of the north-temperate zone, is generally agreed to comprise a homogamic complex (Muller, 1952; Hardin, 1975; Van Valen, 1976) or, perhaps more accurately, several homogamic complexes corresponding to its subgenera, with strong but incomplete barriers between them. The results of Cottam's long-term *Quercus* hybridization program (Cottam et al., 1982) considerably strengthen the experimental evidence (most of the previous hybridization studies in the genus merely analyzed morphological variation in natural populations).

Among other genera of trees and shrubs that probably comprise extensive homogamic complexes are *Eucalyptus* (Pryor, 1959), *Prosopis* (Simpson, 1977), and *Ribes* (Keep, 1962).

Most of the world's flora is made up of tropical woody plants, and the role of hybridization and the presence of homogamic complexes in these groups is largely unknown and remains a matter of dispute. Many systematists who work on tropical woody genera evidently believe that hybridization is absent or unimportant in the organisms they study, e.g., Ashton's (1969) comments on Dipterocarpaceae in Southeast Asia. Ehrendorfer (1970) thought that narrower "niche width" restricted gene flow, and a higher incidence of polyploidy and apomixis in tropical tree species made them much less likely to hybridize than their temperate-zone counterparts. It does appear logical that in species-rich tropical forests population density is low and neighborhood size is small for any one species, as well as for groups of sympatric congeners, so the opportunities for hybridization may be fewer and the hybrids harder to detect than, for example, in a temperate forest with large populations of sympatric *Quercus* species.

At any rate, the critical experimental hybridization trials have not been carried out for tropical woody plants, except for a few economically important genera. For example, strong sterility barriers have been found between Amazonian species of *Theobroma* (Addison & Tavares, 1952). In contrast, *Hevea* in the same region is probably a homogamic complex. In this homoploid genus ($n = 18$), fertile hybrids were easily obtained in experimental gardens, and numerous natural hybrids were reported (Seibert, 1947).

In many genera of tropical woody plants, all or most species share the same relatively high chromosome number and may be considered diploidized paleopolyploids. Thus, most genera of Bignoniaceae have the same chromosome number of $n = 20$; they are probably paleohexaploids based on $x = 7$ (Goldblatt & Gentry, 1979). Such plant groups may be prime candidates for the formation of homogamic complexes. Until the present study, however, a thorough biosystematic investigation on the scale of Nobs's work on *Ceanothus* had not been carried out on any large tropical woody genus or, in fact, on any other woody genus.

SECTION 2. HISTORY AND RELATIONSHIPS OF THE GENUS

Erythrina L. comprises about 112 species distributed throughout the tropical regions of the world and extending into warm-temperate areas such as South Africa, the Himalayas and southern China, the Rio de La Plata region of Argentina, and the southern United States (Krukoff & Barneby, 1974) (Fig. 1). Most species are trees or shrubs, but about 10 species occurring in climates with pronounced dry and/or cool seasons are perennial herbs with large woody rootstocks. *Erythrina* species occur in a very wide variety of habitats, from lowland tropical rainforest to very arid subtropical deserts to highland coniferous forests above 3,000 m.

The distinctiveness of *Erythrina* has long been recognized by legume systematists. Following Bentham (1865), the genus has been placed traditionally in the subtribe Erythrininae of the tribe Phaseoleae, a relationship based principally on the characteristic trifoliolate leaves that *Erythrina*

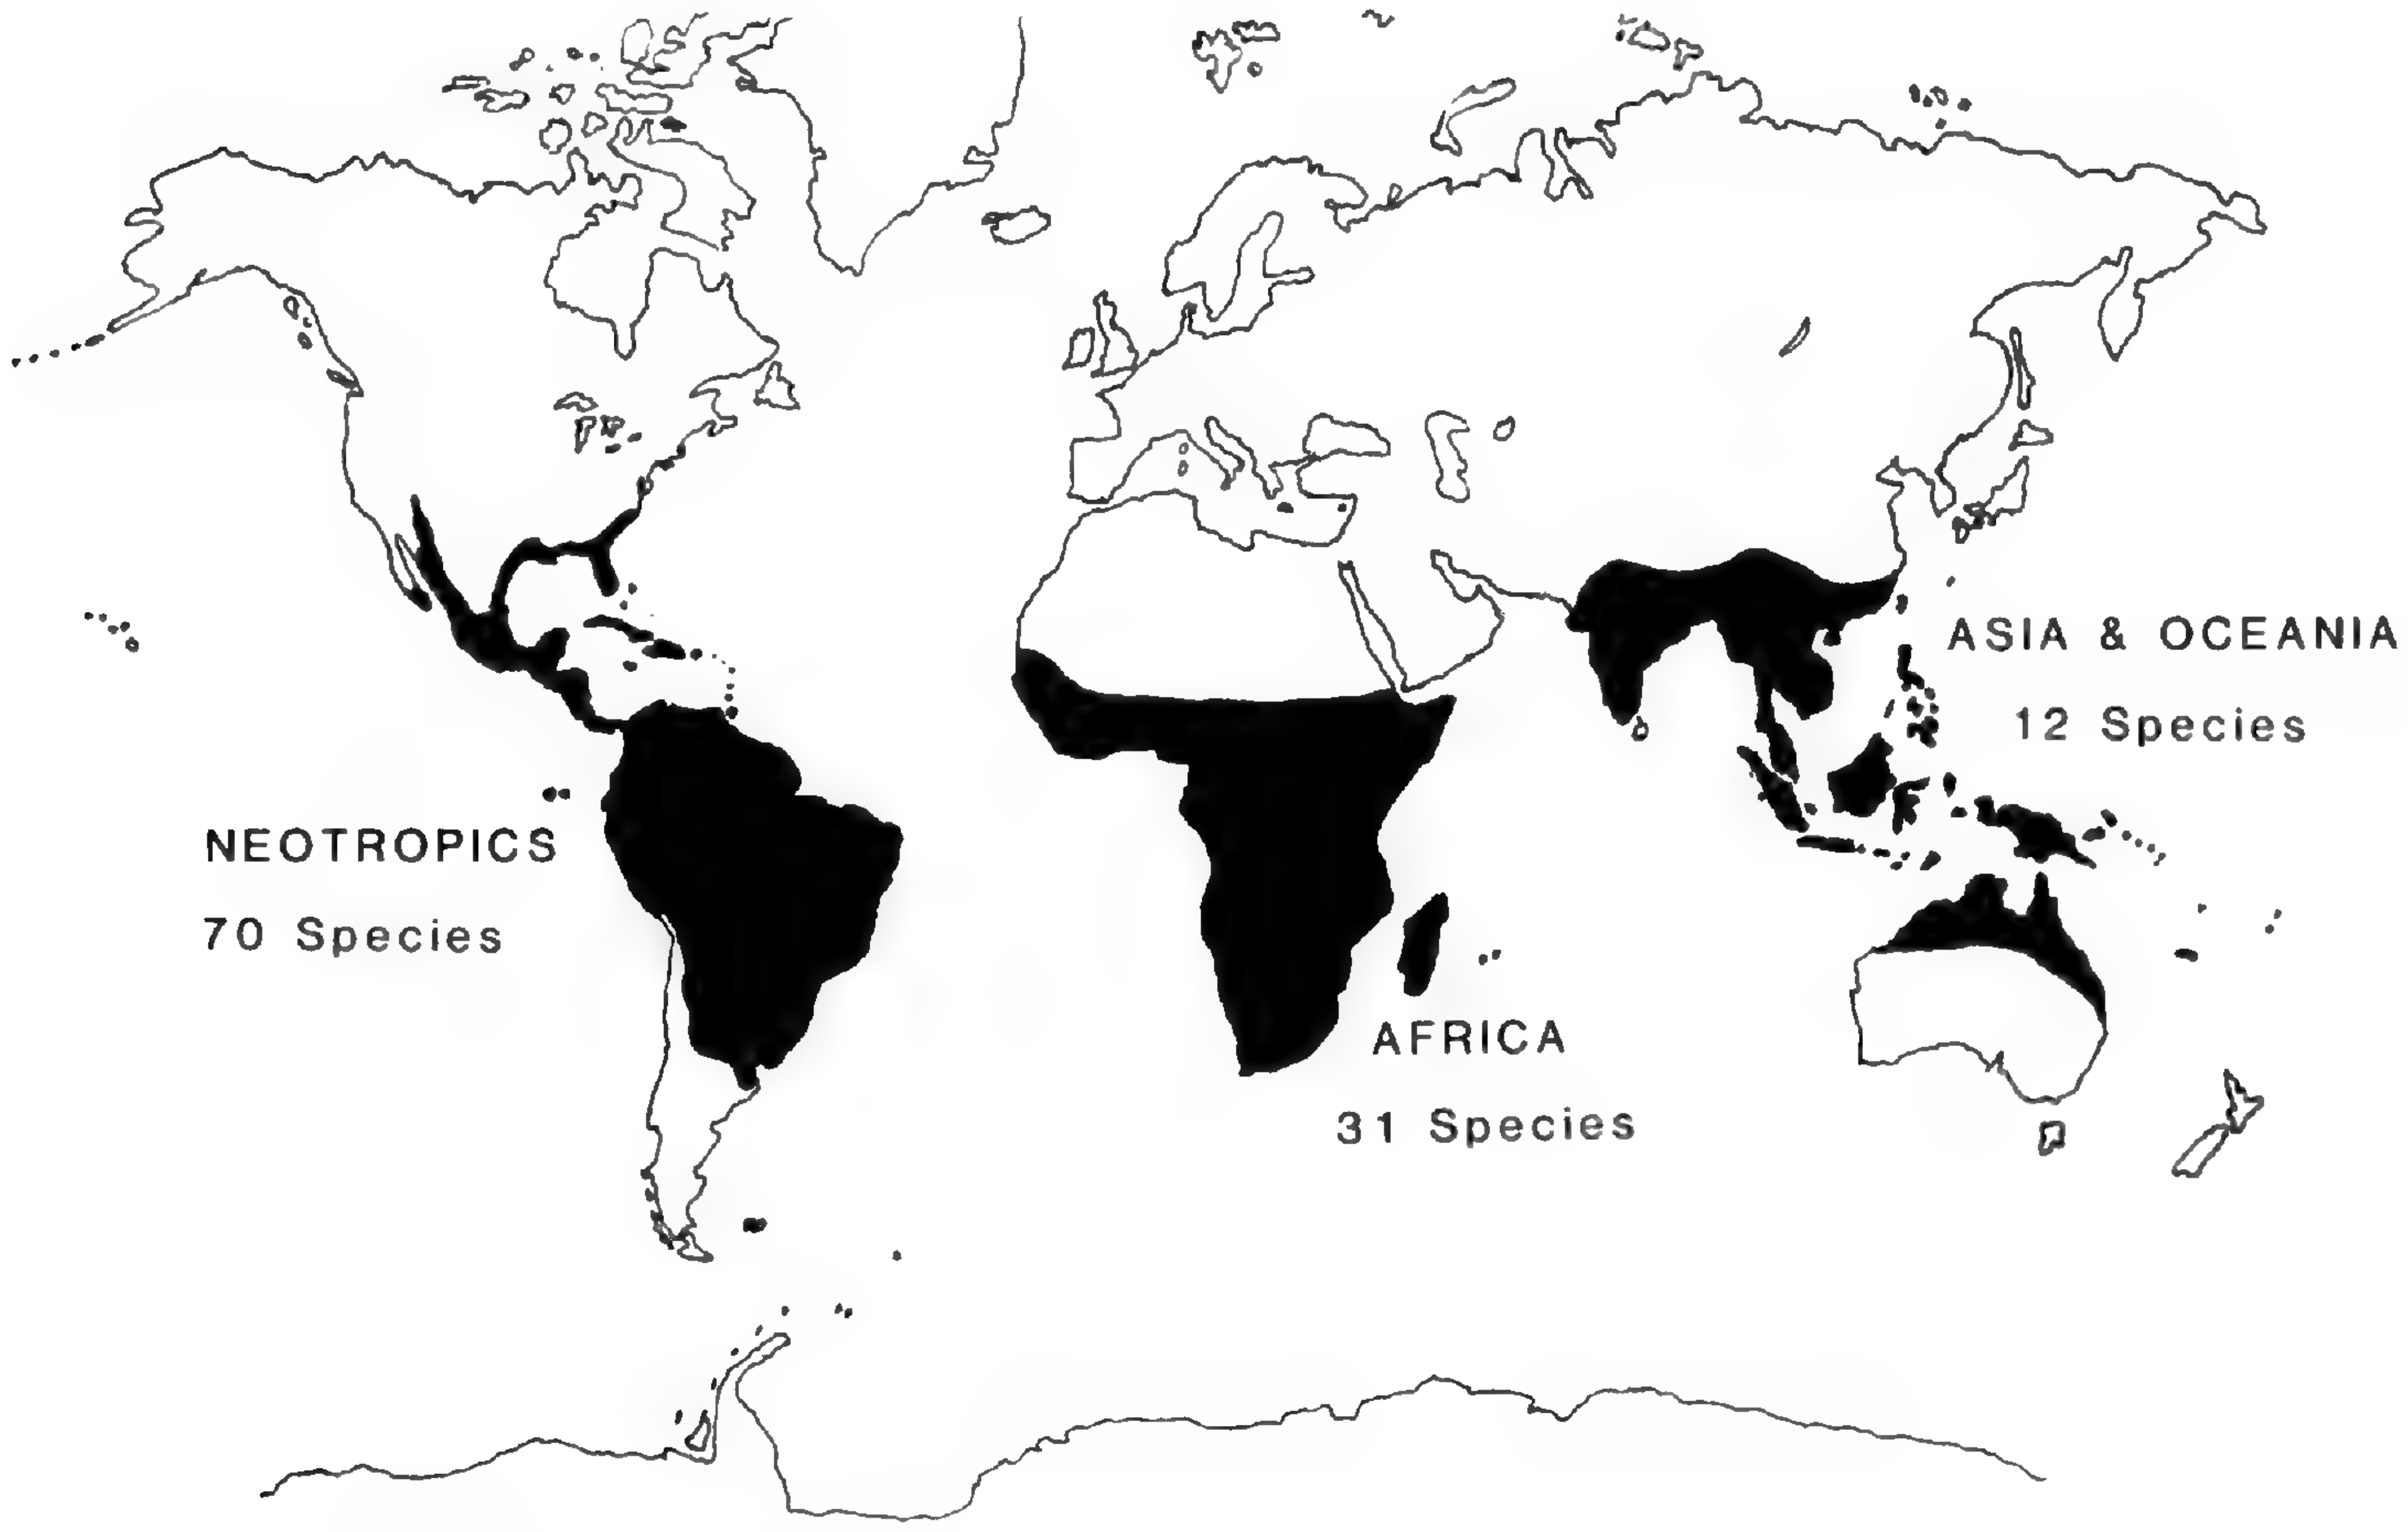

FIGURE 1. *Distribution of* Erythrina.

shares with the rest of the Phaseoleae. In a recent generic treatment of Phaseoleae, Lackey (1981) maintained the traditional classification but remarked that "the relationship of [*Erythrina*] to the remainder of the Papilionoideae is an absolute mystery . . . the genus would have long ago been accommodated outside the Phaseoleae had not the foliage suggested this tribe. In many significant characters, *Erythrina* stands alone among the Phaseoleae."

Besides *Erythrina*, the subtribe Erythrininae contains the genera *Mucuna*, *Strongylodon*, *Butea*, *Apios*, *Spatholobus*, *Cochlianthus*, *Rhodopsis*, and *Neorudolphia*. The relationships among these genera are not close and the erection of the subtribe is largely a matter of convenience to accommodate a loose assortment of genera not easily placed in other subtribes of the Phaseoleae.

Butea alone, the only other arborescent genus in the Phaseoleae, appears to have some true affinities with *Erythrina*. Baretta-Kuipers (1982) found that the unusual wood anatomy of *Erythrina* is very similar to that of *Butea*. In many other important traits, however, *Erythrina* is distinct from *Butea* and from all other legumes. The base chromosome number of $x = 21$, shared by all 86 *Erythrina* species that have been counted, is unique in the Leguminosae and indicates no direct relationship with *Butea* with $n = 9$. The unusual, high activity–low affinity nitrate reductase system present in all *Erythrina* species that have been examined differs in some respects from known nitrate reduction patterns in other angiosperms (Orebamjo et al., 1982). Neither *Mucuna* nor *Butea* (G. R. Stewart, pers. comm. to P. Raven, 1984) shares this trait with *Erythrina*. The *Erythrina* alkaloids, structurally complex isoquinolines nearly universal in the seeds of the genus, are found in no other legumes (Mears & Mabry, 1971).

Although *Erythrina* is quite distinct from the rest of the Leguminosae, and despite its great ecological and morphological diversity, the cytological and phytochemical evidence cited above and the interfertility relationships presented in this paper indicate that the genus is unusually close-knit for its size (Raven, 1974), and there is no doubt that it is monophyletic. As such, the genus is an ideal subject for the biosystematic study of diversification of an entire evolutionary clade.

The origin of *Erythrina*, like its relationship to the rest of the Leguminosae, is obscure. No fossil record of the genus has been reported. In the light of its distribution patterns, pollination, and dispersal mechanisms, and the known history of Leguminosae as a whole, Raven (1974) postulated an Upper Eocene to Upper Oligocene origin for the genus (40–30 m.y. BP), followed by ocean-drift and/or other long-distance dispersal among the three principal tropical regions of America, Africa, and Asia–Oceania. Much diversification of *Erythrina* has occurred independently in Africa and America and to a lesser extent in Asia.

The place of origin of *Erythrina* is unknown, but South America appears most likely since the majority of the putative ancestral groups (as considered by Krukoff & Barneby, 1974) within the genus are found there. Africa is also a possible candidate, since it likewise contains a number of endemic groups. Although *Erythrina* almost certainly originated well after the breakup of West Gondwanaland, it has a basically South American–African distribution that is shared by many angiospermous groups, including the Leguminosae itself (Raven & Axelrod, 1974). The *Erythrina* taxa in "tropical Laurasia," i.e., Asia and Mesoamerica, are clearly derived groups. In Mesoamerica the genus has undergone extensive recent speciation within a single lineage.

PATTERNS OF DIVERSIFICATION: POLLINATION

Erythrina species exhibit a great diversity in floral structure, inflorescence orientation, fruit morphology, seed coat coloration, and vestiture and epidermal ornamentation of foliage and calyces. The infrageneric classification of *Erythrina* is based principally on these characters.

The diversity of floral structure reflects adaptive radiation in *Erythrina* with respect to pollination mechanisms. All *Erythrina* species have red or orange flowers and copious nectar, and are adapted to pollination by nectarivorous birds. There are two distinct syndromes of ornithophily in the genus. All 42 Old World species and 15 of the 70 New World species are pollinated by "perching birds" of several families in the order Passeriformes. Passerine birds cannot hover efficiently or for any length of time, and the inflorescences of passerine-pollinated *Erythrina* are oriented in such a way that the birds can perch while feeding on floral nectar. The corolla standard is usually broad, and the flowers are open, with exposed reproductive parts. Pollen is deposited on the feeding bird's breast. The flowers of passerine-pollinated species of *Erythrina* are diverse in size, form, and orientation, which appears to reflect the variation in size, morphology, and behavior of the pollinators, which range from sunbirds and white-eyes weighing 8–10 g to orioles weighing over 35 g.

The remaining 55 New World species of *Erythrina* (nearly half the genus) are pollinated by hummingbirds (Trochilidae). Hummingbirds are the most specialized of nectarivorous birds and the only ones that hover while feeding. The corolla standard of hummingbird-pollinated *Erythrina* is narrow and conduplicately folded to form a "pseudotube," concealing the wing and keel petals as well as the reproductive parts. The flower resembles the tubular corollas of many gamopetalous hummingbird-pollinated plants, but in *Erythrina* the pseudotube is not sealed on the ventral side where the margins of the corolla standard meet. The inflorescence axis of the hummingbird-pollinated species is erect, and the flowers are oriented outward, providing no perch for the hovering hummingbirds.

Only a small number of the 315 neotropical hummingbird species are *Erythrina* pollinators, and these are all similar in size, bill length, and behavior. The *Erythrina* pollinators are principally specialized "high-reward trapliners," nonterritorial species that follow regular daily foraging routes between widely separated individual plants (Neill, 1987). The flowers of the hummingbird-pollinated *Erythrina* species are much more uniform in size and shape than those of the passerine-pollinated species, and this probably reflects the relative uniformity of pollination mechanisms among the former group.

FRUITS, SEEDS, AND DISPERSAL

The diverse fruit and seed characteristics of *Erythrina* species are indicative of adaptation for different dispersal mechanisms. The putative ancestral species (Krukoff & Barneby, 1974) inhabit coastal, estuarine, or riverine environments and have dull brown floating seeds transported by oceanic or fluvial currents. These species are effective colonizers: *Erythrina fusca* and *E. variegata* both became established on the island of Krakatoa a few years after the cataclysmic eruption of 1883 (Guppy, 1906). Since the review of Raven (1974), new anecdotal evidence has come to light concerning the dispersal of these seeds and their viability following long exposure to salt water. A drift seed of *Erythrina variegata* was recorded after a storm on the beach of Canton Island, a low coral atoll at 3°S latitude in the western Pacific, where *Erythrina* does not occur. The nearest possible source for the drift seed is Samoa, 700 km to the south. The seed, planted in Hawaii, grew into a 20-m tree (from herbarium label of *Degener 35066*, BISH).

Alone in *Erythrina*, *E. subumbrans* of Asia–Oceania has winged, wind-dispersed fruits. The Tanzanian endemic *E. greenwayi* has unusual fruits with narrow winglike ridges, but the fruits are heavy and do not appear to be effectively wind dispersed.

Most of the putative derived species of *Ery-*

thrina have bright red seeds, which persist in conspicuous display on the pods after dehiscence. Red seeds have evidently evolved independently in several lineages of *Erythrina*; one or two species in each lineage have bicolored red and black seeds. The red or red-and-black seeds are presumed to be "imitation arils" (Ridley, 1930) or mimetic berries. According to this theory, they are eaten by frugivorous birds attracted by the bright colors and are dispersed when they pass through the digestive tract unharmed, but there are few actual reports of such "mistake" dispersals. Skutch (1971) recorded an overwintering yellow-throated vireo (*Vireo flavifrons*) eating red *Erythrina* seeds in Costa Rica. I have seen this phenomenon on only one occasion, when in March 1983 in Chiapas, Mexico, I observed a migrant wood thrush (*Hylocichla mustellina*) ingest several red seeds of *Erythrina folkersii* displayed on the pods. A major autumn food item of this bird in eastern North America, before it migrates south, is the bright red, fleshy fruit of *Cornus florida*, which *Erythrina* seeds resemble quite closely (E. Morton, pers. comm.). Thus the dispersal of *Erythrina* seeds as mimetic berries by "naive" migrant birds does seem to be a real, though perhaps infrequent, phenomenon.

The "mimetic berry" theory is fraught with all of the conceptual difficulties common to considerations of the evolution of mimicry. The alkaloids in the seeds of *Erythrina* are toxic, and the deceived bird must survive the passage of the seed through its gut if it is to produce subsequent generations of birds that will disperse subsequent generations of *Erythrina*. (The alkaloids are not released unless the seed coat is broken, and frugivorous birds do not have strong gizzards to grind seeds.) Additionally, the mimic should be rare relative to the model, and the deception must occur frequently enough so that natural selection can act upon it. The question of mimetic seed coloration in *Erythrina* and other legumes is discussed in McKey (1975).

FEATURES OF THE EPIDERMIS

A great variety of special epidermal structures occurs in *Erythrina*, particularly on the abaxial leaf surfaces. These include hairs of many types, epidermal papillae and various "lamellae," and epicuticular wax deposits. The adaptive significance of these features is not known, but they are often diagnostic for particular species or species groups and often aid in identification of sterile material. Patterns of leaf epidermal features and their inheritance in interspecific hybrids are discussed later.

SUBDIVISIONS OF *ERYTHRINA*

The first formal subdivision of *Erythrina* was established by Harvey (1861), with subsequent treatments by Harms (1915), Louis (1935), and Krukoff (1939a, for the American species; 1939b, for the Asiatic–Polynesian species). In the 19th century a number of generic segregates were proposed based on the distinctive floral morphs of certain groups of species: e.g., *Chirocalyx* Meisn., *Micropteryx* Walp., *Duchassaingia* Walp., and *Hypaphorus* Hassk. These segregates were treated as sections or subgenera of *Erythrina* by later monographers. The modern classification of the genus was established by Krukoff & Barneby (1974), who recognized 5 subgenera and 26 sections. I accept their treatment as the systematic basis for the present work; a few taxonomic changes to be published later are anticipated in this paper prior to their formal designation. The infrageneric classification of *Erythrina* is summarized in Table 1. A list of the currently recognized species, with authorities and with changes in synonymy made since Krukoff & Barneby's (1974) conspectus of the genus, is included in Appendix I.

The sections of *Erythrina* are well delimited morphologically and biogeographically, and each appears to be monophyletic. The subgenera also are delimited by several good characters and appear monophyletic, except for the large and heterogeneous subg. *Erythrina*, which includes 70% of the species in the genus. The relationships of the sections comprising subg. *Erythrina* to one another still present a number of unresolved taxonomic and phylogenetic questions.

The following is a short narrative synopsis of the infrageneric classification of *Erythrina* and an outline of evolutionary and biogeographical trends; in the discussion, the taxa used in the experimental studies are emphasized.

Subgenus *Micropteryx* is restricted to South America, except for *Erythrina fusca* in the monotypic sect. *Duchassaingia*. With floating seeds dispersed by ocean currents, *E. fusca* is the only species in the genus to occur in both the Old World and the New World. It is widely distributed along coasts and rivers in the Neotropics and Asia–Oceania, as well as in Madagascar and the Mascarene Islands, but its present native range does not include continental Africa. It often occurs in extensive pure stands in seasonal swamps. With its

wide distribution and presumably primitive features (Krukoff & Barneby, 1974), *E. fusca* or a *fusca*-like ancestor may represent the original progenitor of the entire genus.

Section *Cristae-galli* includes two species, *E. crista-galli*, which forms extensive populations along the estuary of the Río de La Plata in extratropical South America, and *E. falcata*, which inhabits the "Yungas" forest of the eastern Andean foothills and similar subtropical forest vegetation in southeast Brazil. The four species of sect. *Micropteryx* inhabit riverine or upland forests of the Amazon and Orinoco basins and the Planalto of Brazil.

Subgenus *Erythrina*, with 79 species in 17 sections, is distributed throughout the three major tropical regions of America, Africa, and Asia, but no single section occurs in more than one of these areas. The subgenus includes all 55 of the American hummingbird-pollinated species in six different sections which I believe to have been derived from passerine-pollinated groups by convergent evolution in several independent lineages.

Erythrina speciosa of coastal Brazil, in the monotypic sect. *Stenotropis*, is geographically and phylogenetically isolated from the rest of the hummingbird-pollinated species. The herbaceous, hummingbird-pollinated species of sect. *Leptorhizae*, endemic to central Mexico, are probably derived directly from the passerine-pollinated shrubby/ar-

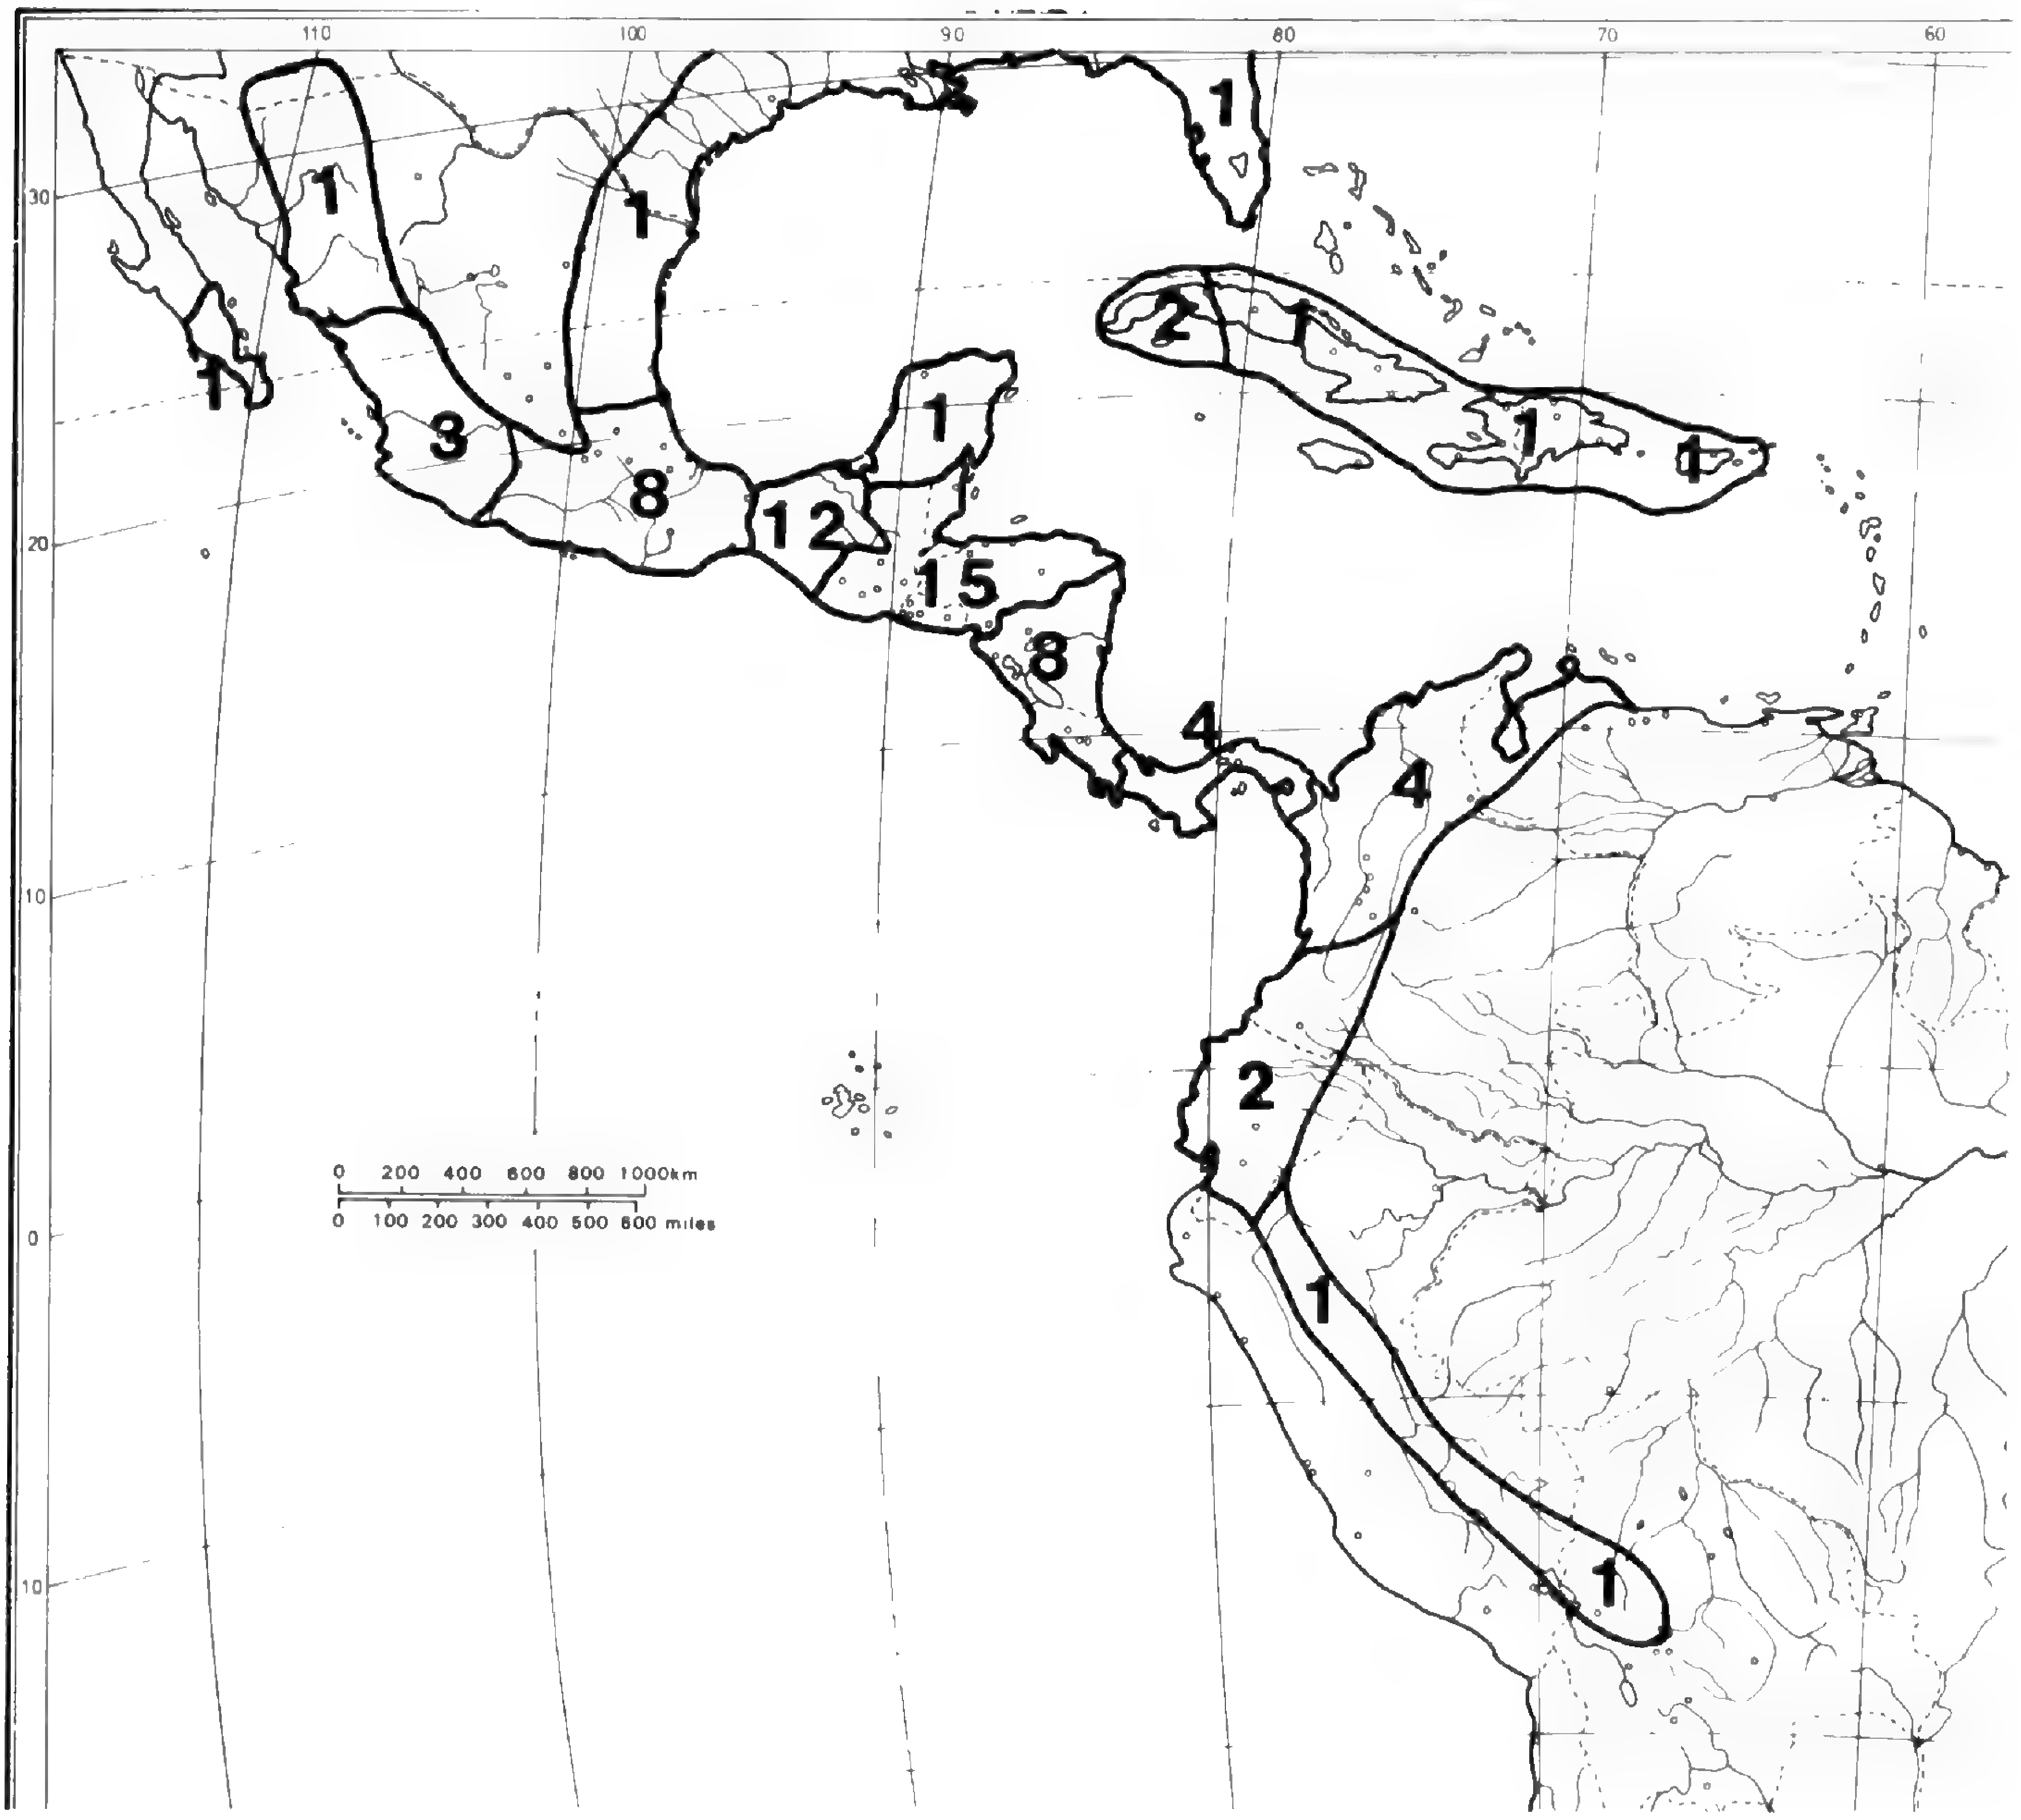

FIGURE 2. *Distribution of* Erythrina *sect.* Erythrina. *The numbers indicate the numbers of species known to occur in each geopolitical region bounded by the heavy black lines.*

borescent sect. *Breviflorae* endemic to the same region. In a parallel manner, the Andean hummingbird-pollinated sect. *Pseudo-edules* may be derived from the Andean passerine-pollinated sect. *Edules*.

The large Mesoamerican-centered, hummingbird-pollinated sect. *Erythrina* (36 species) is closely allied with the remaining hummingbird-pollinated sections; *Corallodendra*, with 9 species in South America and the Antilles, and the monotypic sections *Gibbosae* in southern Central America, and *Cubenses* endemic to Cuba. The relationship of these advanced arborescent hummingbird-pollinated groups to the rest of the genus is not clear, however.

Figure 2 shows the distribution of sect. *Erythrina* and the number of species known to occur in geomorphologically and politically delimited subregions of its range. The greatest concentration of species is in nuclear Central America, particularly in the Mexican state of Chiapas and in Guatemala. Geologically, nuclear Central America is much older than southern Central America. It has been connected to the North American continent since the Cretaceous, whereas southern Central America was only a chain of volcanic islands until the close of the Panamanian isthmus in the Pliocene (Raven & Axelrod, 1974; Coney, 1982). It is most probable that sect. *Erythrina* originated in nuclear Central America following migration of its progenitor from South America, an event that could have occurred either before or shortly after the final formation of the southern Central American land bridge. Species of this section, which comprises nearly one-third of the entire genus, inhabit nearly every forested habitat in the geologically active and climatically complex Mesoamerican region. In contrast to *Erythrina fusca* and other species that form extensive monospecific stands, the species of sect. *Erythrina* generally occur at low population densities. Many have a restricted geographic range and occur in a single vegetation type, in a rather narrow altitudinal belt, or only on particular substrates, such as outcrops of calcareous rock. Sympatry among species in the section is rare, but when it does occur, natural hybrids are generally found. All available evidence indicates that sect. *Erythrina* is an outstanding example of rapid adaptive radiation and speciation in the recent geological past.

The remaining sections of subg. *Erythrina* occur in the Old World, and their affinities to the American sections are not apparent. The South African endemic sects. *Caffrae*, *Humeanae*, and *Acanthocarpae* are the only representatives of the subgenus on that continent. Certain floral, fruit, and seed features of sect. *Caffrae* do suggest an affinity with the monotypic Mexican sect. *Olivianae*, but a plausible explanation of such a connection is difficult to imagine.

The Asian sects. *Suberosae*, *Arborescentes*, and *Hypaphorus* are an autochthonous group with mostly "primitive" features and do not appear to be closely allied with the American and African sections of subg. *Erythrina*. The species of sect. *Suberosae* possess one singularly "advanced" feature: complex reticulate "lamellae" formed by epidermal cells of the abaxial leaf surfaces (this paper, Section 5).

The monotypic subg. *Tripterolobus*, consisting of *E. greenwayi* and endemic to a small area in the Rift Valley of Tanzania, is an evolutionary anomaly. The three-winged follicular pod is unique in the genus, while the flower, as Krukoff & Barneby (1974) indicated, seems constructed from disparate elements of different subgenera.

Subgenus *Chirocalyx*, with 5 sections and 19 species, is restricted to sub-Saharan Africa. Section *Chirocalyx* comprises 14 species which inhabit environments as diverse as the Kalahari Desert, the lowland rainforests of Cameroon, the vast savannas of the Sahel, and the montane forests of eastern Zaire—a radiation reminiscent of sect. *Erythrina* in Mesoamerica, although with fewer species. The remaining sections in subg. *Chirocalyx* are mono- or ditypic, each quite distinct morphologically.

The final subgenus is *Erythraster*, with 13 species in the sole sect. *Erythraster*. It is basically an Old World group with two disjunct, derived species in the Neotropics. *Erythrina variegata*, the coastal-strand, ocean-dispersed species, occurs from Tanzania and Madagascar around the shores of the Indian Ocean and westward through Indonesia, New Guinea, Polynesia, and Micronesia to the Marquesas. The remaining species inhabit upland areas, including four in East Africa and one in Australia. There is one endemic species on each of the islands or island groups of Madagascar, Java-Bali, New Guinea, Tahiti, and the Hawaiian archipelago, and each of these may be derived independently from *E. variegata*. The disjunct *E. velutina*, widely distributed in dry forests of northern South America, the Galapagos, and the Antilles, and its Cuban endemic derivative, *E. grisebachii*, form a distinct species complex together with the Tahitian *E. tahitensis* and the Hawaiian *E. sandwicensis*. All the species of this Polynesian–Neotropical complex have "mimetic berry" red seeds, unlike *E. variegata* and most of the other species in sect. *Erythraster*. *Erythrina variegata* is present on Tahiti but not in Hawaii or the Neotropics. With this pattern of distribution, it appears most likely that these Polynesian–Neotropical disjuncts were established following long-distance dispersal by birds across the Pacific, and not by ocean-drift of *E. variegata* or a *variegata*-like ancestor.

SECTION 3. CHROMOSOME NUMBERS AND MEIOTIC BEHAVIOR IN DIPLOID AND POLYPLOID SPECIES

Erythrina is well known to be relatively uniform cytologically; polyploidy is rare, and aneuploidy is unknown (Lewis, 1974; Goldblatt, 1981a, 1984). The basic chromosome number of the genus is $x = 21$, unique in Leguminosae. Of the 65 species counted prior to the present study, 61 are diploid ($2n = 42$), two are tetraploid ($2n = 84$), one has reports of both diploid and tetraploid races, and one has reports of hexaploid ($2n = 126$) and octoploid ($2n = 168$) races.

The base number for Phaseoleae and probably for subtribe Erythrinineae is $x = 11$, and reduction to $n = 10$ is common in the tribe. *Erythrina* is likely either an allotetraploid based on $n = 11 + n = 10$ or a hypotetraploid $n = (11 \times 2) - 1$ (Goldblatt, 1981b), and thus a paleopolyploid genus.

MATERIALS AND METHODS

Floral buds were collected from trees in cultivation at three botanical gardens in Hawaii: Pacific Tropical Botanical Gardens in Lawai (PT); Waimea Arboretum in Haleiwa (WA); and Hoʻomaluhia Botanic Garden in Kaneohe (HO). Floral buds and/or seeds were collected from wild populations of certain species in Mexico and Costa Rica.

For gametic counts and meiotic analyses, floral buds in developmental series were fixed either in 3 : 1 ethanol : acetic acid or in 6 : 3 : 1 chloroform : ethanol : acetic acid, which generally provided better fixation. After 1–2 weeks in the fixative at room temperature, buds were transferred to 70% ethanol and stored below 5°C. Anthers were squashed in acetocarmine with Hoyer's solution added (Beeks, 1955) to make permanent slides.

For somatic counts, seeds obtained from wild populations were germinated on filter paper. The primary root tips were pretreated in 0.003 M 8-hydroxyquinoline for 4 hours at room temperature, fixed in 3 : 1 ethanol : acetic acid for 2–12 hours, and hydrolyzed in 10% HCl for 10 minutes at 60°C. Root tips were squashed in FLP orcein (Jackson, 1973).

Slides were examined under phase contrast with a Zeiss Universal microscope; chromosomal configurations were photographed with Zeiss MC63 equipment using Kodak Technical Pan film developed for high contrast.

RESULTS

Chromosome Numbers. Chromosome counts and voucher data are listed in Table 2. For cultivated material the original wild-collected voucher is cited if it exists; if not, a voucher made from the garden progeny is cited. All vouchers are deposited at Missouri Botanical Garden (MO) unless otherwise noted.

The gametic count of $n = 42$ for *E. amazonica* reconfirms earlier somatic counts of $2n = 84$ (Atchison, 1947; Goldblatt & Davidse, 1977) for this tetraploid. This species is distributed throughout the northern Amazon basin and in the Guianas, but all the chromosome counts to date have been obtained from populations in the Brazilian state of Maranhão. A more complete sampling of the species range may reveal infraspecific variation in ploidy level, as has been determined for other species with polyploid strains.

My count of $n = 21$ for the tropical Asian *Erythrina suberosa* is diploid and agrees with 13 previous reports for the species. Mehra (1976), however, reported $n = 42$ in three populations in the western Himalayas, at its geographic margin and altitudinal upper limit. As with *E. amazonica*, a cytogeographic survey of ploidy level in *E. suberosa* is desirable.

With the exception of *Erythrina macrophylla*, the remaining 22 chromosome counts listed in Table 2 are all first reports for species. All are diploid ($n = 21$ or $2n = 42$) except the octoploid *E. burana* ($n = 84$). This Ethiopian endemic is closely related to *E. burttii*, which ranges from Ethiopia south to Tanzania, and for which both hexaploid ($2n$ = ca. 126; Atchison, 1947) and octoploid ($2n$ = ca. 168; Goldblatt, 1981a) counts have been obtained.

Chromosome numbers are now known for 86 of the 112 species of *Erythrina* recognized here. Eighty-one species (94%) are diploid, with the remaining 5 species (6%) polyploid or variable in ploidy level. The polyploid species are all in different sections and are not closely related to one another, with the exception of *E. burttii* and *E. burana*. Polyploidization has thus occurred at least four times independently in *Erythrina*. Given the rarity of polyploidy in the genus, it seems likely that the closely related *E. burttii* and *E. burana* were derived from a common polyploid ancestor.

Chromosome counts have yet to be obtained from 25 species of *Erythrina*. Eleven of these are from Africa where three of the five known polyploids occur. Seven uncounted species are South American, where *E. amazonica* is the only polyploid known. Polyploidy is unknown for *Erythrina* in North and Central America, where 42 of the 45 native species have been counted.

Meiosis in Diploid Species. Chromosome size, morphology, and meiotic behavior were similar in all species examined. Observations of individuals of two typical diploid species, *Erythrina berenices* (WA 81s505) and *E. macrophylla* (PT 750420001), are described and illustrated here.

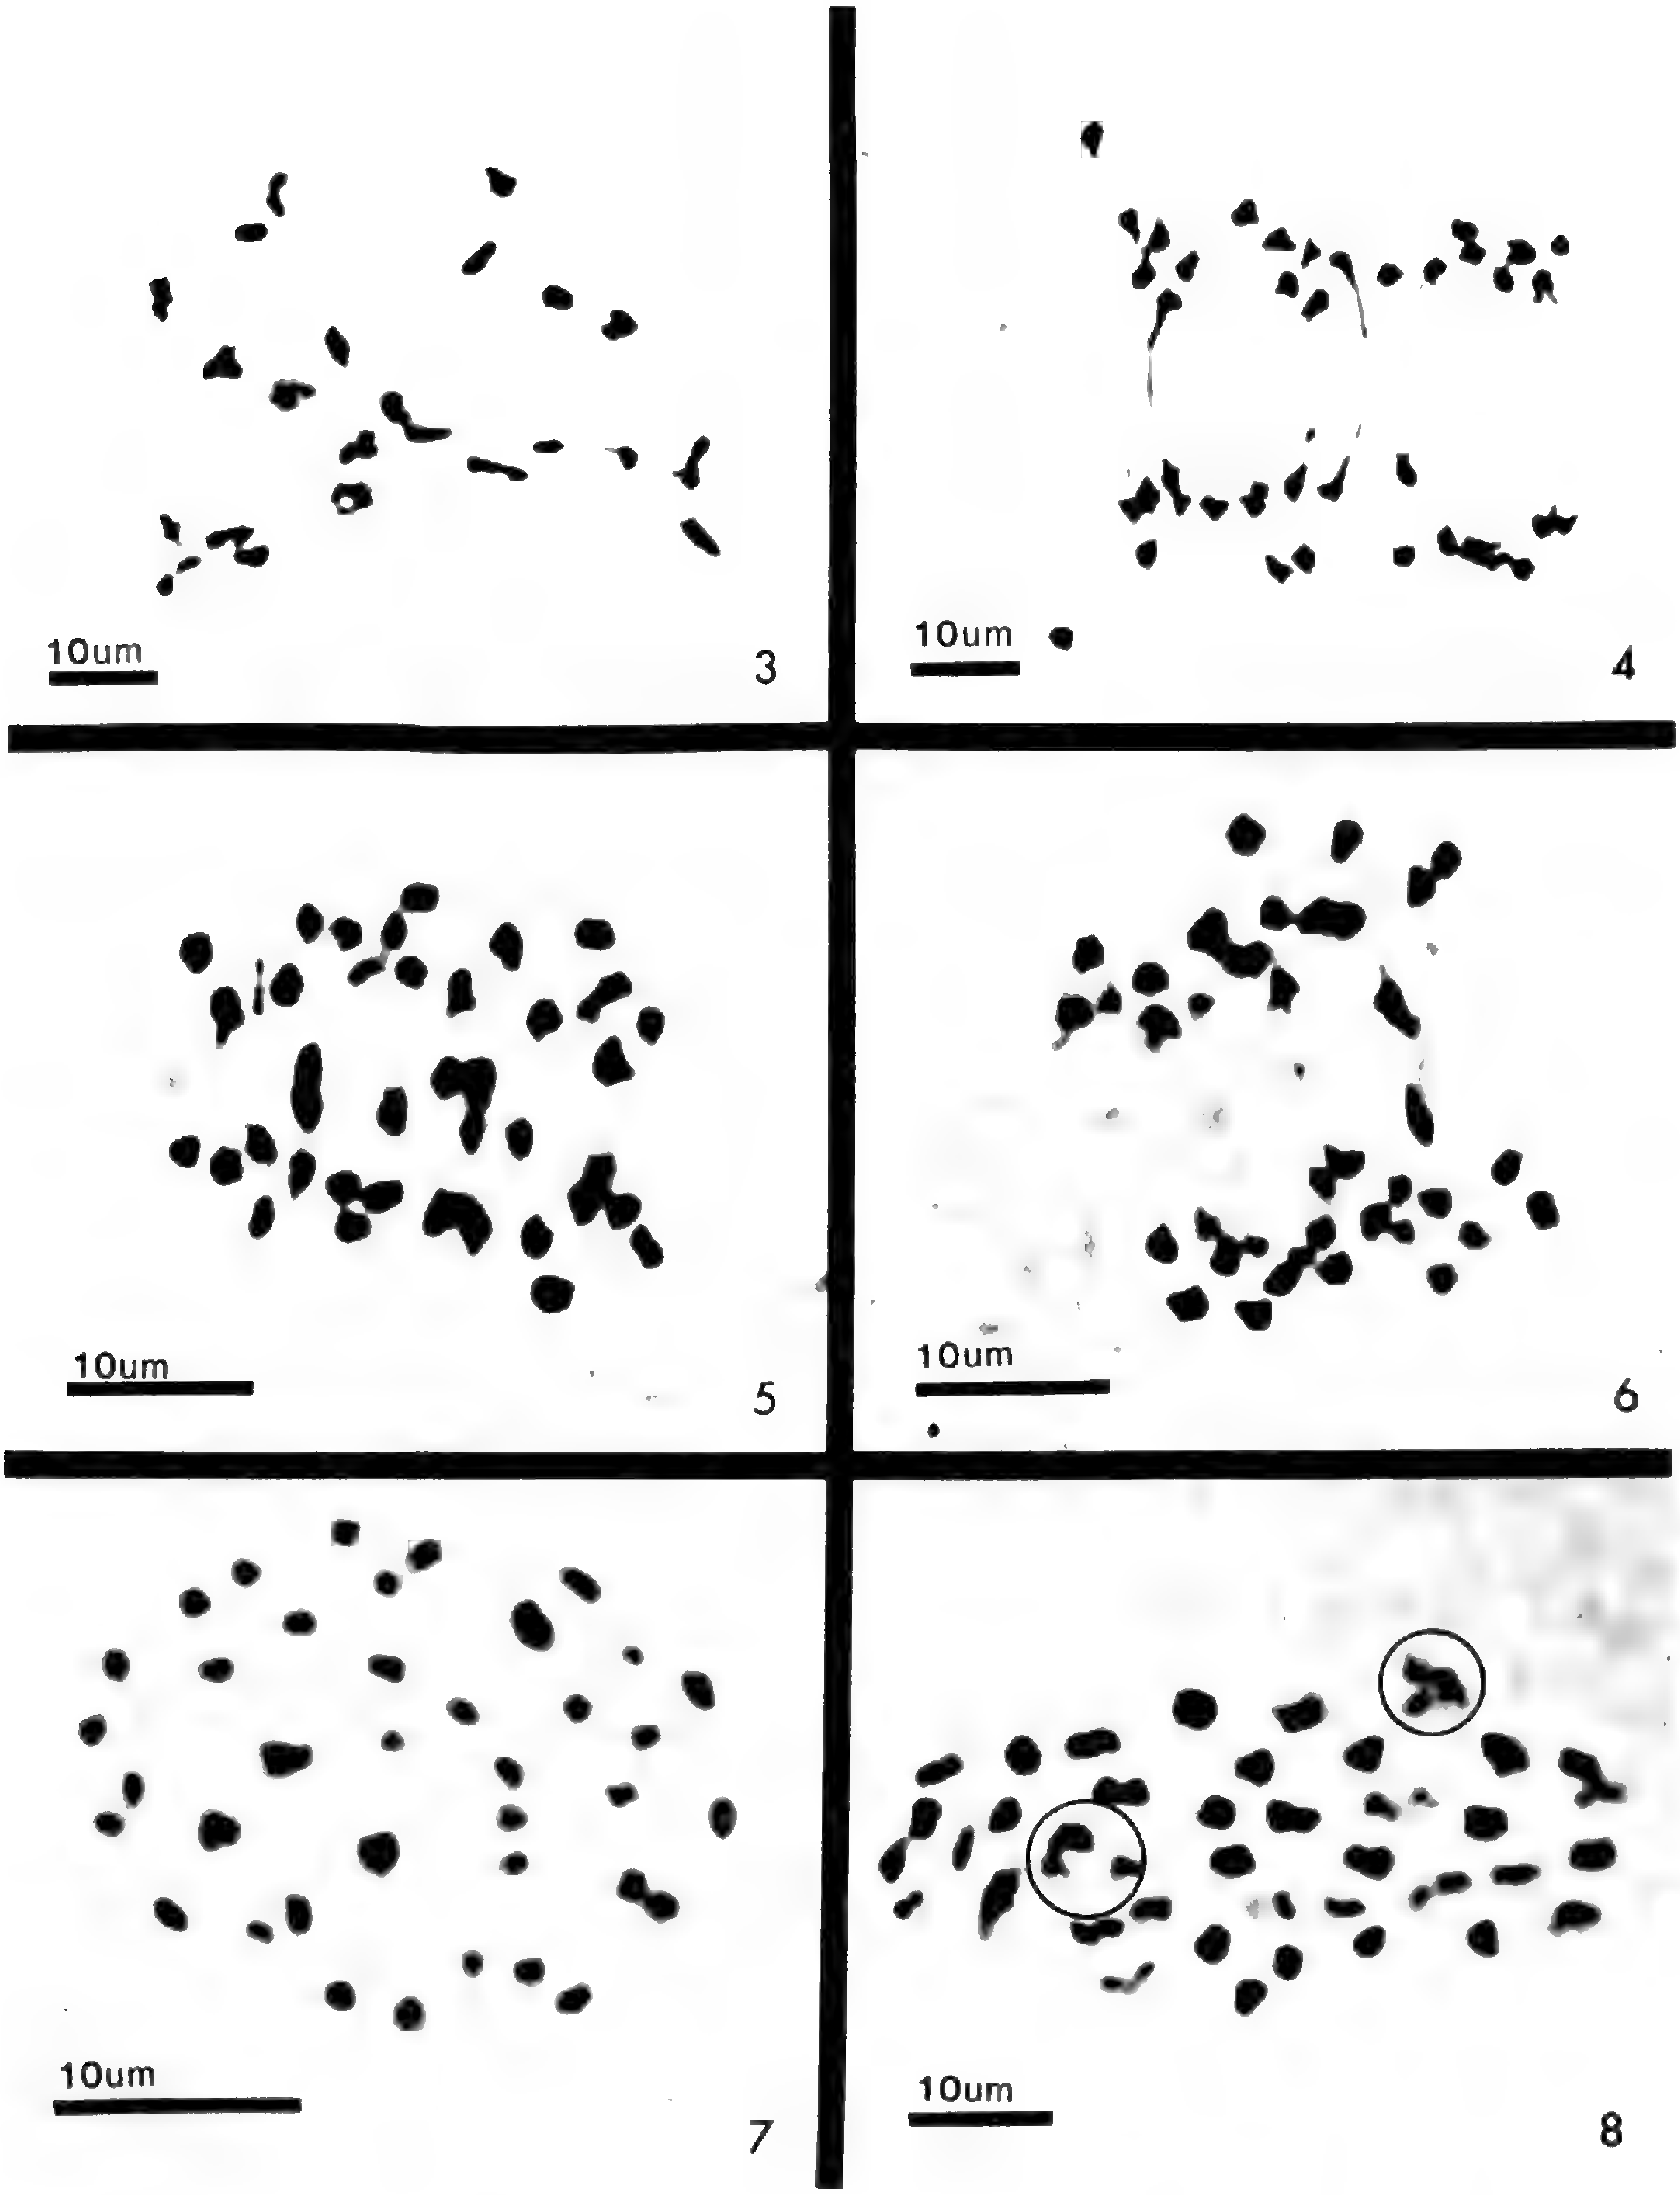
Observations of chromosome pairing at zygotene and pachytene are desirable in meiotic analyses (Jackson, 1984), but these were not feasible in *Erythrina* because of its high chromosome numbers. At diakinesis, 21 bivalents were regularly formed. Each bivalent had either one or two terminal chiasmata. In *E. macrophylla*, the average number of chiasmata per cell was 31.5 ± 1.84 out of 10 cells sampled. This accords with the figures of 31.35 ± 0.54, 31.25 ± 0.61, and 32.08 ± 0.7 chiasmata per cell reported by Jalil et al. (1982) for, respectively, *E. variegata*, *E. resupinata*, and their F_1 hybrid *E.* × *resuparcellii*.

At early to mid diakinesis, the bivalents were generally well separated, thus the gametic chromosome counts listed in Table 2 were usually made at this stage. Toward the later stages of diakinesis and as the nucleolus began to disintegrate, groups of two or more bivalents appeared clumped together in the cell (Fig. 3). Thin strands of chromatin were frequently observed to stretch between bivalents.

TABLE 2. *Chromosome counts of* Erythrina *species reported in this paper. Vouchers are housed at MO unless otherwise indicated.*

Species	*n* =	2*n* =	Voucher Data
E. amazonica Krukoff	42		WA 76s449, cultivated. Brazil. Maranhão: Lapela, *N. T. Silva 4238* (NY).
E. batolobium Krukoff & Barneby	21		Missouri Botanical Garden, cultivated (from wild-collected rootstock). Mexico. Guerrero: Filo de Caballo, 6,300 ft., oak forest, *Neill 5647*.
E. berenices Krukoff & Barneby	21		WA 81s505, cultivated. Mexico. Veracruz: Tlalnelhuayocan, *H. Perales s.n.* in 1981 (NY).
E. breviflora A. DC.	21		Mexico. Guerrero: *H. Iltis 28655*.
E. burana R. Chiovenda	84		PT 740435001, cultivated. Ethiopia. Locality unknown: *F. Meyer s.n.* in 1974. Voucher from cult.: *Neill 5716*.
E. cochleata Standley	21		Costa Rica. Heredia: La Virgen, 10 km SW of Puerto Viejo, 200 m, *Neill 5102*.
E. elenae Howard & Briggs	21		WA 80s614, cultivated. Cuba. Cienfuegos: *Centro de Investigación Forestal s.n.* Voucher from cult.: *Neill 5078*.
E. florenciae Krukoff & Barneby		42	Mexico. Chiapas: Motozintla, Cerro Mozotal, 6,600 ft., *Neill 5600*.
E. gibbosa Cuf.	21		Costa Rica. Alajuela: Cordillera de Tilarán, upper Peñas Blancas valley, below Monteverde reserve, 1,300 m, *Neill 5028*.
E. globocalyx Porsch & Cuf.	21		Costa Rica. San José: Las Nubes, 1,700 m, *Neill 5033*.
E. hondurensis Standley	21		HO 80.037, cultivated. Honduras. Tela: *Hazlett s.n.* in 1980. Voucher from cult.: *Neill 5709*.
E. horrida A. DC.		42	Mexico. Oaxaca: 2 km E of Ixtlán, road to Yavesia, 2,030 m, *M. Sousa 12634* (MEXU).
E. leptorhiza A. DC.	21		Mexico. México: Municipio Ixtapaluca, old Hwy. 190, km 25, 8,300 ft., *Neill 5646*.
E. macrophylla A. DC.	21		PT 750420001, cultivated. Guatemala. Sololá: Godinez, 6,145 ft., *B. A. Krukoff 1975-4* (NY).
E. mexicana Krukoff		42	Mexico. Oaxaca: 14 mi. SW of San Jeronimo Miahuatlán, 4,800 ft., *Neill 5423*.
E. oaxacana (Krukoff) Krukoff		42	Mexico. Oaxaca: 9 km N of Diaz Ordaz, road to Cuajimolaya, 7,700 ft., *Neill 5409*.
E. pudica Krukoff & Barneby	21		Mexico. Chiapas: 15 mi. E of Cintalapa, Hwy. 190, 2,000 ft., *Neill 5440*.
E. sacleuxii Hua	21		WA 74p1296, cultivated. Kenya: Arabuko forest, near coast, *Lavranos 11225* (NY).
E. sigmoidea Hua	21		PT 740192001, cultivated. India: locality unknown, cultivated, *D. A. Millington s.n.* in 1974. Voucher from cult.: *Neill 5715*.
E. smithiana Krukoff	21		PT 740329001, cultivated. Ecuador. Guayas: Manglaralto, *MacBryde & Herrera-MacBryde 690* (NY).
E. sousae Krukoff		42	Mexico. Oaxaca: 14 km S of San Miguel Suchixtepec, 2,100 m, *Neill 5425*.
E. suberosa Roxb.	21		WA 75s960, cultivated. India: Matrimandir Gardens, cultivated. Voucher from cult.: *Neill 5273*.
E. tahitensis Nad.	21		PT 770442001, cultivated. Tahiti: Manupa Ridge, 2,000 ft., *Perlman s.n.* in 1977. Voucher from cult.: *Neill 5177*.
E. tuxtlana Krukoff & Barneby	21		Mexico. Chiapas: 26 km N of Ocozocuautla on road to Malpaso, 2,100 ft., *Neill 5486*.

The characteristic clumping of two or three bivalents became even more common in metaphase I. At anaphase I, long strands of chromatin were frequently observed stretching between disjoining chromosomes, even after the main bodies of the chromosomes were separated by a considerable distance on either side of the equatorial plate (Fig. 4).



FIGURES 3–8. *3–6. Meiosis in pollen mother cells, diploid species of* Erythrina.—*3. Late diakinesis,* E. berenices, *WA 81s505 (n = 21). Clumping of bivalents.—4. Anaphase,* E. berenices, *WA 81s505. Sticky chromatin bridges stretch between disjoined chromosomes.—5, 6. Anaphase,* E. macrophylla, *PT 750420002 (n = 21). Late disjunction of some bivalents.—7. Mitosis in root tip cell of diploid* E. horrida, Sousa 12634 *(2n = 42). Somatic chromosomes are not clumped.—8. Diakinesis in pollen mother cell of tetraploid* E. amazonica, *WA 76s449 (n = 42). Two quadrivalents are circled.*

The chromatin connections between disjoining chromosomes appeared to be in all cases simply "matrix bridges" caused by chromosome "stickiness" (Beadle, 1932). Based on observations at subsequent stages, it is unlikely that any of the observed "bridges" were true dicentric bridges or any other configuration resulting from chromosomal inversions or translocations.

Another frequently observed phenomenon was late disjunction of one or several bivalents at anaphase I (Figs. 5, 6). One or two lagging bivalents were often present even at late anaphase I when most chromosome pairs were completely separated. However, observations of cells at later stages revealed no evidence of nondisjunction or unequal assortment of chromosomes.

In contrast to the chromosome "stickiness" and secondary association of bivalents at meiosis, somatic pairing of homologues was not observed in mitotic root-tip cells. A typical mitotic configuration of the diploid species *Erythrina horrida* ($2n = 42$) is shown in Figure 7, where there is no evidence of pairing or of sticky chromatin connections between chromosomes.

Meiosis in pollen mother cells of the Asian *E. variegata* (as *E. indica* Lam.) was depicted by Sundar Rao (1945) and in several additional Asian species by Mehra (1976). Both reported postsynaptic secondary association of chromosomes at metaphase I and subsequent stages to be common in some species. Mehra (1976) reported aberrant meiosis with 13–21 bivalents, 0–16 univalents, and 0–2 B chromosomes in a diploid strain of *E. suberosa*, while a tetraploid strain of the same species exhibited normal meiosis with 42_{II}. Jalil et al. (1982) reported normal meiosis with 21_{II} in the artificial hybrid *E.* ×*resuparcellii* (*E. resupinata* × *E. variegata*).

Pollen fertility, as estimated by Alexander's double stain technique (Alexander, 1969) was uniformly high in all *Erythrina* species examined. Seventeen individuals belonging to eight species, used as parentals in the experimental hybridization trials, had a mean pollen fertility of 95% (at least 500 grains counted per sample). Such high fertility suggests that the chromatin "bridges" and late disjunction of bivalents observed in most cells at anaphase I are not indicative of meiotic aberrations, do not result in a high frequency of aborted cells, and therefore most cells receive the correct complement of 21 chromosomes following meiosis I and II.

Meiosis in Polyploid Species. Among the tetraploid species of *Erythrina*, only a single strain of *E. amazonica* was available for analysis (WA 76s449; PT 760356001). In several individuals of this strain, 42 bivalents were observed in some cells at diakinesis and metaphase I, while in others one or two quadrivalents were clearly visible (Fig. 8). In contrast to the merely "sticky" postsynaptic associations seen in the diploids, the quadrivalents in *E. amazonica* appeared to be true multivalents resulting from synaptic pairing at prophase. The configuration of this species at meiosis I, then, is $38\text{–}42_{II}$ and $2\text{–}0_{IV}$. The formation of occasional quadrivalents did not disrupt normal disjunction, however, as no cells at telophase I or subsequent stages were observed with other than 42 chromosomes.

At diakinesis and metaphase I of the octoploid *E. burana*, considerable clumping of chromosomes was evident in all cells examined. With a large number of chromosomes crowded together, the configurations were not completely resolvable and it was not possible to determine whether synaptic multivalents were actually formed.

DISCUSSION

The postsynaptic secondary association of bivalents at meiotic metaphase observed in diploid *Erythrina* species has been reported from many other plant groups. According to a theory introduced by Darlington (1930) and amplified by Lawrence (1931), secondary pairing is due to attraction of homologous or homeologous chromosomes when the degree of homology is not close enough to result in synaptic pairing, and is presumed to be indicative of allopolyploidy. In a recently formed autotetraploid, homology between the two pairs of chromosomes will be nearly complete and a multivalent will be formed at pachytene. In an allotetraploid or in an "old" tetraploid in which the genes of homeologous chromosomes have diverged to some extent, two bivalents result; they may later form a secondary association at metaphase I or late diakinesis due to attraction between the homeologous chromosomes making up the two bivalents. Secondary pairing does not always occur, however; it is a relatively loose association and does not affect disjunction at anaphase I.

This interpretation of secondary pairing and its relation to allopolyploidy has been borne out by quantitative studies of the spatial distribution at metaphase I of marked homeologous chromosomes in the allohexaploid *Triticum aestivum* (Kempanna & Riley, 1964). In other plant groups such a rigorous quantification of secondary pairing has not been obtained, but a number of workers have inferred a history of polyploidy in groups with meiotic secondary pairing, particularly for those with high chromosome numbers suspected to be paleopolyploids. For example, Venkatasubban (1944), in a cytological study of Bignoniaceae, found a base number of $n = 20$ for the family and a presumed ancestral base number of $x = 10$, since up to 10 "secondarily associated" pairs of bivalents were present at metaphase I in many species. The evidence from secondary pairing is not unequivocal, however; in the case of Bignoniaceae, Goldblatt & Gentry (1979) believed $n = 20$ to be a paleohexaploid of a base number $x = 7$, with aneuploidy from $n = 21$.

Both Sundar Rao (1945) and Mehra (1976) noted secondary pairing in *Erythrina*, and the latter author cited it as evidence for an ancestral lower base number for the genus. On the basis of present knowledge, however, it is not possible to state unequivocally that the observed meiotic patterns in diploid *Erythrina* species are due to secondary pairing of specific homologous or homeologous chromosomes, and not simply to random nonhomologous "stickiness" of chromosomal matrix material. Multivalent formation in *E. amazonica*, a neopolyploid, does appear to be a result of true synaptic pairing of homologous chromosomes.

The hybridization trials carried out in *Erythrina* (described below) reveal a high degree of structural and genic homology in the chromosomes of all species, and it is probable that virtually any *Erythrina* genome can combine with that on the same ploidy level of any other species in the genus to form a viable F_1 hybrid. Whether tetraploid *E. amazonica* is of autoploid or alloploid origin, then, it must have two highly homologous sets of chromosomes. It is somewhat surprising that more than two quadrivalents are not usually formed in meiosis I of *E. amazonica*. It is possible that the species contains a specific gene that suppresses multivalent formation and promotes strict homologous pairing of bivalents, similar to the Ph gene which performs this function in hexaploid *Triticum aestivum* (Riley & Chapman, 1958).

SECTION 4. EXPERIMENTAL HYBRIDIZATION AND SELF-COMPATIBILITY

MATERIALS AND METHODS

Experimental hybridizations and self-compatibility trials were conducted at Pacific Tropical Botanical Garden and Waimea Arboretum February–July 1982 and February–April 1984. Although the living *Erythrina* collections at the two gardens share many accessions from the same sources, the species complement of mature, flowering individuals was different at each garden. The use of both gardens allowed a broader inclusion of taxa in the experimental studies than would have been possible otherwise.

In addition, self-compatibility trials and interspecific hybridizations were conducted with natural populations of *Erythrina chiapasana* and *E. goldmanii* at El Sumidero Canyon National Park in Chiapas, Mexico in February 1983. The two species are parapatric at El Sumidero and hybridize naturally (this paper, Section 6).

In all, 32 species were used in the interspecific hybridization trials, in 155 hybrid combinations including reciprocals. Species from throughout the worldwide distribution of *Erythrina* were used in the trials; four of the five subgenera and 12 of the 27 sections were represented. The monotypic African subg. *Tripterolobus* was the only subgenus not included. Eighteen species were tested for self-compatibility. All species used in the trials are diploids ($n = 21$) except *E. amazonica*, a tetraploid ($n = 42$). Attempts were made to hybridize *E. amazonica* as the pollen parent with several diploid species.

The hybrid combinations were selected to represent different "taxonomic distances" between the female and male parental species: "narrow hybridizations" between species of the same section, "medium hybridizations" between species of different sections in the same subgenus, and "wide hybridizations" between species of different subgenera. The narrow hybridizations involved mostly species within sect. *Erythrina*. The medium and wide hybridizations included crosses of sect. *Erythrina* to other sections and subgenera, as well as representative hybridizations not involving sect. *Erythrina*, selected to include the maximum taxonomic diversity and geographic range of the genus.

Constraints on the Experimental Protocol. Shortly after the initiation of the pollination trials, certain constraints imposed by *Erythrina* breeding systems became apparent. Other constraints were imposed by the fact that the experimental subjects were trees exposed to the vicissitudes of the weather and to local, uncontrolled variation in other factors that may affect reproductive success, such as soil fertility and moisture, and insolation. These considerations required a somewhat different experimental protocol and a different statistical treatment of the results than has been customary with biosystematic studies of greenhouse-grown herbaceous plants.

The proportion of fruit set in intraspecific and interspecific pollinations was quite low (see Results, below) and the incidence of postfertilization abortion of young fruits was very high. Pollination success and fecundity varied greatly among individuals of the same species. Some trees were effectively "female sterile": they produced no fruits either spontaneously (i.e., from "open-pollinated" flowers) or from controlled pollinations. At the same time, conspecifics and even individuals from the same accession, which were presumably at least half-siblings of the "female sterile" individuals, produced fruits spontaneously in abundance and produced fruits quite readily from both intraspecific and interspecific controlled pollinations. For many species only a single tree was available, so the use of intraspecific outcrossing success rate as a control was not possible for those species.

Another constraint was the often limited number of flowers per tree that were accessible each day. On many trees only one or a few inflorescences producing three or four new flowers each day were accessible for hand-pollination. The time required to emasculate, isolate, and pollinate each flower individually also limited the number of flowers that could be treated each day. Another practical consideration was the amount of land and labor required for growing the hybrid progeny at the Hawaiian botanical gardens. It was desirable to obtain progeny of many different hybrid combinations, so with limited resources large F_1 families of any particular combination could not be accommodated.

One positive aspect of *Erythrina* reproductive systems that influenced the experimental protocol was the relatively high viability of the seed. Among the hybrids, 45% of the seeds germinated and produced healthy F_1 plants. This high viability meant that large seed lots of any particular combination were not necessary to ensure that at least some progeny would survive to maturity.

The above considerations and constraints led to the development of procedures designed to maximize the number of "narrow," "medium," and "wide" hybrid combinations without undue emphasis on any particular combination. Once several well-formed maturing fruits were produced for any combination, pollinations of that combination were ceased and new combinations were attempted. When possible, species combinations were repeated using several different individuals as female and/or male parents. For self-compatibility trials as well, pollinations within an individual were terminated once several semimature fruits had developed.

In the course of the pollination trials it soon became apparent that certain individual trees of several species were more fecund, successful female parents than others. To the extent possible, pollination trials were concentrated on the more successful females, within the limitations imposed by the number of flowers available. Hybrid combinations or self-pollinations that failed to set fruit were repeated up to 50 times or more, but for many combinations fewer than 10 flowers were pollinated due to limitations of time and available flowers.

Pollination Techniques: Hybridization. The development of suitable techniques to emasculate, isolate, and pollinate the flowers involved considerable trial and error. Nylon mesh bags of several types were used initially to isolate the flowers, but these proved to be too unwieldy, requiring elaborate, heavy wire frames or other means of support so the mesh did not touch the flowers. Also, in rainy weather the high humidity within the mesh bags tended to cause all the flowers to abort.

A simple alternative technique that proved successful was to isolate each flower individually. Floral buds were emasculated at the latest possible stage of development, i.e., on the day before anthesis and pollen release. The tightly closed corolla standard was carefully peeled open, and the anthers were excised with dissecting scissors sterilized in 95% ethanol between each emasculation. If an anther released pollen before removal, the flower was not used in the experiment. Following emasculation, the corolla standard was folded back over the pistil and sealed with plastic Scotch tape. This effectively protected the stigma from any chance pollen deposition and also prevented it from drying out. The following day the corolla was reopened and the standard excised. After pollination a small cone of aluminum foil, formed over the point of a pencil, was placed over the stigma and pinched lightly onto the style. This helped to hold the pollen on the stigma in the face of rain and wind, and isolated the stigma from any other pollen deposition. The cap remained on the stigma throughout the development of the fruit.

For the open-corolla, homogamous species of *Erythrina* adapted to pollination by passerine birds, this technique ensured that the pollen was applied while the stigma was receptive. In most species receptivity was signalled by presence of a wet, sticky exudate on the stigmatic surface on the day of anthesis. For the closed-corolla, protandrous species (primarily sect. *Erythrina*) adapted to hummingbird pollination, the style had not elongated fully and the stigma was not yet receptive on the day following emasculation. The stigma was thus pollinated prematurely by this method, but the pollen held in place by the aluminum cap evidently remained viable at least until the next day when the stigma became receptive, and these species did set fruit with premature pollination. An alternative method, to wait two days following emasculation to pollinate the protandrous species, yielded no better results and was logistically more complicated.

Stephenson (1981) presented evidence from an extensive literature review that in many plant species, particularly massively blooming trees, only a small fraction of pollinated flowers produce mature fruits; the majority are aborted at an early stage of growth before large amounts of nutrients are channelled into them. The number of fruits that can be matured is usually limited by resource availability, not by pollination. Furthermore, flower and fruit abortion is selective: some species selectively shed self-pollinated flowers. They mature fruits from self-pollinated flowers only when fruit set is low and/or when "higher quality" fruits from cross-pollinated flowers are removed. Therefore there may be "mate competition" within a plant among fruits of different paternity.

In this study attempts were made to reduce, to the extent practical, the effects of resource limitation and competition on mating success. All flowers except the hand-pollinated ones were removed from the inflorescence. Once a few fruits were set on an inflorescence, all flower buds were removed. Until fruits were set, buds were left to develop into flowers available for further pollination trials. Most inflorescences bloomed continuously for several weeks, producing a few new flowers each day, so failed matings could be attempted repeatedly.

An individual inflorescence was treated with pollen from a single source. This eliminated mate competition among the flowers within the inflorescence. An individual tree often had several inflorescences, each pollinated with a different species of male parent, so there could have been interinflorescence competition among mates.

To further reduce resource competition and channel available nutrients into the hand-pollinated flowers, most untreated inflorescences and spontaneous, open-pollinated fruits (those accessible with clipper poles) were removed from the crowns of the trees.

In all species, seeds matured approximately 60 days after pollination. At maturity the hybrid fruit was removed and the number of mature seeds, aborted seeds, and undeveloped ovules was recorded. Length and width of each mature seed were measured for comparison with seeds produced from intraspecific matings.

Tests for Self-Compatibility, Autogamy, and Apomixis. For self-pollinations and intraspecific outcrosses, anthers were not emasculated, but the corolla standard of the flower bud was sealed with tape prior to dehiscence to prevent chance deposition of nonself pollen on the stigma. When the stigma became receptive, pollen from the same tree (for selfs) or from different conspecific trees (for outcrosses) was applied, and a cap of aluminum foil was placed over the stigmas in the same manner as in the intraspecific hybridizations.

The pollen for the outcrosses was a mixture from all available conspecific trees in the botanical garden, including individuals from the same accession as the female parent as well as from different accessions. For the self-compatibility trials carried out in the natural populations of *Erythrina chiapasana* and *E. goldmanii* at El Sumidero, the pollen for the outcrosses was a mixture of at least five different individuals in the population.

The treated flowers of an individual inflorescence were either all selfed or all outcrossed to eliminate within-inflorescence mate competition.

The abortion of young fruits during the first two to three weeks following fertilization was very high for selfs and intraspecific outcrosses, as well as for interspecific hybridizations. Fruit set data were taken at least four weeks following pollination, after which abortion of the developing fruits was negligible. Complete data on intraspecific reproductive success, including mature seed production and seed size, germination success, and viability of the progeny, were obtained only for cultivated *Erythrina guatemalensis* and *E. crista-galli*. Several individuals of these species from different accessions were available for the trials, and they were the most successful female parents in the interspecific hybridizations. For comparative analyses, then, the intraspecific data were particularly desirable for these two species. Because of space and labor limitations, intraspecific progeny could not be raised for all species.

In the flowers of sect. *Erythrina* and the other hummingbird-pollinated sections of the genus, the anthers and stigma are positioned close to one another. Initial observations indicated that, although the flowers are protandrous, autogamy may sometimes take place. Autogamy was tested by isolating entire inflorescences in wire-framed nylon mesh bags. After all the flowers had either aborted or set fruit, the mesh was removed. Six species were tested this way at Pacific Tropical Botanical

Garden during a period of relatively dry weather (May 1982) to minimize abortion of flowers caused by high humidity inside the mesh bags.

Autogamous fruits were obtained only on the most distal flowers (the last to open) on inflorescences of two individuals of *Erythrina guatemalensis* (Results, Table 4). These individuals were tested for agamospermy. On three inflorescences of each plant, all the flowers on the distal one-third of the inflorescence were emasculated before dehiscence, and the stigmas were covered with aluminum foil caps to prevent any pollen deposition on the stigma. Fruit set was monitored in the same manner as in the pollination trials.

Statistical Analysis of Results. The protocol described above was necessitated by the flowering patterns and reproductive traits of *Erythrina*, by practical limitations of breeding trees in the heterogeneous environments of open-air botanical gardens, and by the goal of obtaining viable progeny of as many "narrow," "medium," and "wide" hybrid combinations as possible. The resulting small and very unequal sample sizes for different hybrid combinations as well as for selfings and intraspecific outcrosses meant that outcomes of particular combinations could not be compared statistically. Instead, for statistical analyses hybrid combinations and intraspecific matings were pooled into broad categories based on taxonomic distance (assumed for the purposes of the study to be a true representation of relative genetic and phylogenetic distance) between the female and male parents. The five experimental treatments are: self-matings, intraspecific outcrosses, and the three categories of hybrid combinations—"narrow," "medium," and "wide" hybridizations.

For statistical analyses, mating success for each treatment was expressed as the proportion of hand-pollinated flowers producing mature fruit (i.e., a fruit with at least one fully developed, normal-sized seed). The commonly used analysis-of-variance (ANOVA) tests (e.g., Sokal & Rohlf, 1969; Statistical Analysis Institute, 1982) are designed to test the significance of differences between means of continuously variable data. ANOVA tests are inappropriate for categorical (either/or) data, such as mating success, where the outcome of a pollination attempt falls into one of only two categories. A multiple comparison test for differences between proportions, appropriate for categorical data, was devised by Alan R. Templeton for these analyses. Templeton's test allows for pairwise comparisons of all combinations of the five treatment categories; also, categories can be pooled to test various hypotheses regarding mating success (e.g., all intraspecific vs. all interspecific matings).

The null hypothesis for the test was that there is no difference in proportion of mature fruits produced among any of the pollination treatments. This is a corollary of the central hypothesis of this research: that there are no interspecific or self-incompatibility barriers to mating within *Erythrina*, that any pair of gametes from any species in the genus are equally likely to pair successfully, form a viable zygote, and grow into a healthy adult sporophyte regardless of the infrageneric taxonomic position or putative phylogenetic distance between the parents.

Templeton's test is an inequality that compares the differences between proportions with their variances. Proportions are subjected to an arcsine–square root transformation to set the variance independent of the mean; the variance is inversely proportional to the sample size. The 95% confidence limits of the proportion are:

$$X = \arcsin\sqrt{\frac{F}{N}} \pm 1.96\sqrt{\frac{1}{4N}},$$

where F = number of mature fruits (successful matings); N = number of flowers pollinated (attempted matings).

For small sample sizes ($N < 50$), the arcsine–square root transformation is corrected:

$$X = \frac{1}{2}\left(\arcsin\sqrt{\frac{F}{N+1}} + \arcsin\sqrt{\frac{F+1}{N+1}}\right).$$

For the general case, the null hypothesis is rejected at $P = 0.05$ if the inequality is true:

$$\left|\sum a_i X_i\right| > 0.98\sqrt{\frac{a_i^2}{N_i}},$$

where X_i = the arcsine–square root transformed proportion of successful matings in the ith category; N_i = sample size (total number of flowers pollinated in the ith category); and a_i = a weighting factor set so that $|\sum a_i| = 0$.

The a_i for each category is proportional to the sample size N_i.

For pairwise comparisons between categories i and j, the inequality is simplified; the H_0 is rejected at $P = 0.05$ if it is true that

$$|X_i - X_j| > 0.98\sqrt{\frac{1}{N_i} + \frac{1}{N_j}}.$$

For a test of "highly significant" difference at

$P = 0.01$, the term "0.98" on the right side of the inequality is replaced by the value "1.28."

Several individuals of *Erythrina guatemalensis* and *E. crista-galli* were the most fecund, successful females in the interspecific hybridizations as well as the intraspecific matings. For all categories employing these two species as female parents, separate multiple comparison tests were used to compare mating success. These comparisons included both selfings and intraspecific outcrosses for *E. guatemalensis* but only selfings for *E. crista-galli*, which had only one individual in flower at each garden (Pacific Tropical and Waimea) when the pollinations were conducted.

Separate statistical tests were carried out for the self-compatibility trials of individual species. For those species with analyzable data on fruit set of self-pollinations vs. intraspecific outcrosses, the data were ordered into 2 × 2 contingency tables. With small sample sizes and values of less than 5 in many cells of the contingency tables, the standard chi-square test was not appropriate; so Fisher's exact probability was computed for the outcomes (Sokal & Rohlf, 1969). For the pooled self-compatibility data including all species tested, the sample size was large enough for a chi-square test.

F_1 Hybrid Viability. The F_1 hybrid seeds were planted within a few weeks after harvest. To the extent possible, seed lots of each hybrid combination were divided for propagation at two sites. The F_1 plants were raised by the horticulturists at Pacific Tropical and Ho'omaluhia Botanical Gardens, who monitored germination success, growth, and vigor of the hybrids. Evaluations were made approximately once each six months using a standardized form. Survivorship, growth rates, and indications of chlorosis or other abnormalities were recorded.

The multiple comparison test described above for analysis of fruit set was employed for a statistical evaluation of hybrid viability, defined as the proportion of seeds in each category that germinated and survived as healthy plants for six months (after which mortality in the garden was negligible). Viability of the "narrow," "medium," and "wide" F_1 hybrids was compared, together with that of the "narrow" F_2 hybrids in sect. *Erythrina* (see below). Seeds from controlled intraspecific matings of *Erythrina guatemalensis* and *E. crista-galli* were planted along with the hybrids. For each of these species a separate multiple comparison test was conducted for viability of "intraspecific" seed vs. hybrid seed having these two species as female parents.

F_1 Hybrid Fertility. Many of the narrow hybrids between species in sect. *Erythrina*, produced in 1982, grew to be 4-m trees and produced flowers by February 1984. By several different measures of fertility, these F_1s were compared with the parental species and their meiosis examined. As an estimate of pollen fertility, percentage of stainable (nonaborted) pollen was determined for the F_1 hybrids and their parents using Alexander's double stain technique (Alexander, 1969) (at least 500 grains counted per sample) and compared with a one-tail *t*-test.

Fecundity of F_1 Hybrids. As discussed earlier, one goal of the hybridization study was to assess the relative fitness of the hybrids in comparison with their parents. The viability, vigor, meiotic regularity, and pollen fertility of the hybrids are indicators of fitness, but a more direct measure is their relative reproductive success vis-à-vis that of the parental species. During the period of this study the F_1 hybrids, although some of them produced flowers and fruits, did not grow into full-sized adult trees, so a thorough assessment of hybrid fecundity and fitness was not possible. However, a preliminary indication of reproductive success was obtained from the two-year-old narrow hybrids in sect. *Erythrina* that flowered in the spring of 1984.

Controlled self-pollination of some of these F_1 hybrids was conducted in order to obtain seed for a limited number of F_2 families. The multiple comparison test was employed for pairwise comparisons of mating success (proportion of hand-pollinated flowers producing mature fruits) between the selfed F_1s and their parental species. Different categories of parental matings varied among themselves in mating success, and several types of parental matings were compared with the selfed F_1s. The pairwise comparisons of fruit set included: 1) selfed F_1s vs. their own parental matings, i.e., the original hybridizations that produced the F_1s used in the trials; 2) selfed F_1s vs. all paired combinations of the parental species, including the reciprocals that failed to produce F_1 hybrids; 3) selfed F_1s vs. selfed parental species. The logic for using these particular groupings of parental matings in the comparative assessment of F_1 reproductive success is discussed in the Results.

Viability of F_2 Hybrids. Many of the F_1s also produced fruit and mature seed spontaneously on open-pollinated inflorescences, almost certainly the result of autogamy. F_2 seed lots from selfed flowers, and some from open-pollinated flowers, were planted along with the 1984 F_1 hybrids. The viability of the F_2 progeny was compared with that of the F_1s.

Studies of Previously Synthesized Hybrids. A few *Erythrina* hybrids have been produced in the past by horticulturists and are commonly grown in tropical and subtropical regions. Two were available at the Hawaiian gardens: *Erythrina* ×*bidwillii* and *E.* ×*sykesii.* Studies of meiosis, pollen fertility, and fruit set from controlled self-pollinations were conducted on these plants with the methods described above.

Hybrid Names. In this paper horticultural convention (Brickell et al., 1980) is followed for the hybrid names. For artificial hybrids when the female parent is known, the female parent is first in the hybrid formula name. When the female parent is not known, as in natural hybrids, the order of the constituent species names is alphabetical.

RESULTS AND DISCUSSION

The results of the experimental hybridizations, self-compatibility trials, and studies of viability and fertility of the progeny are presented in summary form for the statistical analyses of the data. In addition, more complete data sets, listing the results obtained from individual plants, are presented in certain of the tables below.

There are several reasons for this more thorough reporting of the data. The first is to provide the most complete information available on the ancestry of each individual in the F_1 and subsequent hybrid generations. The full documentation is necessary for the studies on the inheritance of various traits in the hybrids. Studies of morphological inheritance were initiated in this paper (Section 5), and research on the inheritance of micromolecular and macromolecular traits in the interspecific hybrids is anticipated for the future. In addition, some of the hybrid plants with their colorful flowers are likely to be propagated widely as ornamentals; the tables presented here serve as public documentation of the parentage of these cultivars. Finally, it is hoped that some of these experiments will be repeated with the same parental and hybrid trees in the Hawaiian botanical gardens. The documentation of the results for individual plants of traits probably indicative of reproductive success, such as pollen fertility and fruit set, will allow investigation of the possibility that such traits may change through time with the maturation of the plant.

Self-Compatibility. The results of the self-compatibility trials are shown in Table 3. The low percentage of mating success in the pooled data for all species—6% fruit set for selfings and 10% for outcrosses—is due to a high incidence of postzygotic abortion of young fruits and to failure of pollen tubes to reach the ovules, but the relative importance of these two factors is not known. For the pooled totals, the difference in fruit set between selfs and outcrosses is nonsignificant.

Statistical comparison of fruit set in selfs vs. outcrosses was possible in four species. In only one of these, the natural population of *Erythrina goldmanii* at El Sumidero, was fruit set significantly higher in outcrosses than in selfs, and then but marginally so at $P = 0.05$.

In six additional species, self-pollinated flowers set fruit, but only one individual of the species was available, so the outcrossing control was not possible. In nine species, no fruits were set from self-pollinated flowers, but in four of these the outcrossing controls yielded no fruits either. Failure of fruit set, then, is evidently a consequence of overall low fecundity in *Erythrina* and not of self-incompatibility per se.

Self-incompatibility has previously been reported for seven species of *Erythrina*: *E. senegalensis* and *E. speciosa* (East, 1940); *E. crista-galli* (Fryxell, 1957); *E. mitis* and *E. poeppigiana* (Arroyo, 1981); *E. leptorhiza* (Hernández & Toledo, 1979); and *E. montana* (Hernández, 1982). Only for *E. montana* was the assertion of self-incompatibility supported by evidence from experimental self-pollinations and outcrossing controls. Calculation of Fisher's exact probability for the data presented in Hernández (1982), however, reveals that the difference in fruit set between selfs and outcrosses in *E. montana* is nonsignificant ($P = 0.25$). My evidence for self-compatibility in *E. senegalensis* and *E. crista-galli* contradicts the earlier reports of self-incompatibility in these species, which were based merely on the failure of isolated cultivated trees to produce seed spontaneously. Feinsinger et al. (1979) provided evidence from experimentally controlled pollinations that *E. fusca* and *E. pallida* are self-compatible.

There is thus no reliable evidence for genetic self-incompatibility in any species of *Erythrina*. It appears safe to assume that genetic self-incompatibility—at least the classical single-locus, multiple S-allele, stigma- or style-mediated model of self-incompatibility (Nettancourt, 1977)—is completely absent from the 112 species in the genus. If this is true, it would invalidate some of the evidence that Arroyo (1981) advanced to support her assertion that tropical woody Papilionoideae are predominantly self-incompatible. Five of the

27 species Arroyo listed in that habitat/life form category as self-incompatible were *Erythrina* species. There are very few comparable studies on other genera of tropical woody Papilionoideae. With the information presently available, it is not known if *Erythrina* is an anomaly, or if self-compatibility is common in this group of plants. Because low fecundity and high rates of flower and fruit abortion are probably characteristic of these plants, greater caution is required in carrying out and interpreting self-incompatibility tests than has customarily been taken.

It is true that fruit set is frequently lower in self-matings than in outcrosses. This may be due not to genetic self-incompatibility, but rather to multiallelic inbreeding depression, expressed either in the progamic phase as failure of pollen tubes to reach the ovules (Mulcahy & Mulcahy, 1983) or as postzygotic abortion of young fruits.

Although *Erythrina* species are genetically self-compatible, the production of seed from selfed flowers in natural populations may be quite limited. A flowering tree visited by pollen-bearing birds will receive many geitonogamous pollinations (pollen from a different flower on the same individual) as well as xenogamous pollinations (pollen from a different individual). The reduced fruit production from self-pollinations, as well as the relatively poor viability of selfed seed (see section on F_1 viability below) suggests that progeny derived from selfed flowers are low in "quality" relative to progeny derived from outcrossed flowers. The selective abortion of low-quality selfed fruits, cited by Stephenson (1981), may be operative in *Erythrina*. Interfruit competition may be very intense under natural conditions, since such a small proportion of pollinated flowers develops into mature fruits. Therefore it is possible that most successful progeny are derived from outcrossing, and that the level of inbreeding in most *Erythrina* populations is quite low in spite of self-compatibility and a large proportion of geitonogamous pollinations. This is still speculative; the significance to mating success of mate competition among male parents has not been explored in *Erythrina*.

In regard to flower and fruit abortion, the attempts to increase mating success by eliminating the effects of competition and resource limitation in the experimental pollination trials were only partially successful. Certainly the fruit maturation rates of 25% or more obtained in some of the outcrossing trials represent an increase in fruit production over

TABLE 4. *Tests for autogamy and agamospermy in* Erythrina *at Pacific Tropical Botanical Garden.*

I. Test for autogamy

Species	Accession Number	Inflorescences Bagged	Flowers	Fruits	Seeds

II. Test for agamospermy (in individuals exhibiting autogamy)

Species	Accession Number	Inflorescences Treated	Flowers Emasculated	Fruits Set
E. guatemalensis	750419001	3	30	0
E. guatemalensis	720999001	3	66	0

the percentages found in natural populations. Usually the percentages of fruit maturation were much lower, however, and in all cases the majority of pollinated flowers were aborted early in development. The factors promoting flower and fruit abortion are several, including nutrition and resource limitation, competitive effects, possible damage to the flowers caused by emasculation, and factors such as adverse weather conditions, in addition to the factor under consideration here: the genetic compatibility of the female and male parents. Neither for the self-compatibility trials nor for the experimental hybridizations was it possible to sort out all of these variables.

Autogamy and Agamospermy. The results of the tests for autogamy and agamospermy are shown in Table 4. Autogamous fruits were produced only on two individuals of *Erythrina guatemalensis.* Significantly, these were rather "fecund" trees with relatively high mating success from controlled hand-pollinations. The autogamous fruits were produced only from the uppermost three fascicles of flowers on an inflorescence—the last flowers to bloom. They evidently were produced, in part, because of the occasional breakdown of protandry, which prevents autogamy on most flowers of *E. guatemalensis* and the other species that are adapted to hummingbird pollination (Neill, 1987).

Although autogamous fruits were produced in my limited trials only on *Erythrina guatemalensis,* I believe that occasional autogamy is widespread in the genus. Cultivated trees of many species produce some fruits spontaneously in the absence of evident pollen vectors.

The fact that autogamous fruits are produced only on the latest flowers of an inflorescence suggests that the breakdown of protandry may be an adaptive mechanism that allows some seed set in the absence of the appropriate avian pollen vectors. Each inflorescence, although it may produce 75 or more flowers, will mature only a few fruits, so fruit set on the lower, earlier-blooming flowers of the inflorescence must inhibit the formation of fruits on the upper, later-blooming portion. It is likely that autogamous fruits from the ultimate flowers of the inflorescence will be produced only if some allogamous fruits (from either xenogamous or geitonogamous pollinations) have not already been produced on the lower portion of the inflorescence.

The two *Erythrina guatemalensis* trees that produced autogamous fruits were tested for agamospermy (Table 4). No fruits were produced when stigmas were isolated from pollen deposition, so agamospermy is not indicated. Agamospermy is almost unknown in the Leguminosae (Arroyo, 1981) and it is unlikely to occur in *Erythrina.*

Hybridization Trials: Mating Success (Fruit Maturation). The complete results of the hybridization trials are listed in Appendix II. From 1,671 hybridization attempts in 155 hybrid combinations, 98 mature fruits were produced in 47 hybrid combinations, for an overall hybrid mating success of 6%, in 30% of the attempted combinations.

TABLE 5. *Proportion of hand-pollinated flowers producing mature fruit: all diploid* Erythrina *species.*

Pollination Treatment	Flowers Pollinated	Fruits Matured	Proportion Fruit Set
Selfed	515	29	5.6%

Medium hybrid vs. wide hybrid	N.S.
Intraspecific vs. hybrids	N.S.
Outcross + narrow hybrids vs. self + medium + wide	$P < 0.01$

[1] N.S. = not significant ($P > 0.05$).

For the statistical analysis of mating success in selfs, intraspecific outcrosses, and hybridizations (Table 5), data from the diploid species only were included. The tetrapoloid *Erythrina amazonica* as male parent, after numerous pollination attempts with the diploids *E. guatemalensis* and *E. crista-galli* as female parents, produced one hybrid seed with each of the females. Neither of the seeds germinated, however, so there are no successful hybrids between *Erythrina* species of different ploidy levels. Since the results from *E. amazonica* are not germane to the hypotheses of the interfertility of diploid species and the formation of homogamic complexes, they were excluded from the statistical analysis.

The results for the diploid species in Table 5 indicate that the highest mating success was obtained with intraspecific outcrosses and "narrow" hybridizations (within sections). "Medium" hybridizations (intersectional, intrasubgeneric) and selfings were intermediate in mating success, and "wide" (intersubgeneric) hybrids were the least successful of the five treatment classes. A general trend, then, is evident: interspecific matings between closely related species (within sections) are just as likely to succeed as intraspecific matings. Mating success diminishes with increasing "taxonomic distance" between the parents (intersectional and intersubgeneric hybridizations). Mating success is also somewhat lower in selfings than either intraspecific outcrosses or hybridizations between closely related species.

This overall trend, shown by the percentages of fruit maturation in Table 5, is not a strong one; the differences between treatments are for the most part nonsignificant. The multiple comparison test revealed only three significant differences among the ten possible pairwise combinations. Fruit maturation in narrow hybridizations was significantly higher than in self-mating ($P < 0.05$). Intraspecific outcrosses and narrow hybridizations also had higher fruit maturation than wide hybridizations; in these comparisons the difference was highly significant ($P < 0.01$).

Because the pooled fruit maturation data for all species may obscure the heterogeneity in results among different species, it is instructive to examine the patterns of mating success in a few selected species. *Erythrina guatemalensis* as female parent accounted for 30% of all mature fruits in the pollination trials and 33% of all the hybrid fruits. Thirty-three hybrid fruits were produced from *E. guatemalensis* as female; of these, 30 (90%) were from a single genetic individual, a clone represented by one tree at each garden (PT 700018001, WA 74c1453). The pattern of mating success for *Erythrina guatemalensis* (Table 6) is very similar to the overall results for the combined species trials.

TABLE 6. *Proportion of hand-pollinated flowers producing mature fruit: female parent =* Erythrina guatemalensis*; male parents = diploid species.*

Pollination Treatment	Flowers Pollinated	Fruits Matured	Proportion Fruit Set
Selfed	33	3	9%
Intraspecific outcross	28	7	25%
Narrow hybridization (within section)	86	21	24%
Medium hybridization (between sections, within subgenus)	54	5	9%
Wide hybridization (between subgenera)	185	7	4%
Total	386	43	11%

Multiple comparison test for differences between treatments in proportion of fruit set

Self vs. outcross	N.S.
Self vs. narrow hybrid	N.S.
Self vs. medium hybrid	N.S.
Self vs. wide hybrid	N.S.
Outcross vs. narrow hybrid	N.S.
Outcross vs. medium hybrid	N.S.
Outcross vs. wide hybrid	$P < 0.01$
Narrow hybrid vs. medium hybrid	N.S.
Narrow hybrid vs. wide hybrid	$P < 0.05$
Medium hybrid vs. wide hybrid	N.S.
Outcross + narrow hybrid vs. self + medium + wide	$P < 0.01$

The *E. guatemalensis* trees were unusually fecund; fruit maturation was much higher than the overall average for intraspecific outcrosses (25%) and narrow hybridizations (24%). As in the combined species results, fruit maturation was significiantly higher in intraspecific outcrosses and narrow hybridizations than in wide hybridizations ($P < 0.01$ for both pairwise comparisons), and for narrow hybridizations vs. medium hybridizations the difference was marginally significant ($P < 0.05$).

The data set for *Erythrina crista-galli* as female parent (Table 7), although not so extensive, shows that the neat congruence of mating success and taxonomic distance evidenced by *E. guatemalensis* does not always apply. *Erthyrina crista-galli* as female, represented by one genetic individual at each of the two gardens, produced 16% of all the hybrid fruits in the trials, but it produced 49% of the "medium" and "wide" hybrid fruits. Fruit maturation was higher in the medium and wide hybridizations than in the few narrow hybridizations. (Only one species, *Erythrina falcata,* is in the same section with *E. crista-galli,* so the opportunities for narrow hybridization were limited.) There are no significant differences, however, in any of the pairwise comparisons between pollination treatments for *E. crista-galli*; the variances are large because the sample sizes are rather small.

For intersectional hybridizations (the "medium" and "wide" categories combined) mating success in *Erythrina crista-galli* as female parent was significantly higher than in *E. guatemalensis* (multiple comparison test for proportions, $P < 0.05$). This is illustrated by the results of attempted reciprocal hybridizations between these two species, which are in different subgenera. Sixty-four pollination attempts to produce the hybrid *E. guatemalensis* ♀ × *E. crista-galli* ♂ yielded a single fruit with two seeds, neither of which germinated. Only ten attempts at the reciprocal cross of *E. crista-galli* ♀ × *E. guatemalensis* ♂ yielded four fruits, 15 seeds, and eight vigorous F_1 plants. In all, *E. crista-galli* as female parent produced seeds from seven hybrid combinations with species in six sections and three subgenera. Five of these combinations in all three subgenera survived as healthy F_1 plants. *Erythrina crista-galli,* in short, was a singularly successful "wide hybridizer."

Summing up the contrasting results in fruit maturation for *Erythrina guatemalensis* and *E. crista-galli, E. guatemalensis* hybridized very readily with species in the same section, much less so with more distantly related species. *Erythrina crista-galli,* in contrast, hybridized with a number of species in different subgenera with apparently equal facility, regardless of the formal taxonomic relationships and presumed phylogenetic affinities between *E. crista-galli* and the male parents. These

F_1 medium vs. F_1 wide	N.S.
All F_1 hybrids vs. F_2 narrow hybrids	$P < 0.01$

differences in mating success probably reflect individual variation rather than real and consistent interspecific differences in crossability.

F_1 Hybrid Viability. Viability of the F_1 hybrids was high and equal to or higher than normal viability of progeny within species. Overall, 143 (52%) of the 273 F_1 hybrid seeds germinated; 120 of these (44% of the total) survived as healthy F_1 plants. In other words, most of the F_1 seeds either germinated and grew vigorously or they did not germinate at all: the survival rate of those that germinated was 84%.

There were few instances of weakness in the hybrids. Two individuals completely lacked chloroplasts and died soon after germination: a narrow hybrid, *Erythrina macrophylla* × *E. berteroana*, and a wide hybrid, *E. crista-galli* × *E. speciosa*. In both cases, though, siblings from the same cross grew into healthy green plants. About 10 other hybrid plants in different combinations were chlorotic, with yellow-green foliage, and died within 1–2 months. Several others at first appeared chlorotic, but after several months they recovered the normal green color and grew vigorously.

The comparative viablity of narrow, medium, and wide hybrids is summarized in Table 8. Among the F_1 hybrids viability (defined as successful germination and survival of the plant for at least six months) was highest for narrow hybrids, intermediate for wide hybrids, and lowest for medium hybrids. The difference between viability of narrow and medium hybrids was statistically significant ($P < 0.01$), but between narrow and wide hybrids it was not.

Included in Table 8 is the viability data for the "narrow F_2" hybrid seed produced in 1984 from the two-year-old narrow F_1s within sect. *Erythrina*. Germination success of the F_2s was very low, an unexpected and anomalous result; the difference in viability between both the narrow F_1 hybrids (51%) and the wide F_1s (41%) vs. the narrow F_2s (11%) was highly significant (both comparisons, $P < 0.01$).

Viability data for the intraspecific and hybrid progeny of maternal *Erythrina guatemalensis* and *E. crista-galli*, respectively, are presented in Tables 9 and 10. The intraspecific progeny of these two species were grown for two purposes: to compare their viability with that of the hybrids from the same female parents, and to carry out a study of intraspecific variation of morphological traits among siblings. The second goal was thwarted, however, because of the poor germination of the intraspecific seeds. Although the seed lots were not large to begin with, viability of the seed derived from selfings was particularly low: all seven selfed

seeds of *E. crista-galli* failed to germinate, as did all but one of 12 selfed seeds of *E. guatemalensis.* This could be an expression of inbreeding depression in the self-progeny, but this possibility must be corroborated with larger samples.

Among the hybrids derived from *Erythrina guatemalensis* and *E. crista-galli* females, the pattern of F_1 viability (Tables 9, 10) and its relationship to "taxonomic distance" between the parents was similar to the pattern of mating success discussed earlier (Tables 6, 7) for the same two species. Among the progeny of *E. guatemalensis*, viability of narrow hybrids was significantly higher than that of medium and wide hybrids. Among the progeny of *E. crista-galli,* by contrast, there was no correlation between F_1 hybrid viability and the degree of relatedness of the parentals.

A complete listing of the F_1 hybrid plants produced during 1982–1984 is contained in Tables 11–13. In all, there are 120 individuals in 33 hybrid combinations (21% of the 155 attempted combinations): 22 narrow hybrid combinations (34% of 65 attempted combinations); four medium hybrid combinations (15% of 27 attempts); and seven wide hybrid combinations (11% of 64 attempts). The number of individual F_1 hybrids for each combination ranges from one to nine.

Nineteen of the 22 narrow hybrid combinations are between species in sect. *Erythrina.* There is one narrow hybrid combination in each of sections *Cristae-galli, Chirocalyx,* and *Erythraster.* The medium and wide hybrids include species combinations in nine of the 26 sections of *Erythrina* and four of the five subgenera. In seven of the hybrid combinations, one parental species is native to the New World and the other is native to the Old World.

In summary, the viable F_1 hybrids obtained between the diploid species of *Erythrina* include representative crosses that bridge the entire range of taxonomic diversity and geographic distribution of the genus. Interspecific crossability appears to be largely a function of individual variation in fecundity of the female parent and only partially a function of taxonomic/phylogenetic distance between male and female parents. Given the results obtained in these experiments, it may be expected that with sufficient time, perseverance, and selection of compatible and fecund individual genotypes, any diploid *Erythrina* species could be crossed with any other to produce a viable F_1 hybrid.

Sexual Maturation and Fertility of F_1 Hybrids. Some F_1 hybrids not only were very rapid

in growth rates, but they also produced flowers at an exceptionally early age. Many of the narrow hybrids between species in sect. *Erythrina* grew to be 4-m trees within two years after the seeds were sown, and most flowered within that time. Such sexual precocity is unknown in the parental species. Seeds from intraspecific matings were sown concurrently and in the same nursery with the hybrids; none grew as rapidly or flowered as early as most of the hybrids. None of the parental species, in cultivation, have been known to produce flowers in less than three years from seed.

An even more phenomenal case of precocious flowering was the intersectional (medium) hybrid *Erythrina crista-galli* × *E. fusca*. Two sibling individuals of this combination (PT 840231001 and -002) produced flowers when they were still small plants in nursery pots less than five months after the seeds were sown. The parentals are both large- to medium-sized trees and are not known to flower in the wild or in cultivation before at least several years of growth.

Twenty-five of the two-year-old F_1 hybrid plants flowered during February–March 1984. All were narrow hybrids within sect. *Erythrina*, and represented nine hybrid combinations. These are listed in Table 14 with the pollen fertility of each individual. Also included in Table 14 is the pollen fertility of each of the parental individuals from which these hybrids were derived.

With two exceptions, the pollen fertility of the F_1 hybrids was above 95%. The pollen fertility of the hybrids ($\bar{X} = 97.6\%$) was slightly but significantly higher ($P < 0.05$) than the fertility of the parentals ($\bar{X} = 95.0\%$). Eighteen of the 25 hybrid individuals had pollen fertilities higher than either of their parents. For this trait at least, the narrow hybrids in sect. *Erythrina* clearly exhibited interspecific heterosis.

Meiosis in pollen mother cells was examined in several of the F_1 hybrids in sect. *Erythrina*. An example is *Erythrina guatemalensis* × *E. macrophylla*, HO 82.288-A (Figs. 9, 10). Meiotic behavior in this hybrid can be compared with meiosis in its male parent *E. macrophylla*, PT 750420002 (Figs. 5, 6).

As in the parental species, meiosis in the hybrids was characterized by clumping of bivalents at late diakinesis and metaphase I and by "sticky" chromatin bridges and late disjunction of some bivalents at anaphase I. The normal meiotic process was, however, not disrupted. Nondisjunction or unequal assortment of chromosomes during meiosis I was not observed, and all cells examined at telophase I or subsequent stages had the expected number of 21 chromosomes. Meiotic behavior in the F_1 hybrids within sect. *Erythrina*, in short, was identical to the behavior described above for the parental species.

The only intersectional F_1 hybrid to flower by November 1984 was the five-month-old *Erythrina crista-galli* × *E. fusca*. Pollen fertility in this hybrid (PT 840231001) was 81%. This was lower than the pollen fertility of either parent (*E. crista-galli*, WA 74p840, 96.1%; *E. fusca*, WA 74s99, 96.3%) but probably not low enough to affect substantially fertility and mating success of the hybrid. Only limited material was available for analysis of meiosis in pollen mother cells of *E. crista-galli* × *E. fusca*. In some cells, several quadrivalents ap-

peared to be formed at metaphase I (Fig. 11). In other cells, meiosis was normal with 21 bivalents at metaphase I. Without more thorough cytological analyses, it is not possible to state whether or not meiosis is significantly disrupted in this hybrid. Nondisjunction and unequal segregation of some chromosomes may contribute to the partial reduction in fertility of the pollen.

Fecundity of F_1 Hybrids. Fruit maturation from the controlled self-pollinations of the two-year-old F_1 hybrids in sect. *Erythrina* (Table 15) was very low, less than 3%, and nine of the 12 F_1s produced no fruits from controlled selfing. In common with the usual pattern of results in experimental pollinations of *Erythrina* parentals, much of the failure in fruit maturation was due to postzygotic abortion of young fruits, within one or two weeks after fertilization. Most of the F_1s did produce a few fruits spontaneously, on open-pollinated inflorescences. Animal pollen vectors were not present in the garden plots, and it is most likely that these open-pollinated fruits were produced by autogamy.

Hybrids: mean pollen fertility = 97.6% ± 3.0%.
Parentals: mean pollen fertility = 95.0% ± 4.1%.
Differences in pollen fertility, hybrids vs. parentals: $t = 2.28$; DF = 39; $P < 0.05$.
* Indicates hybrids with higher pollen fertility than either parent.

Also in Table 15 are comparisons of fruit maturation in the selfed F_1 hybrids vs. their parents. Several combinations of parental matings are included in the analyses. Fruit maturation was much lower in the selfed F_1s (3%) than in the original hybridizations which produced these F_1s (22%) ($P < 0.01$).

The second pairwise comparison of fruit maturation in Table 15, selfed F_1 hybrids vs. all of their parental hybrid combinations (including reciprocals), may be more biologically meaningful than the first comparison for the following reason: the female parents of the F_1 hybrids were very fecund, with higher than average fruit maturation. The male parents (pollen donors) of the F_1s generally had lower fruit maturation when employed as females in the hybridization trials; many of the reciprocal crosses produced no hybrid fruit at all. If it is assumed that fecundity (fruit maturation) is a quantitatively heritable trait, then an F_1 hybrid might be expected to be intermediate in fecundity between its two parents, providing there is no reduction in fruit maturation in the hybrid caused by incompatibilities between its constituent genomes. The proportion of fruit maturation expected in the F_1s, then, should approximate the proportion in all the parental hybrid combinations, including

the failed reciprocal hybridizations. By this measure, the second pairwise comparison in Table 15, fruit maturation in the F_1 hybrids, is still much lower than the 15% fruit maturation in the parental generation; the difference is highly significant ($P < 0.01$).

There are several possible reasons for the reduced fruit maturation in the F_1 hybrids in sect. *Erythrina*. The first is that the low fecundity is in fact a consequence of hybridity caused by genic incompatibility between the parental genomes. It is evidently not, however, a matter of "hybrid sterility" in the usual sense of the term, in which the microgametophytes (pollen) and/or megagametophytes (embryo sacs) borne on the F_1 sporophyte are abortive and nonfunctional (Grant, 1953; Stebbins, 1958). The pollen fertility of the F_1 hybrids, as discussed above, was exceptionally high; the pistil and ovules also appeared to develop normally in the hybrids. Much of the failure of fruit set in the selfed F_1s was at the postzygotic stage (abortion of young fruits). If the reduced fecundity was truly a consequence of hybridity and intergenomic incompatibility, it is probably best considered as a case of "hybrid breakdown" (Grant, 1953; Stebbins, 1958) expressed as low viability of the F_2 embryos.

There are other possible explanations for the low fecundity of the selfed F_1s that do not invoke hybrid breakdown or other effects of hybridity. The first is that it may be a consequence of self-mating, the opposite effect from the apparent heterosis evidenced by the exceptional vigor of the F_1 plants. Fruit set in the selfed F_1s was significantly lower than the one in the selfed parentals, which in turn were significantly lower in fruit set than the hybridizations. For both parental and F_1 selfings, the high incidence of fruit abortion may be an expression of inbreeding depression, a result of the homozygous pairing of deleterious recessive alleles in the genomes of the embryos. This possibility could be tested by controlled cross-pollinations between F_1s, a step that was not taken initially because the goal of the F_1 selfings was to produce F_2 plants with no more than two constituent genomes.

Another possible reason for the low fecundity in the F_1s may simply be the juvenility of the F_1 plants themselves. Although the F_1s were very vigorous and flowered precociously at two years of age, they were not yet full-sized trees. At their size, they might not be able to draw on sufficient resources for the full fruit crop of a larger adult.

In short, the variables accounting for reduced fecundity in the narrow F_1 hybrids still need to be sorted out. This should be possible once the F_1 trees attain their full adult size and several categories of matings within and between individuals are carried out.

Viability of F_2 Hybrids. The viability of the F_2 hybrid seed, obtained from selfed and open-pollinated F_1 plants in sect. *Erythrina* (Table 16), was

significantly lower than viability of the F_1 hybrids. This was shown in Table 8, where the F_2s were compared with all the narrow F_1 hybrids; the difference was highly significant ($P < 0.01$). In Table 16 the viability of the F_2 seed is compared specifically with that of their own parents, i.e., with the F_1 seed lots producing the parents of the F_2s. The viability of the F_2s (13%) was significantly lower ($P < 0.01$) than that of their F_1 parent generation (61% viability).

In Table 16 the viability of the F_2 seed and of their F_1 parents is also compared with seed from intraspecific matings in *Erythrina guatemalensis* (including seed from selfings and intraspecific outcrosses, the only intraspecific viability data available for sect. *Erythrina*). The F_1 hybrid seed was significantly higher in viability than the intraspecific seed ($P < 0.05$). The viability of the intraspecific seed (19%) was somewhat higher than that of the F_2 seed, but the difference was nonsignificant.

In summary, the viability of F_1 hybrid seed was significantly higher than F_2 seed derived from selfed F_1 matings and higher than seed derived from intraspecific matings. If the very high F_1 viability is truly an expression of interspecific heterosis, this hybrid advantage is not retained in the F_2 generation, when the F_2s are derived from selfed F_1 hybrids.

It is possible to interpret the reduction in F_2 viability with respect to F_1 viability as "hybrid breakdown." However, with the data presently available, the reduced viability of the F_2s derived from selfed F_1s could also be interpreted as an expression of inbreeding depression. It could also be interpreted simply as an absence of the heterotic advantage possessed by the F_1s, since the viability of the F_2s was not significantly lower than that of the intraspecific progeny. These three alternatives cannot be differentiated with the presently available information. Additional progeny trials of F_1, F_2, and intraspecific seed lots are needed to test the possibility that hybrid breakdown may be expressed in the F_2 generation of *Erythrina* hybrids.

In any case, the lowered average viability of the F_2s was a function only of poor germination of the seed. The seeds that did germinate produced healthy plants with normal growth and vigor at six months of age. There were no indications of chlorosis or other debilities in the F_2 plants.

Studies of Previously Synthesized Hybrids. Nine artificially produced *Erythrina* hybrids, all between

species of different sections, have been reported prior to this study (Table 17). Krukoff & Barneby (1974) described most of these; in the same paper they described some putative natural hybrids between sympatric Mesoamerican and African species. The parentage of only two of the artificial hybrids is known for certain; both of these F_1s are "wide" intersubgeneric hybrids and are reported to be fertile.

The oldest and best-known *Erythrina* hybrid is *E.* ×*bidwillii* Lindley, synthesized from *E. herbacea* (sect. *Erythrina*) ♀ and *E. crista-galli* (sect. *Cristae-galli*) ♂ in Australia in the 1840s and since spread around the world as a cultivar by propagation of cuttings. Krukoff & Barneby (1974) reported *E.* ×*bidwillii* to produce viable seed and also that "no Mendelian segregation of phenetic characters is observed in the F_1 or subsequent generations." They further claimed that this hybrid had naturalized in Fiji and was therefore a stabilized "neospecies."

I examined *E.* ×*bidwillii* in cultivation at Foster Garden, Honolulu (FG 64.2035). Meiosis in pollen mother cells was normal with 21 bivalents at metaphase I. Pollen fertility was 63%, comparable to Graham & Tomb's (1974) report of 76% normal pollen for this hybrid. I attempted to produce an F_2 generation by controlled self-pollination of 60 flowers over a period of several weeks. Young fruits were obtained but they invariably aborted before two weeks of development. I have not seen mature spontaneously produced fruits on any cultivated plants or herbarium specimens of *E.* ×*bidwillii*, so the reports of its viable seed production are questionable.

I made limited attempts (12 trial pollinations) to backcross *E.* ×*bidwillii* to one of its parents, *E. crista-galli*. The pollinations all failed, but given the reasonably high pollen fertility of *E.* ×*bidwillii*, it is likely that with perseverance some backcross progeny could be obtained.

The other previously reported hybrid of known parentage is *Erythrina* ×*resuparcellii* Srivastava (a *nomen nudum*, not validly published), a hybrid between the perennial herb *E. resupinata* (sect. *Suberosae*) ♀ and *E. variegata* (sect. *Erythraster*) ♂ (Jalil et al., 1982). The F_1 is a branched shrub, and in other morphological traits is also intermediate between the two parents. The flowers, however, resemble those of the female parent much more closely than those of the male. This hybrid was not available to me, but Jalil et al. (1982) reported that it had normal meiosis in pollen mother cells with 21_{II} at metaphase I, pollen fertility of 62%, and viable seed.

Erythrina ×*sykesii* Barneby & Krukoff was the only other hybrid among those listed in Table 17 available to me for experimental studies. This

[1] Known or presumed parental species combinations are listed below each hybrid binomial; question mark preceding hybrid combination indicates uncertain parentage. Numbers in parentheses following species refer to sections to which species belong (Table 1).

hybrid was reputedly produced under cultivation in Australia in the 19th century, but its parentage is unknown. Krukoff & Barneby (1974) believed the parents to be *E. lysistemon* (sect. *Caffrae*) and *E. americana* (syn. *E. coralloides*) (sect. *Erythrina*). Based on study of floral and leaf morphology, I believe instead that the parents are *E. lysistemon* and *E. speciosa* (sect. *Stenotropis*). Since I have obtained both reciprocal hybrids of *E. speciosa* × *E. lysistemon* (Table 12), these F_1s can be compared with *E.* ×*sykesii* when they come into flower.

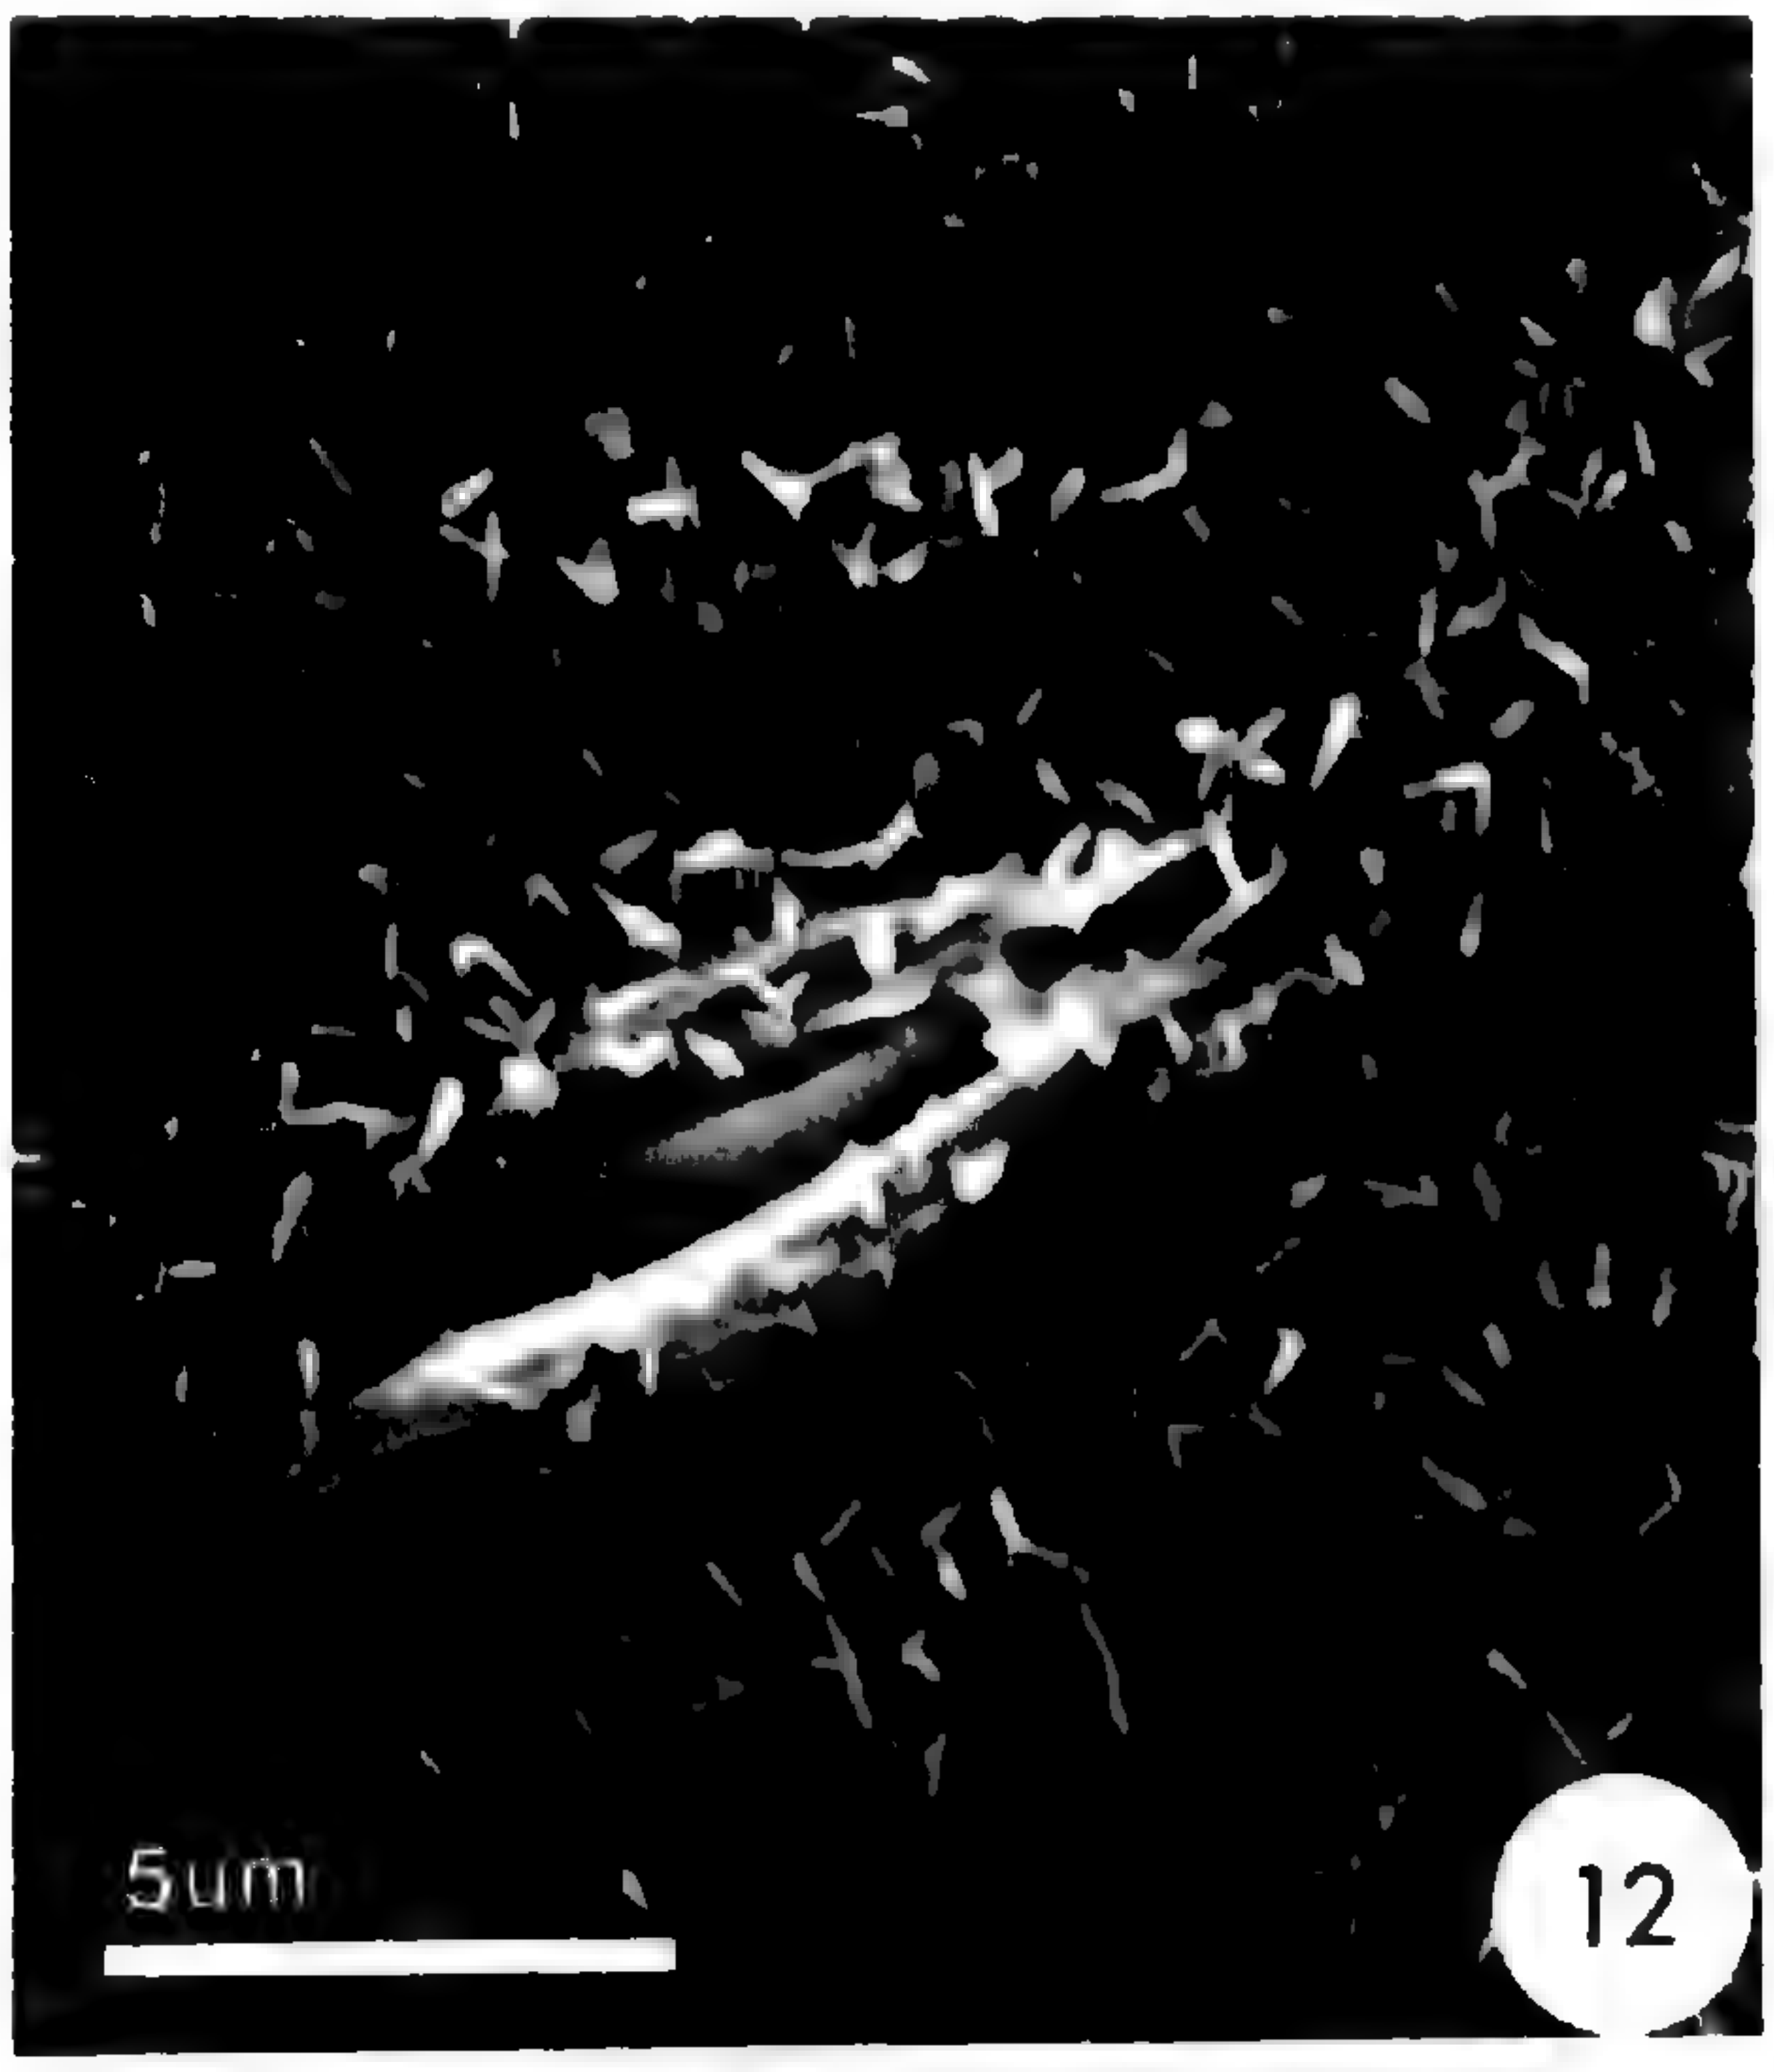
I examined cytologically several individual ramets of *E.* ×*sykesii* (WA 76p864, WA 75s1706, Foster Garden FL.669) and attempted to produce F_2 plants by controlled self-pollination. Meiosis in PMCs was apparently normal, with 21 bivalents at metaphase I. Pollen fertility was 81–84%, which agreed closely with results reported earlier for the same taxon by Graham & Tomb (1974). However, no mature fruits were obtained from 65 attempts at selfing. Young fruits with partially developed seeds were produced in abundance as with *E.* ×*bidwillii*, but these always aborted within two to three weeks following pollination.

Erythrina ×*bidwillii*, *E.* ×*resuparcellii*, and *E.* ×*sykesii* are the only intersectional or intersubgeneric hybrids that have been tested for fecundity at this time. An F_2 generation was reportedly obtained from *E.* ×*resuparcellii* (Jalil et al., 1982), but the other two may be incapable of producing F_2 progeny, at least from selfing of the F_1. Zygotes, embryos, and young fruits are formed, but the fruits abort before maturity. These "wide" hybrids, then, may be subject to hybrid breakdown expressed as inviability of the F_2 hybrid embryos borne on the F_1 hybrid sporophyte. As discussed in the previous section, the cause of mating failure in the F_1 hybrids is subject to different interpretations. Whether or not F_2 hybrid breakdown is a general phenomenon in *Erythrina* remains to be investigated.

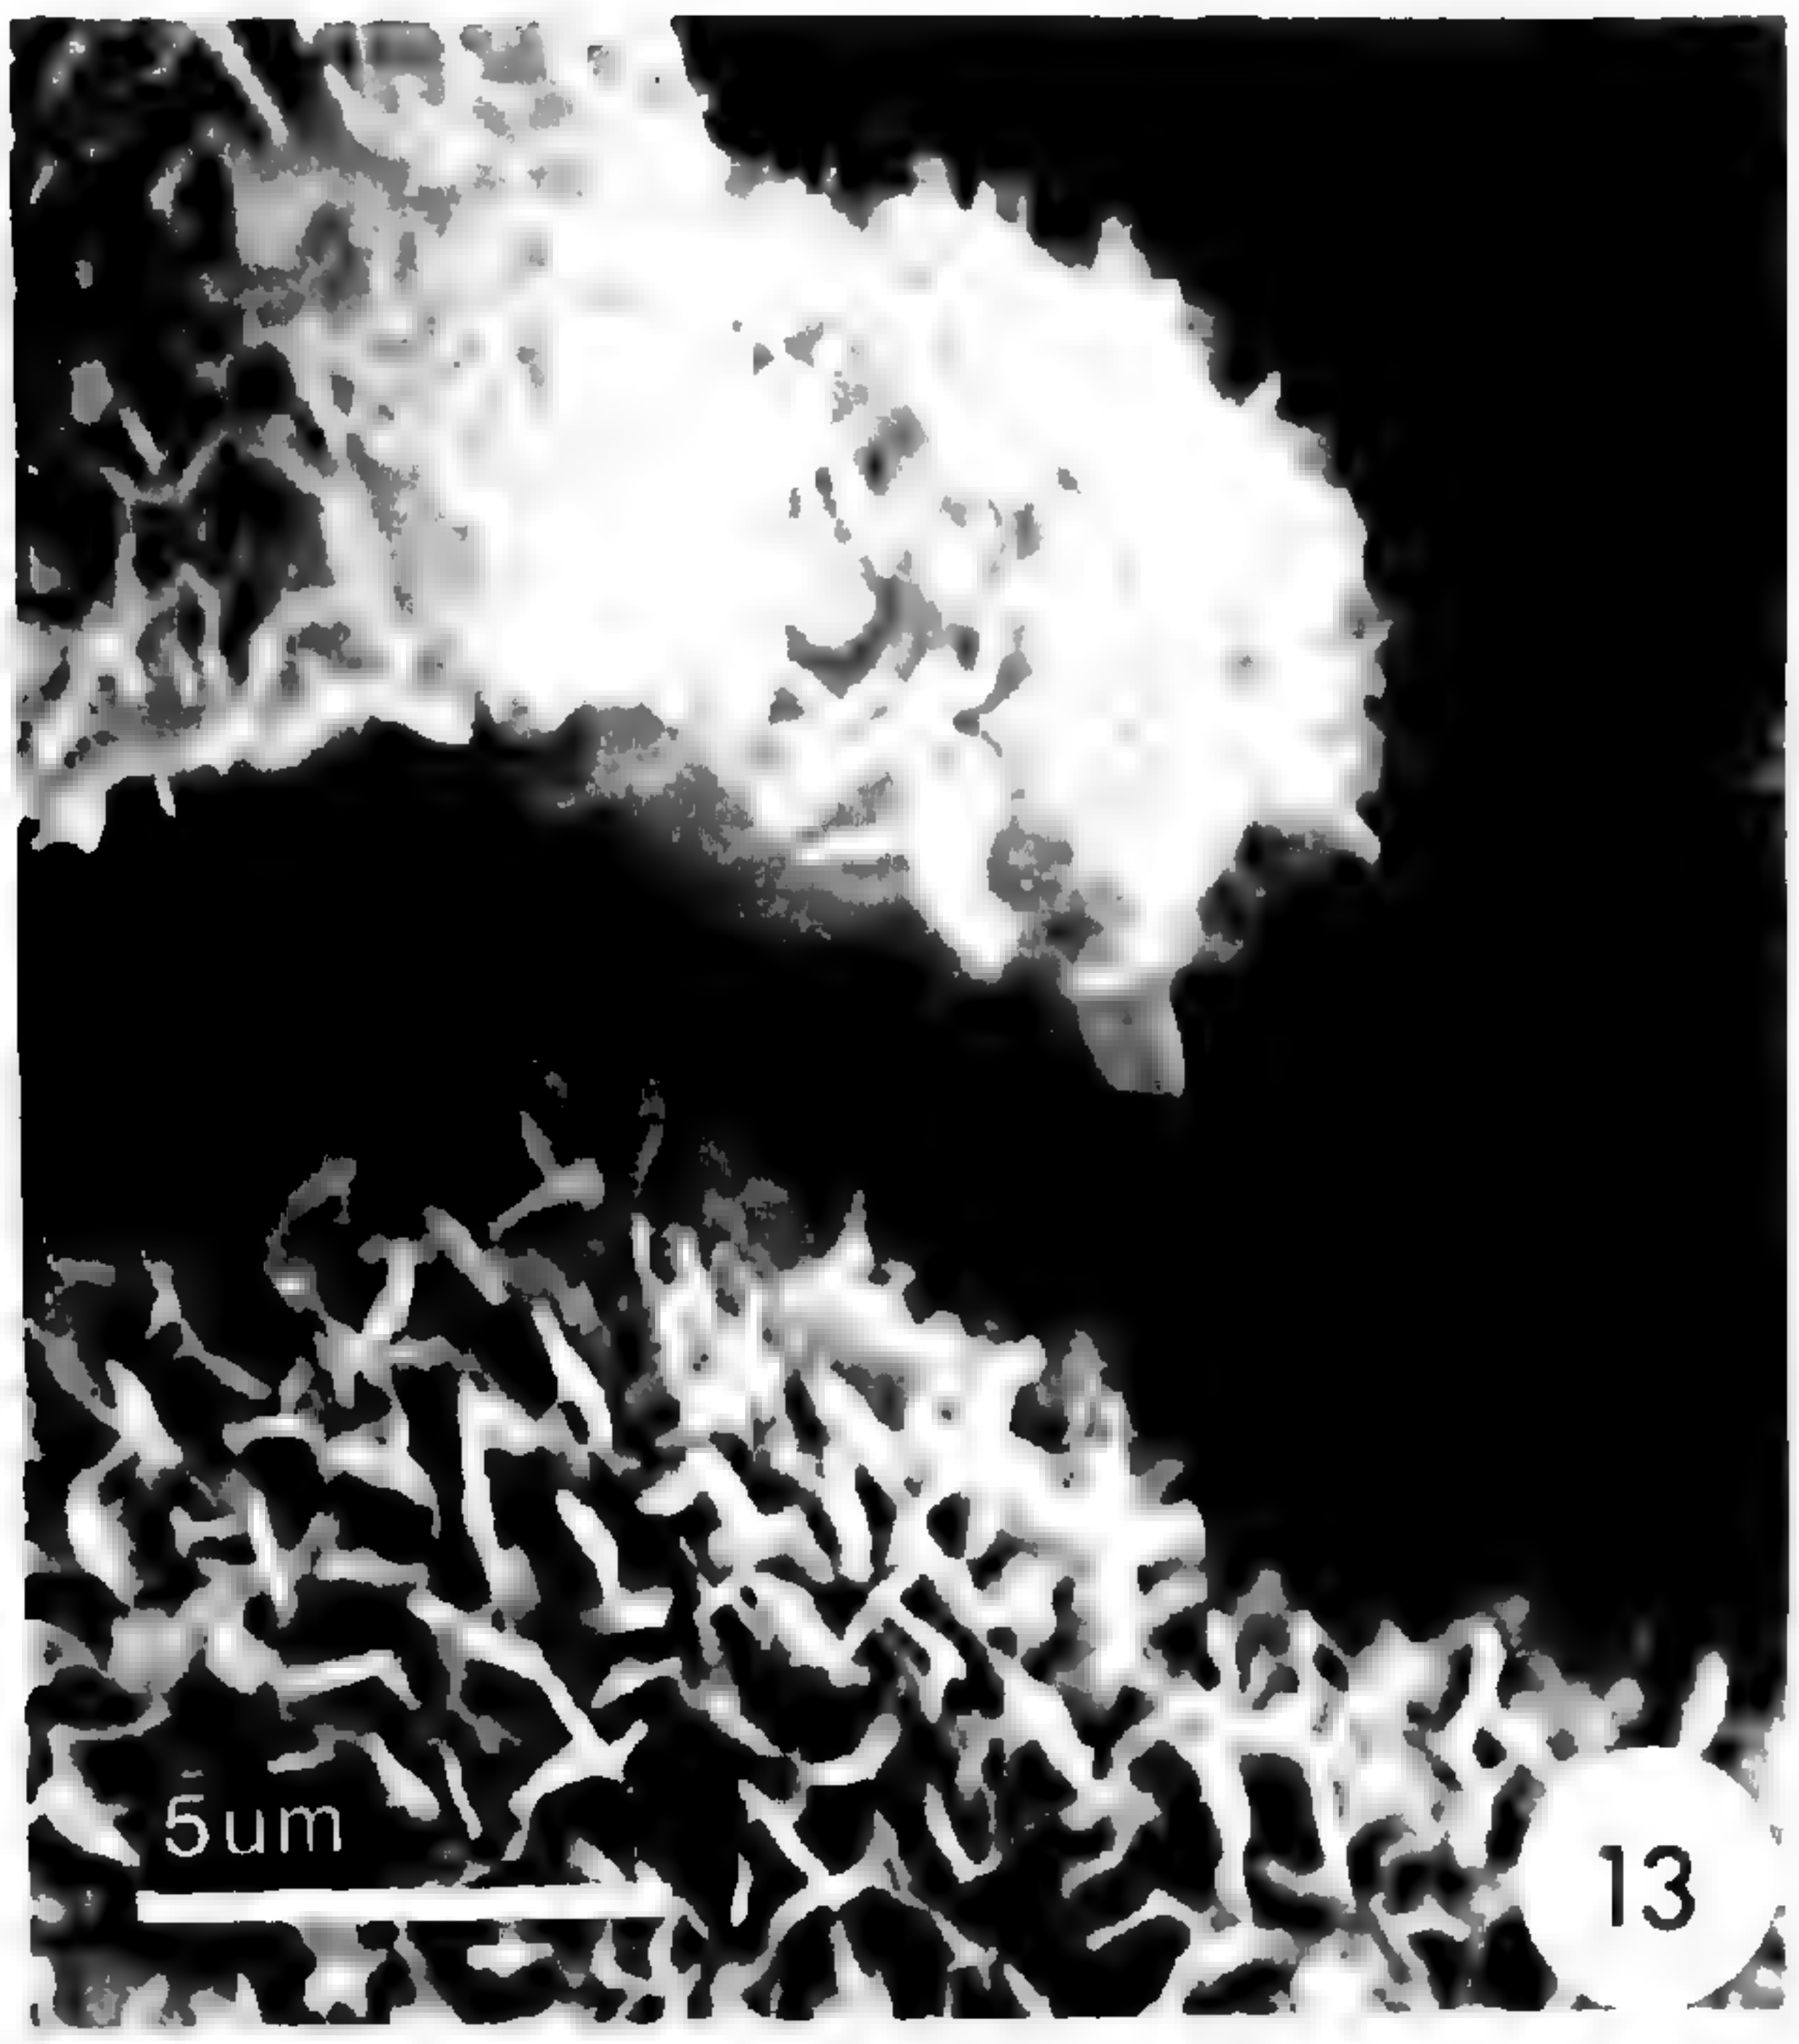
CONCLUSIONS: EXPERIMENTAL HYBRIDIZATIONS AND SELF-COMPATIBILITY TRIALS

From the information presented in this section, a series of generalizations regarding breeding systems and species relationships in *Erythrina* can be outlined:

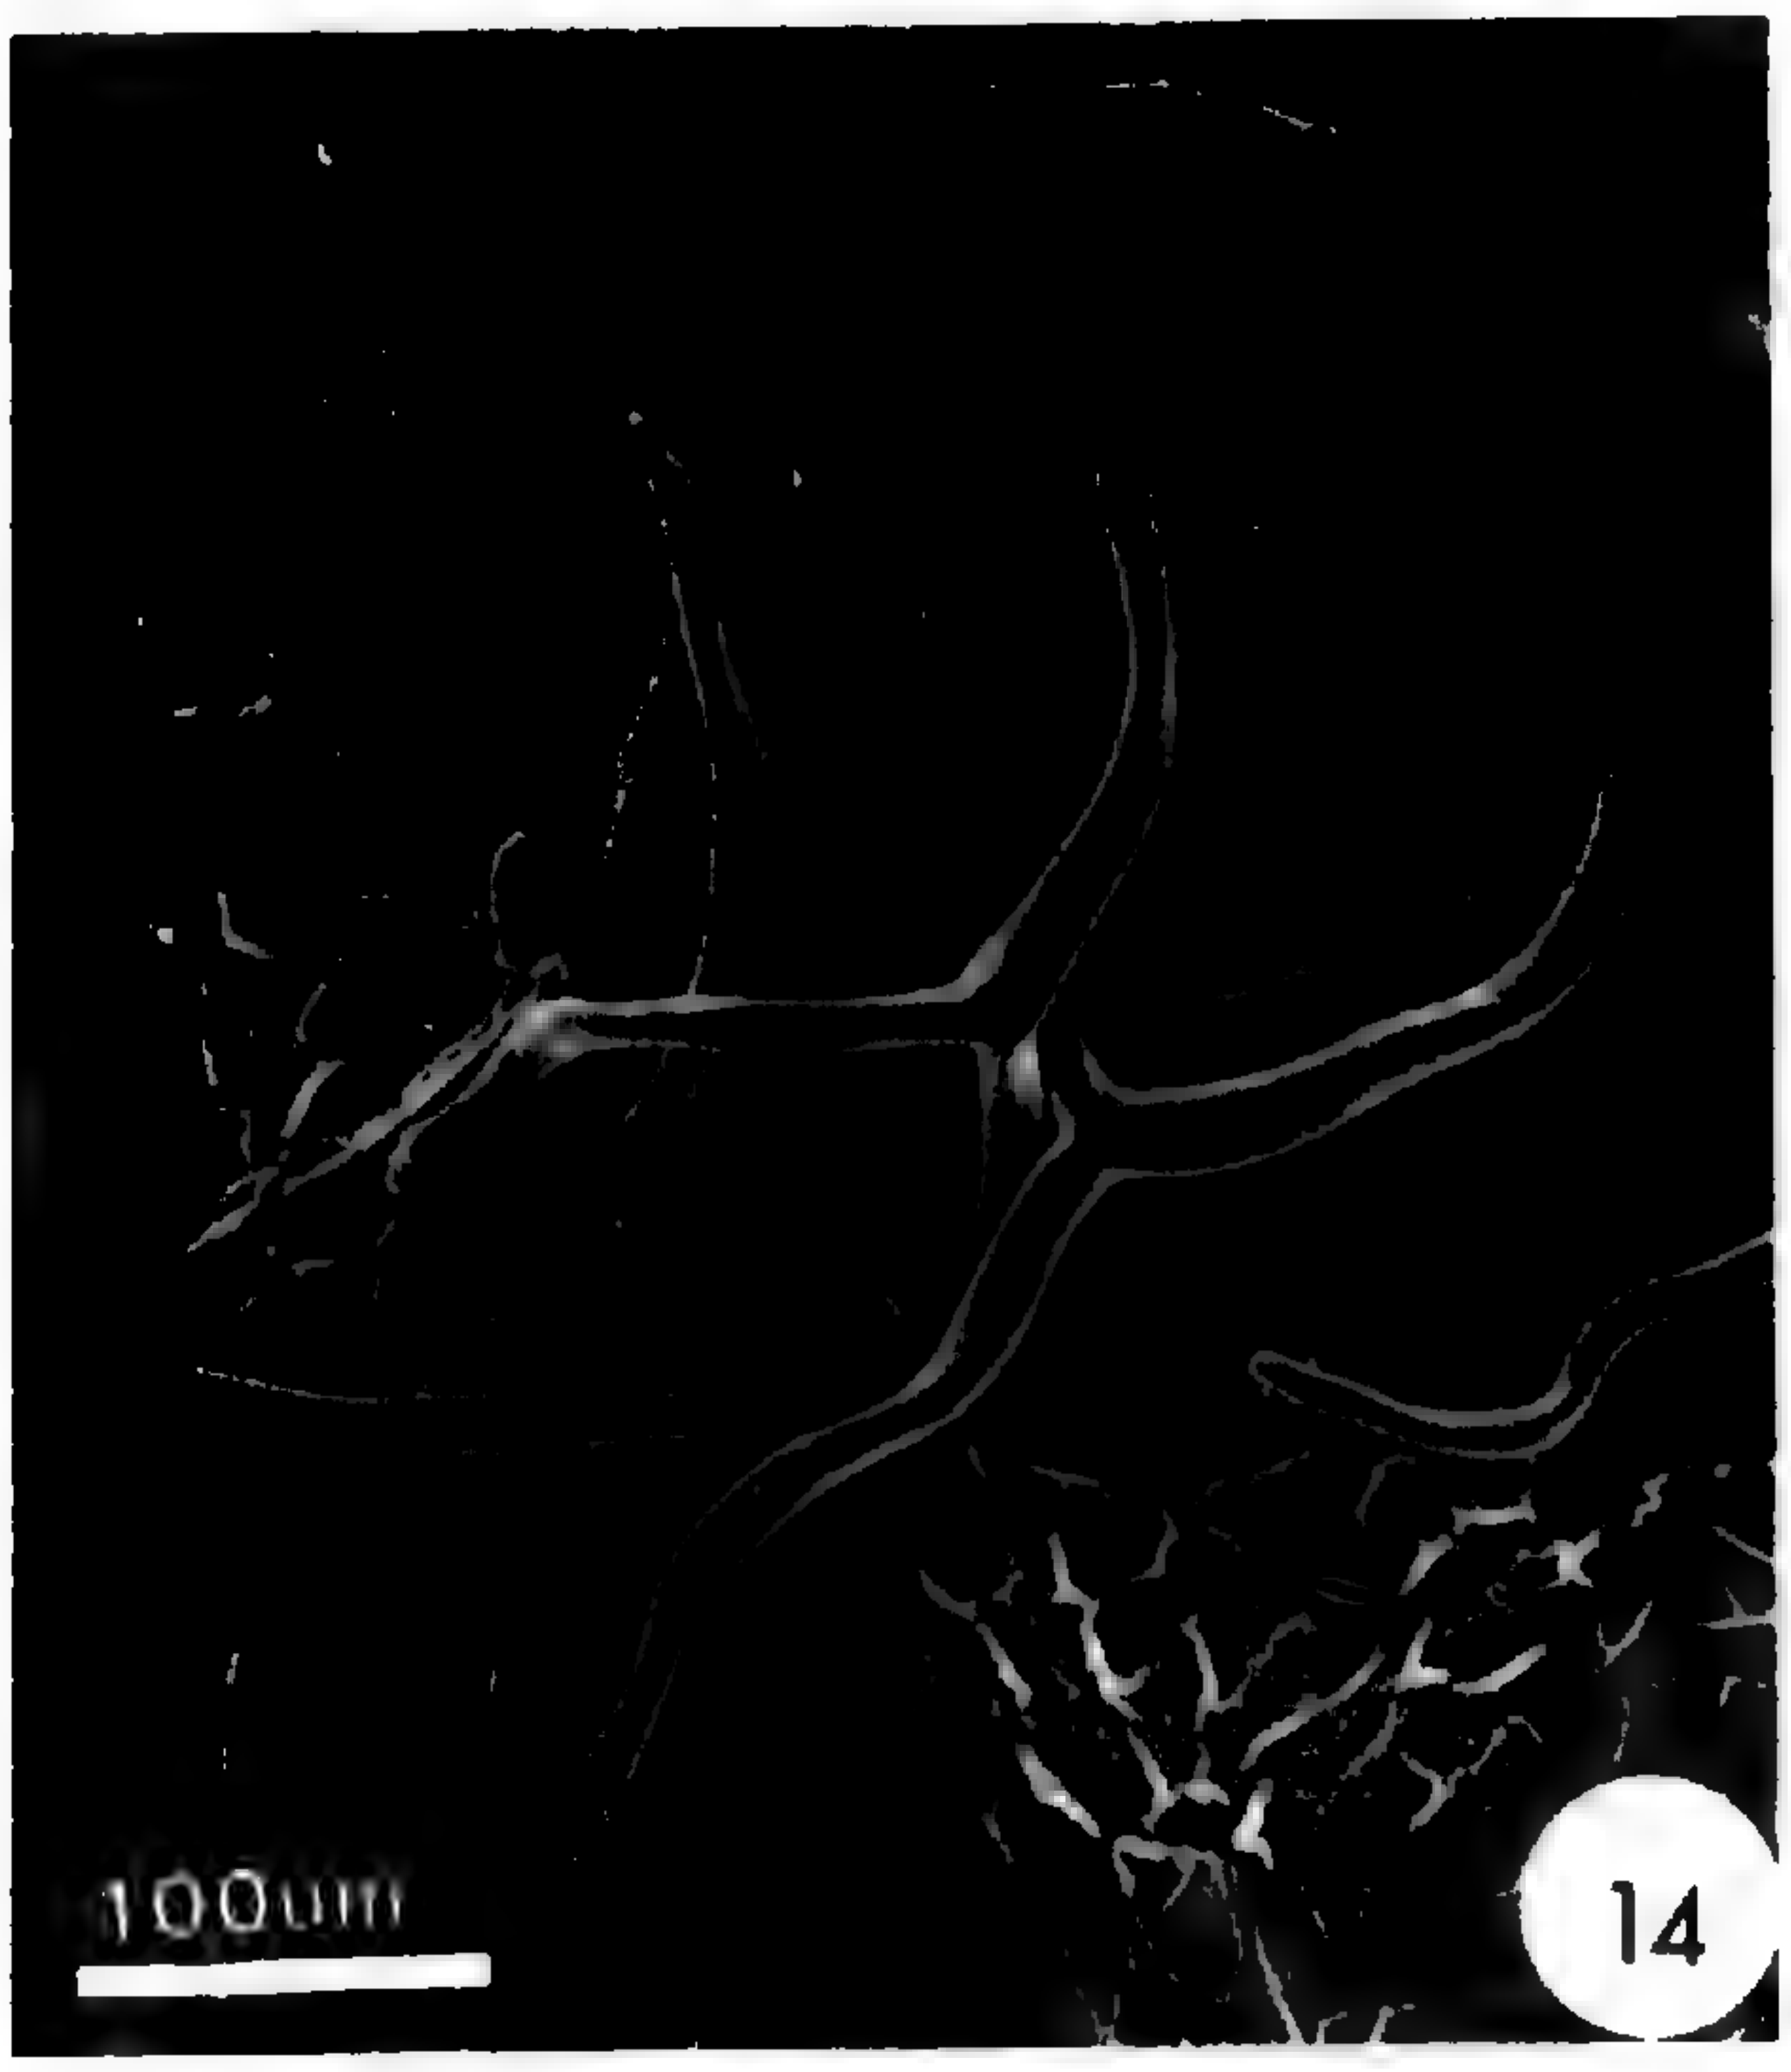
1. Even under the most carefully controlled conditions, mating success (proportion of pollinated flowers producing mature fruits) is low in all *Erythrina* species. This is true even when the effects of "resource competition" are eliminated by removing most flowers from an inflorescence as well as all of the spontaneously produced fruits on the tree, and pollinating only a few selected flowers per inflorescence. Mating failure results partly from prefertilization abortion of pollinated flowers, but also to a large extent from postfertilization abortion of young fruits.



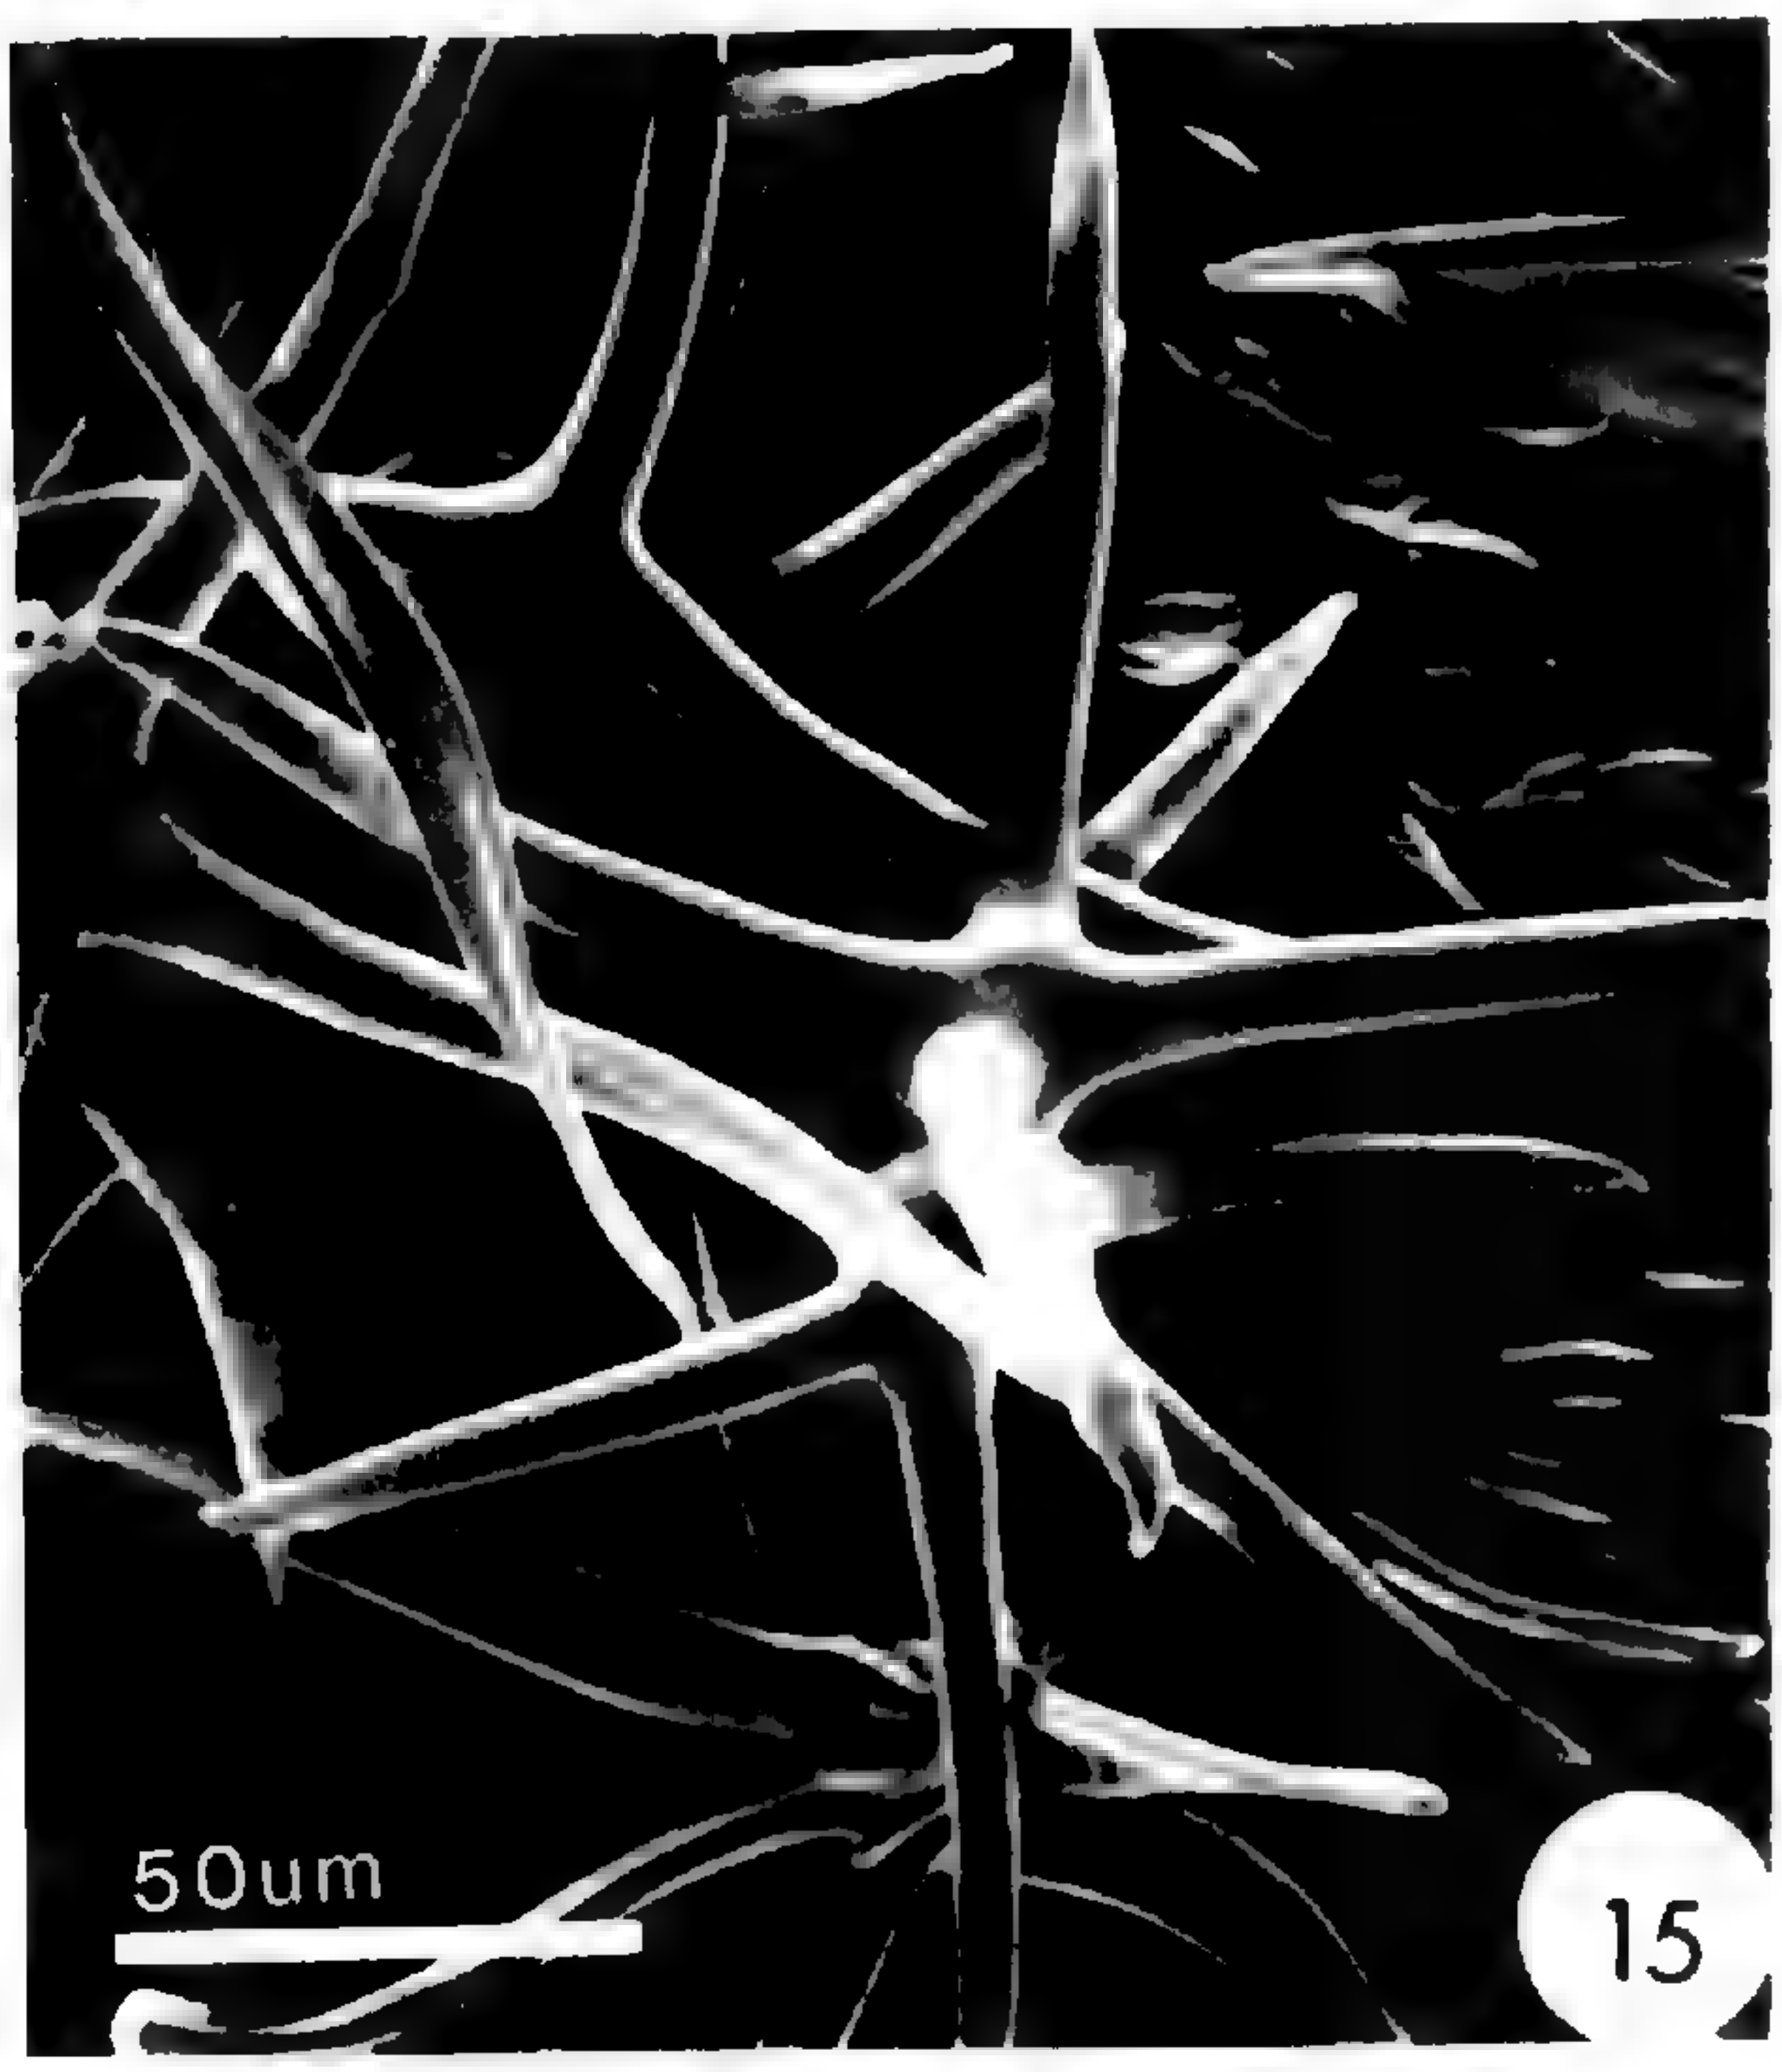
12



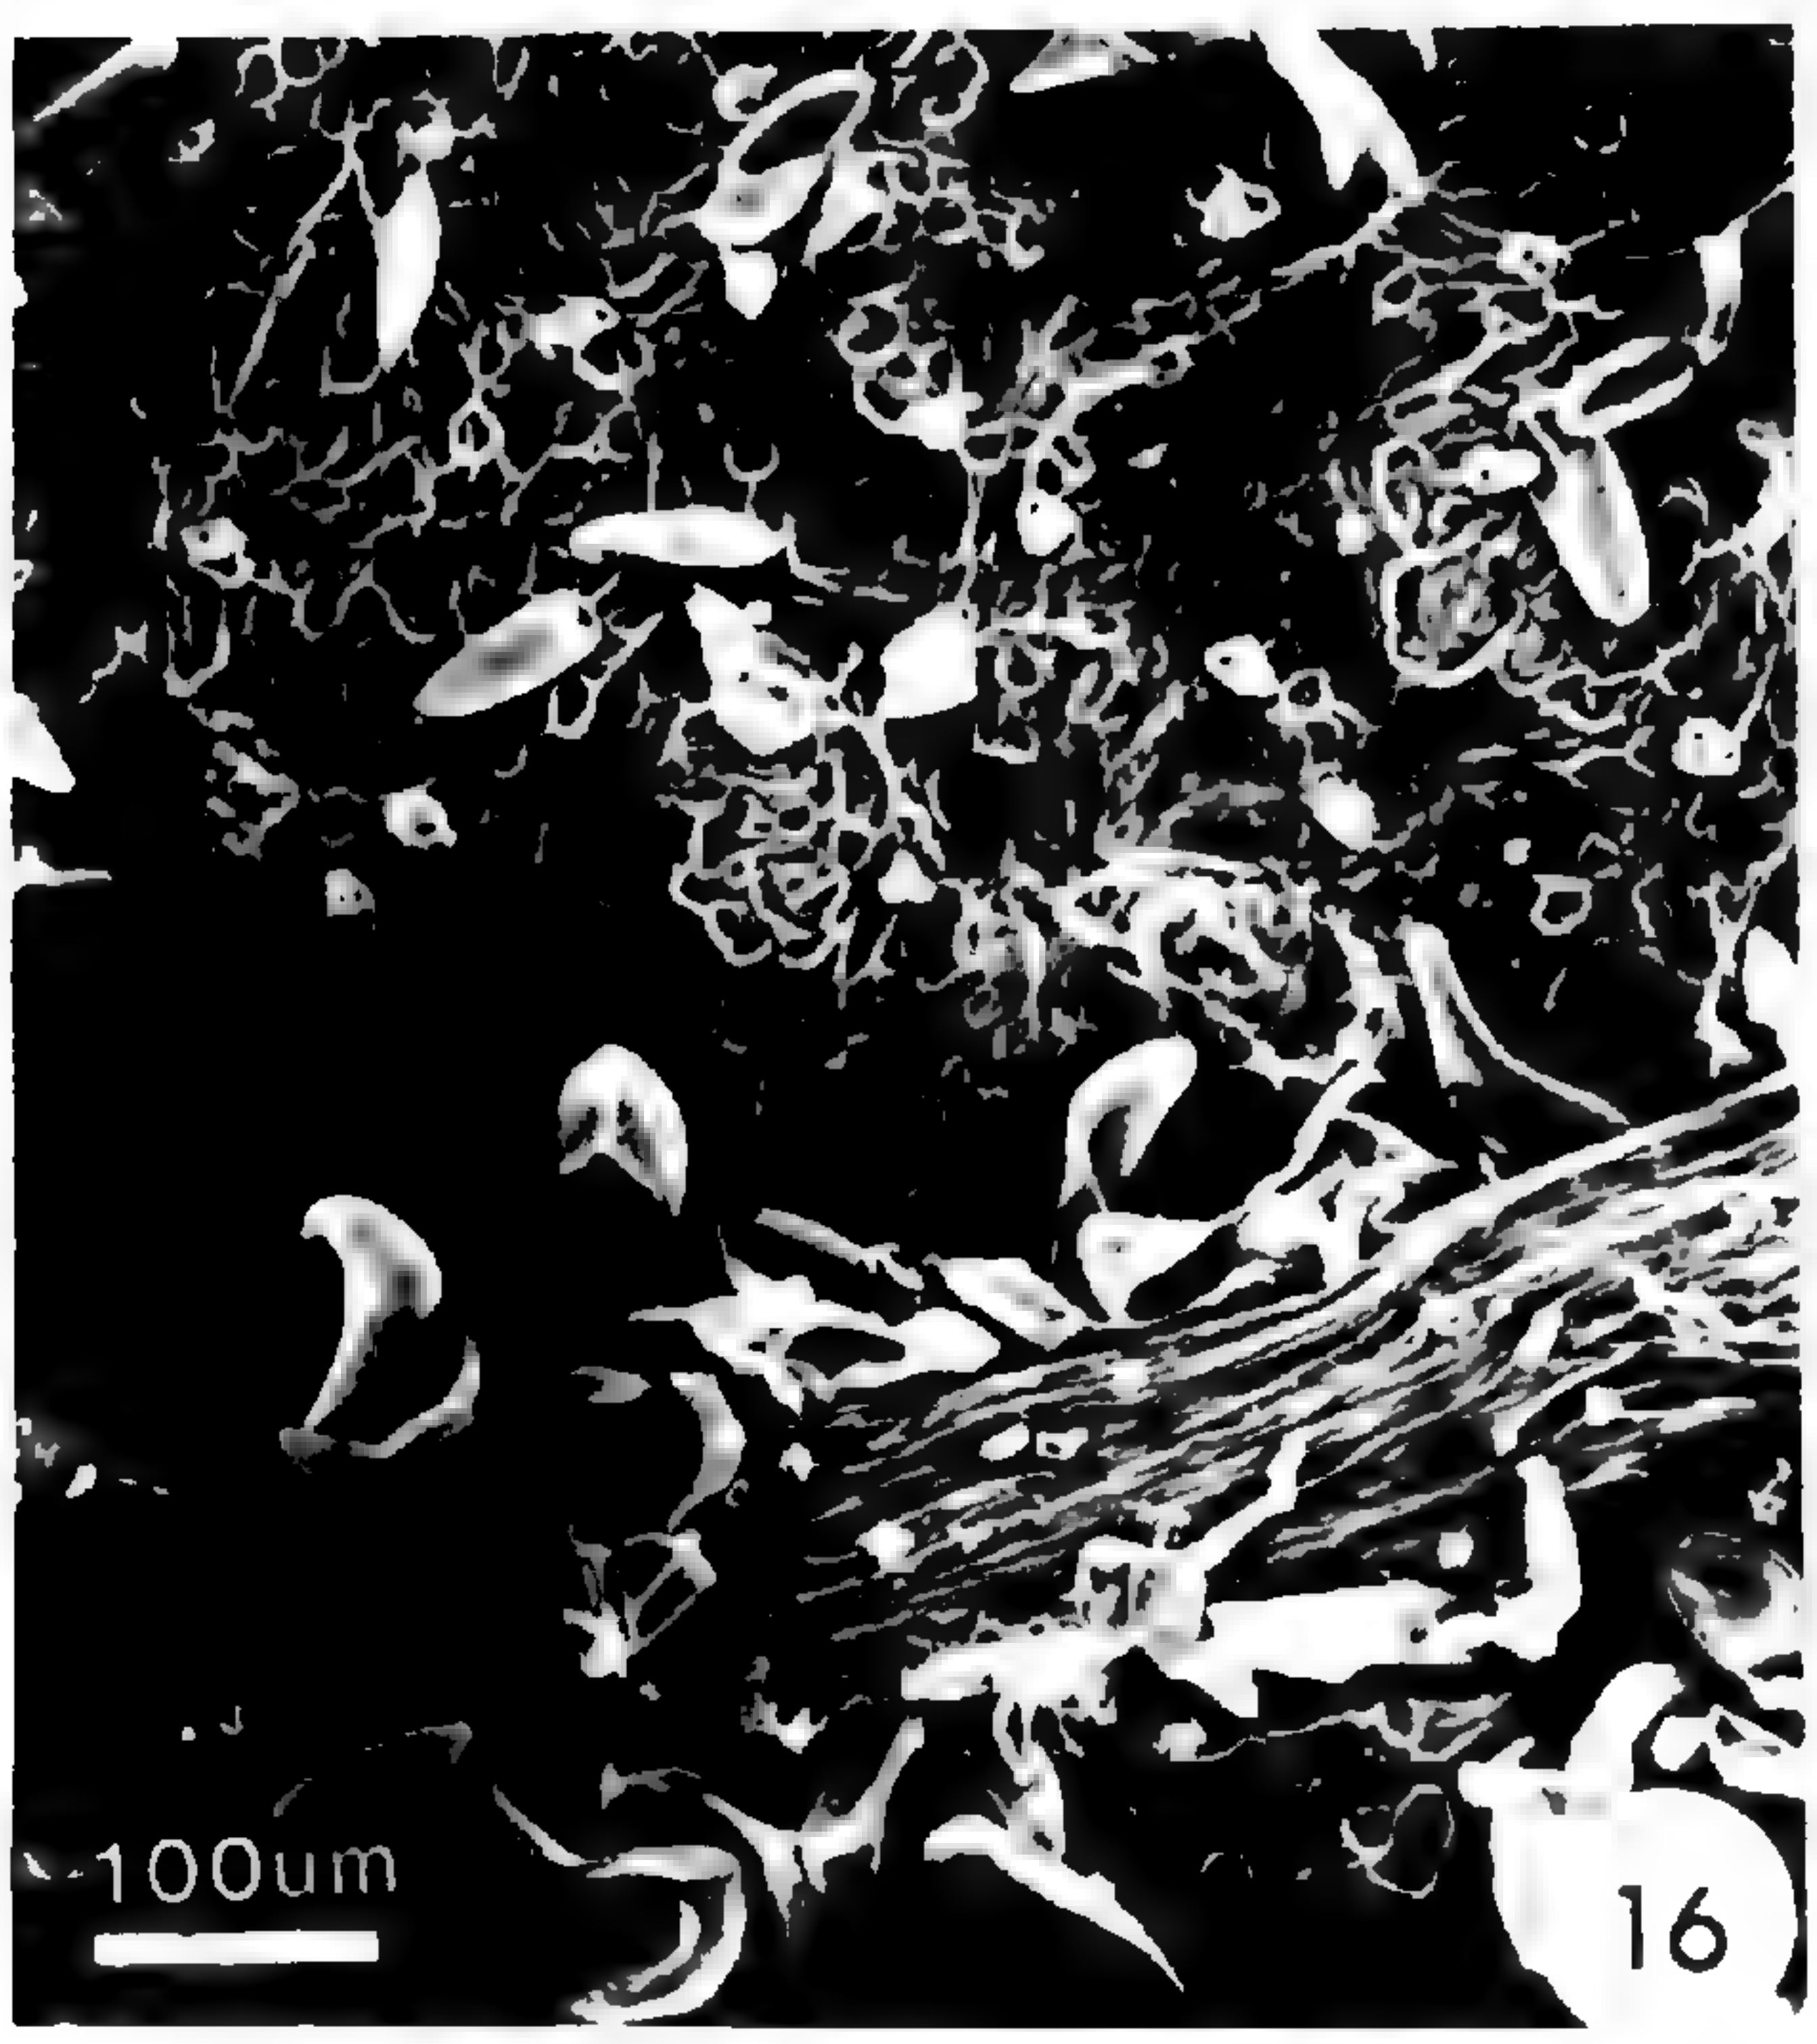
13



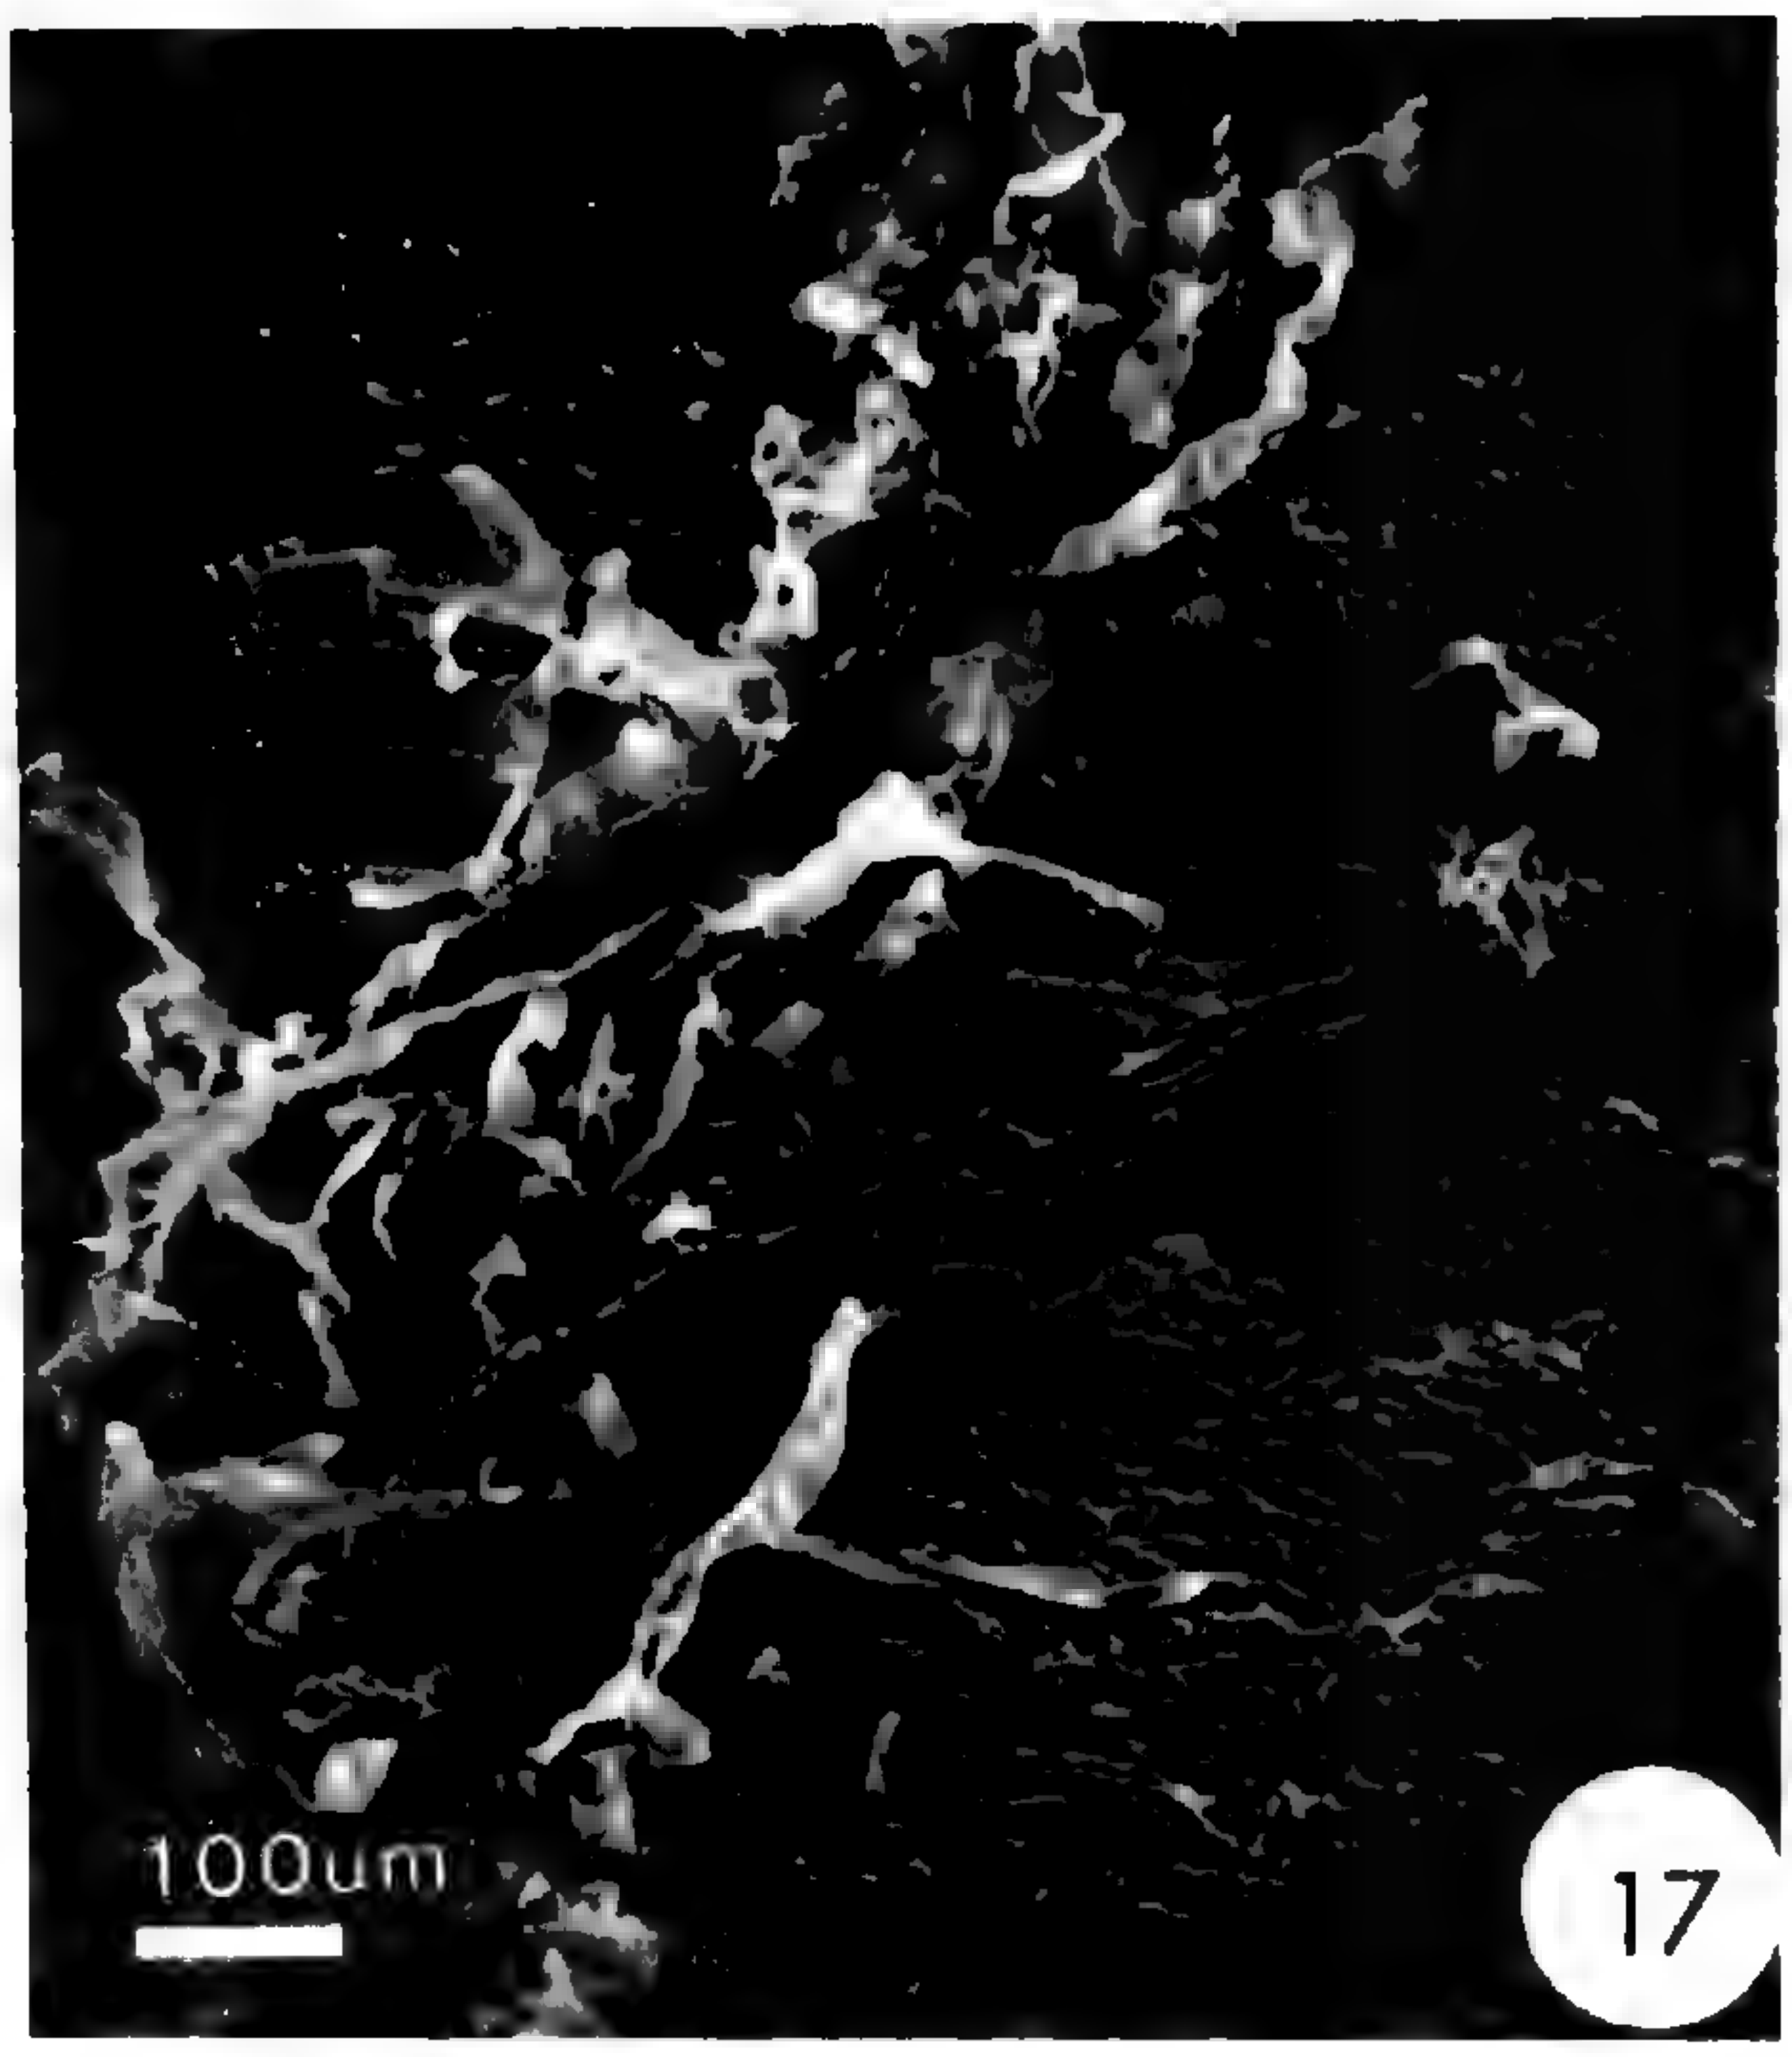
14



15



16



17

2. Gametophytic or sporophytic self-incompatibility systems of the "classical" model, mediated by inhibition of pollen tubes in the style or stigma and governed by a single-locus, multiallelic S-gene, are evidently not present in any of the *Erythrina* species examined. Self-incompatibility in this strict sense is probably absent from the entire genus. There is considerable individual variation in fecundity, and some individuals may be cryptically female-sterile, but if an individual produces seed from outcrossing it will also produce some seed from self-mating. For some individuals and some populations, mating success is lower in selfing than in outcrosses, but much of the mating failure is expressed postzygotically by abortion of young fruits. This is probably an expression of inbreeding depression, the consequence of increased homozygosity for any number of deleterious recessive alleles, rather than the action of a specific S-allele. Inbreeding depression may also be expressed in the progamic stage as inhibition of pollen tubes.

3. Spatial separation of anthers and stigma in some *Erythrina* species, and protandry in other species, limits autogamous pollinations. For the protandrous species at least, this mechanism is not absolutely effective; autogamous fruits are occasionally produced. Autogamy occurs only with the ultimate flowers on an inflorescence and may be an adaptive feature of the breeding system to produce some seed as a "last resort" if no "high-quality" (i.e., outbred) seed was produced on earlier flowers of the inflorescence.

4. The hybridization trials indicate that matings between closely related species (within sections) are just as likely to produce viable progeny as are matings within species. Mating success is usually higher, in fact, in interspecific hybridizations within sections than in self-mating. At increasing taxonomic distance between parental species, there is a general trend to lower mating success in the hybridization trials. This trend is not universally applicable, however. Viable F_1 hybrids have been produced between the most distantly related groups of species in the genus—between species of different subgenera indigenous to different continents. It is probable that viable F_1 hybrids can be obtained between any two diploid species in the genus *Erythrina*.

5. F_1 hybrids between the closely related species in sect. *Erythrina* exhibit interspecific heterosis by several measures: viability of the F_1 seed is higher, and the F_1 plants are more vigorous, sexually precocious, and have higher pollen fertility than the parental species. Pollen fertility is somewhat lower in hybrids between more distantly related species, but these hybrids are generally comparable in viability and vigor with the parental species.

6. A reduction in fecundity is exhibited by the F_1 hybrids, at least when the F_1s are selfed. This lowered mating success is not due to "hybrid sterility" per se, since the gametes produced by the F_1 hybrid function normally. Mating failure is expressed postzygotically by abortion of young fruits and evidently is a consequence of inviability of the F_2 hybrid embryo. An alternative explanation may be that mating failure in the selfed F_1s is a consequence of inbreeding depression.

These experiments support the first two hypotheses presented in the introduction: 1) the species in sect. *Erythrina* can hybridize freely with each other, and there are no internal qualitative or quanitative postmating isolating barriers between the species; and 2) hybridization between more widely divergent species is also possible; there is generally a quantitative reduction in mating success in the wider hybridizations, but this probably does not constitute an absolute barrier to the formation of F_1 hybrids. The only major unanswered question regarding interspecific compatibility among diploid *Erythrina* is the possibility of hybrid breakdown in the F_2 and subsequent generations. F_2 breakdown, if it exists, does not form an absolute isolating barrier within sect. *Erythrina*, but it may form an absolute barrier in hybridizations between more widely divergent species.

SECTION 5. INHERITANCE OF PHENETIC TRAITS IN INTERSPECIFIC HYBRIDS

The fact that plant species with large morphological discontinuities can be hybridized, and that large hybrid progenies can be grown together in a common garden, has allowed for analyses of the genetic basis of these phenetic differences (review in Gottlieb, 1984). A thorough genetic analysis, of course, requires at least the study of segregating

progeny in the F_2 generation. In the absence of large F_2 families, however, preliminary characterization of the inheritance of morphological characters can be obtained from F_1 hybrids.

A study of the inheritance of phenetic traits in artificially produced hybrids serves several purposes beyond that of genetic analysis. Firstly, it allows for confirmation of hybridity in the hybrid progeny. In any experimental hybridization, there exists the possibility that the cross may be spurious; the progeny could result from contamination of self-pollen on the stigma, or from agamospermy. However, if the progeny possess a character present in the male parent but absent in the female, their hybrid nature is reasonably confirmed.

A second purpose for studying the inheritance of morphological traits in artificial hybrids is to generate information on the patterns of variation to be expected when hybridization occurs in nature. If, as Raven (1980) and Grant (1981) have suggested, there is a great deal of hybridization in flowering plants that passes undetected as such, then study of the products of artificial hybridization may help in the discovery and confirmation of hybrids in natural populations. This method was used effectively, for example, by Nobs (1963) in his biosystematic study of *Ceanothus*. Some of the artificial F_2 hybrid segregates of *Ceanothus* closely resembled stabilized populations with restricted ranges recognized as species. Nobs used this evidence to support his hypothesis that these species were of hybrid origin and were derived from pairs of extant, more wide-ranging species.

A similar study, combining artificial hybridization and analysis of natural hybridization, conducted by Gillett & Lim (1970) on *Bidens* in

Hawaii, has been questioned by Ganders & Nagata (1984). They showed that some of the putative natural hybrids were merely intraspecific variants, and Ganders & Nagata concluded that adaptive divergence was more important than hybridization in the evolution of *Bidens* in the Hawaiian Islands. Although all of the 17 Hawaiian *Bidens* species are in fact interfertile, natural hybridization is rare because they are mostly allopatric. Evidently Gillett & Lim used too few characters and ignored intrapopulation variation. An important caveat is to avoid a too facile interpretation of hybridization results when applying them to the study of processes in nature.

In this research, two sets of phenetic traits were examined in the *Erythrina* hybrids and their parent species: 1) features of the epidermis of abaxial leaf surfaces, and 2) morphology and color of the flowers.

EPIDERMAL FEATURES OF *ERYTHRINA* LEAVES

Characters of the leaf are second only to those of flowers in their use and value in taxonomic studies (Stace, 1984). Studies of the inheritance of leaf surface characters in interspecific hybrids have recently been carried out in *Aloe* and *Gasteria* (Liliaceae) (Cutler, 1972), in *Ilex* (Baas, 1978), and in *Quercus* (Cottam et al., 1982).

Erythrina species possess a wide variety of leaf surface characters. These have figured prominently in the taxonomic delimitation of the species (Krukoff, 1939a, b; Krukoff & Barneby, 1974). In these previous works the surface characters

were not studied with high magnification or anatomical sectioning, however, and the structure of some of the surface characters was misinterpreted. This is discussed below in the description of epidermal characters. Leaf epidermal features of a few species of *Erythrina* have also been surveyed using scanning electron microscopy (Ayensu, 1977).

Materials and Methods

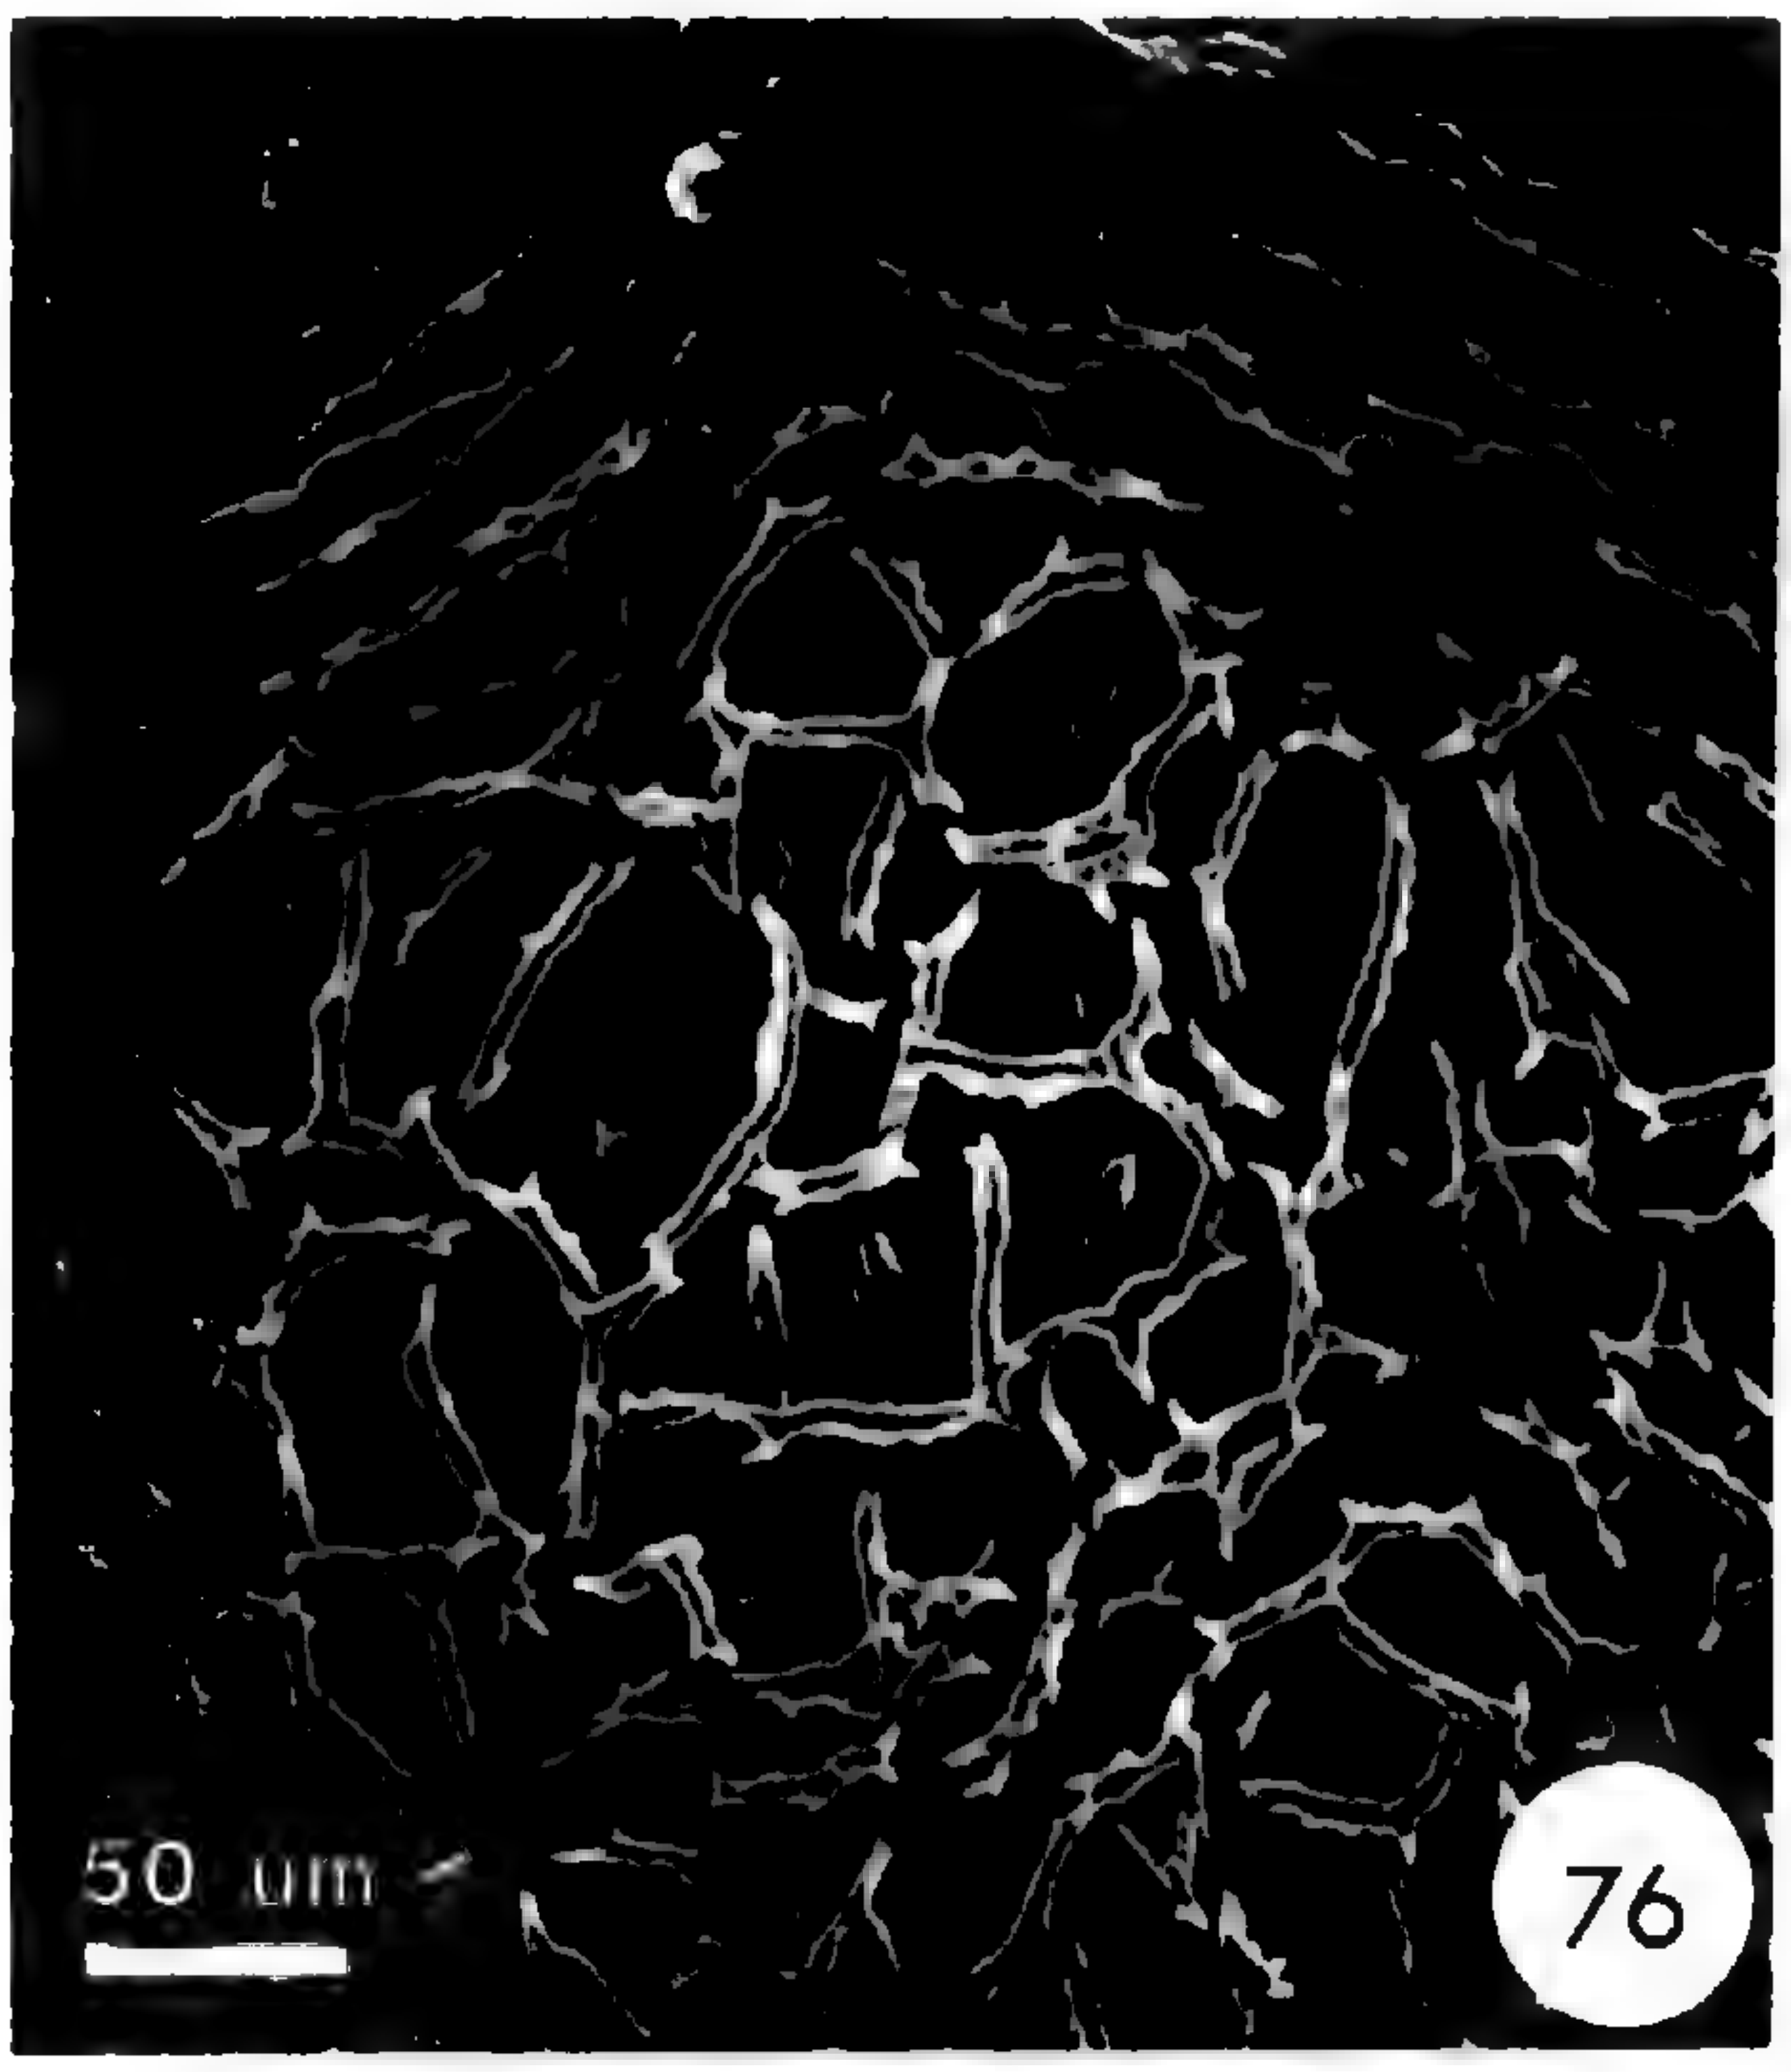
In this study, only the abaxial surfaces of leaves were examined. All samples were obtained from mature, fully expanded leaves, which were pressed and dried as in preparation of herbarium specimens. The specimens were gold-coated with a Polaron E5000 sputter-coater and observed with an Hitachi 450-S scanning electron microscope. For a few selected species, anatomical sections of paraffin-embedded leaves were prepared by Dr. Hiroshi Tobe of Chiba University, Japan.

Results

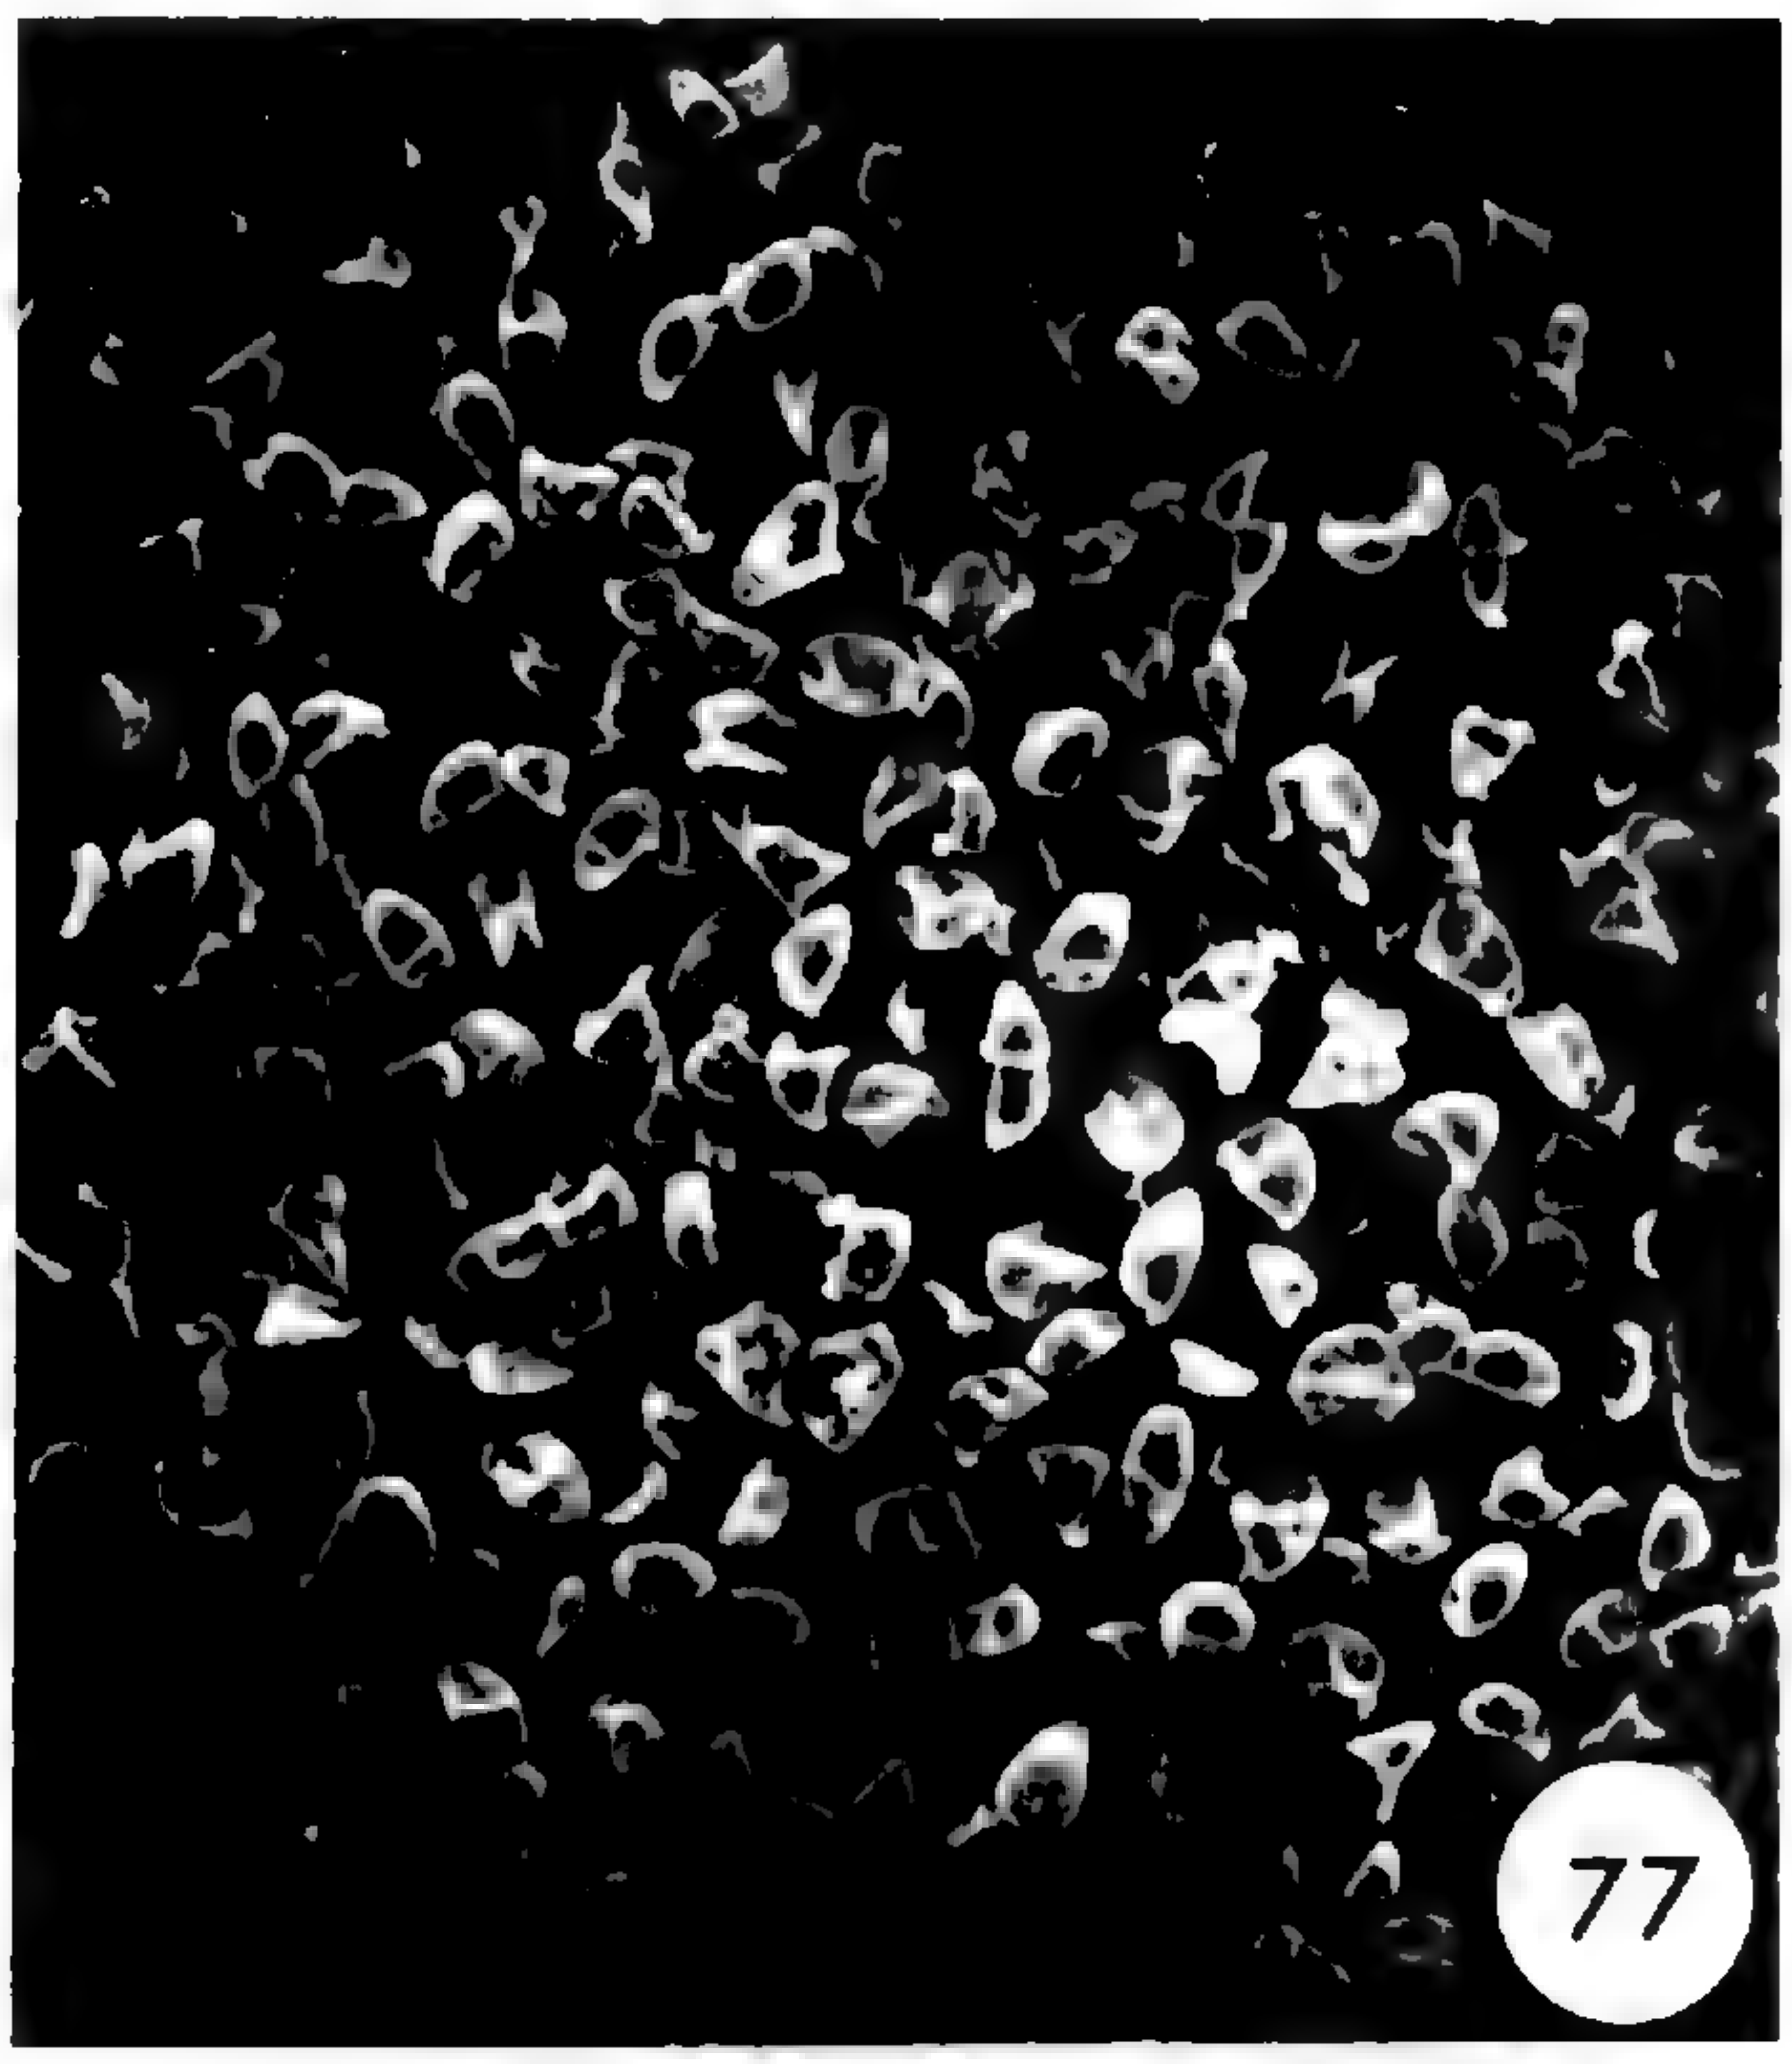
Survey of Leaf Epidermal Features in Erythrina

Epicuticular Wax. Platelets of epicuticular wax cover the abaxial leaf surfaces of many *Erythrina* species. The wax gives a whitish, glaucous appearance to the leaf observed without magnification. The platelets are 1–3 μm in size, are oriented randomly on the leaf surface, and vary in density (Figs. 12, 13). Epicuticular wax is consistently present in some species, but in others its presence or absence is variable even among individuals of a single population.

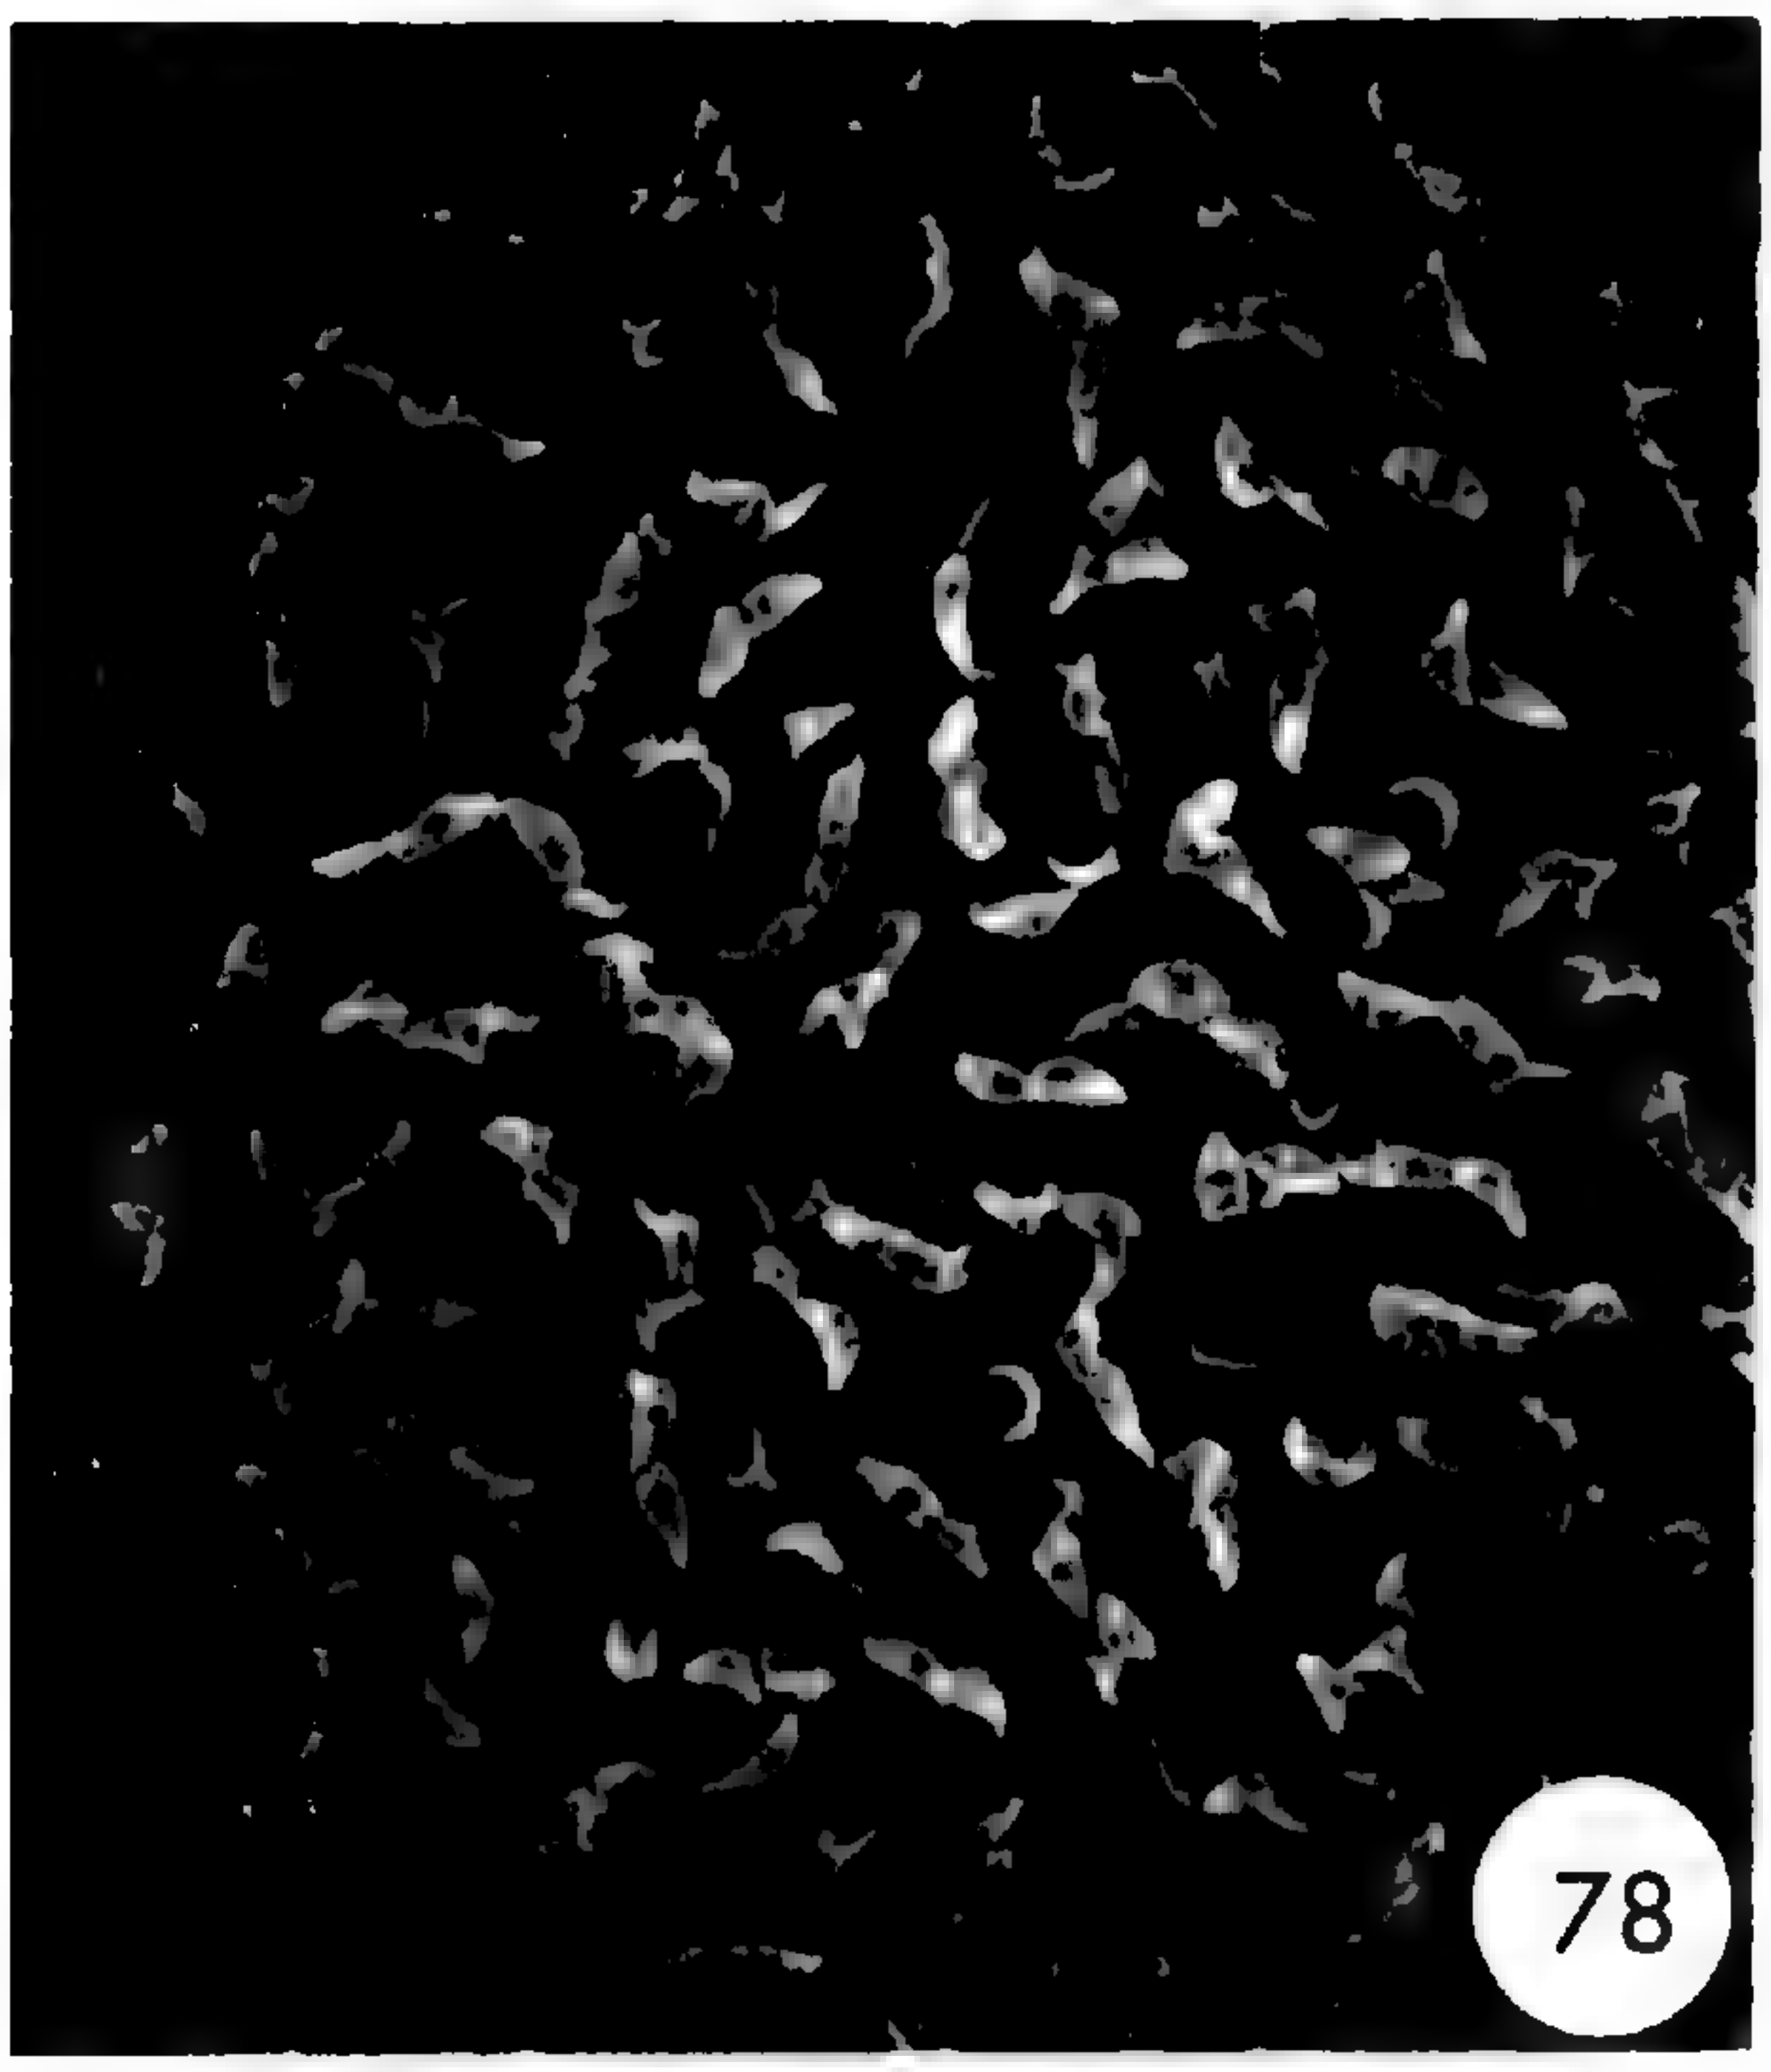
Multicellular Branched Hairs. Several types of



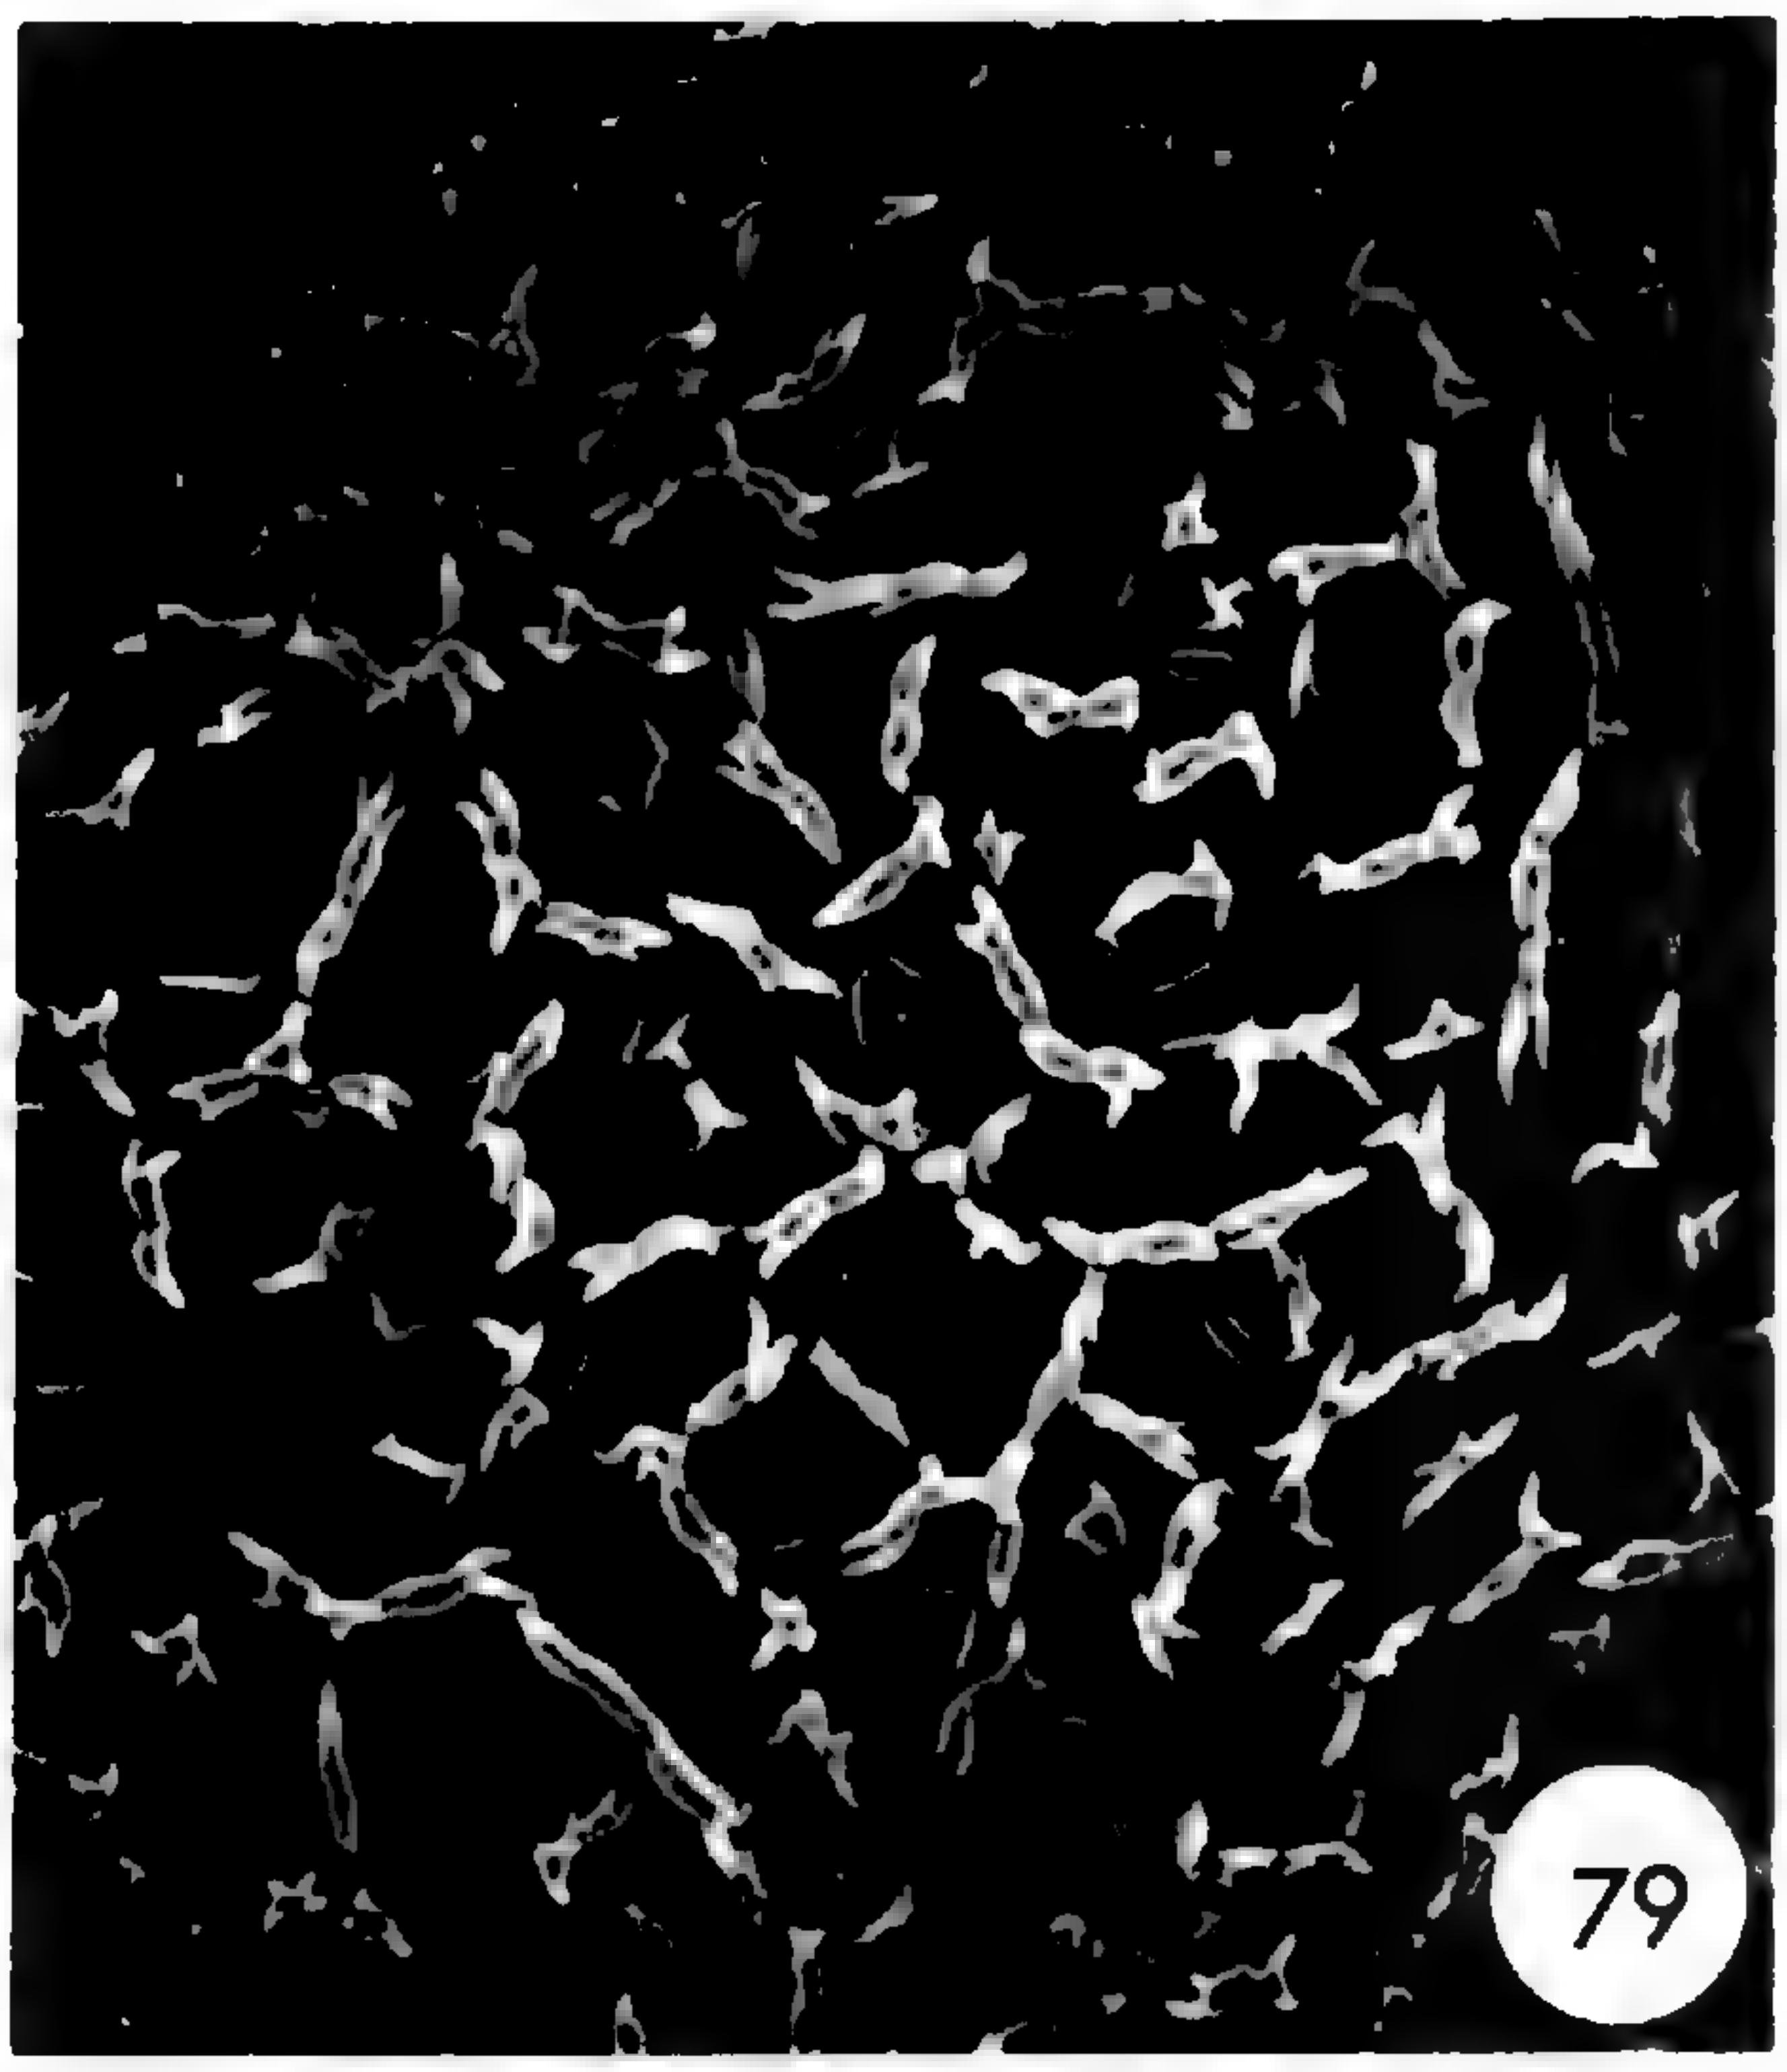
76



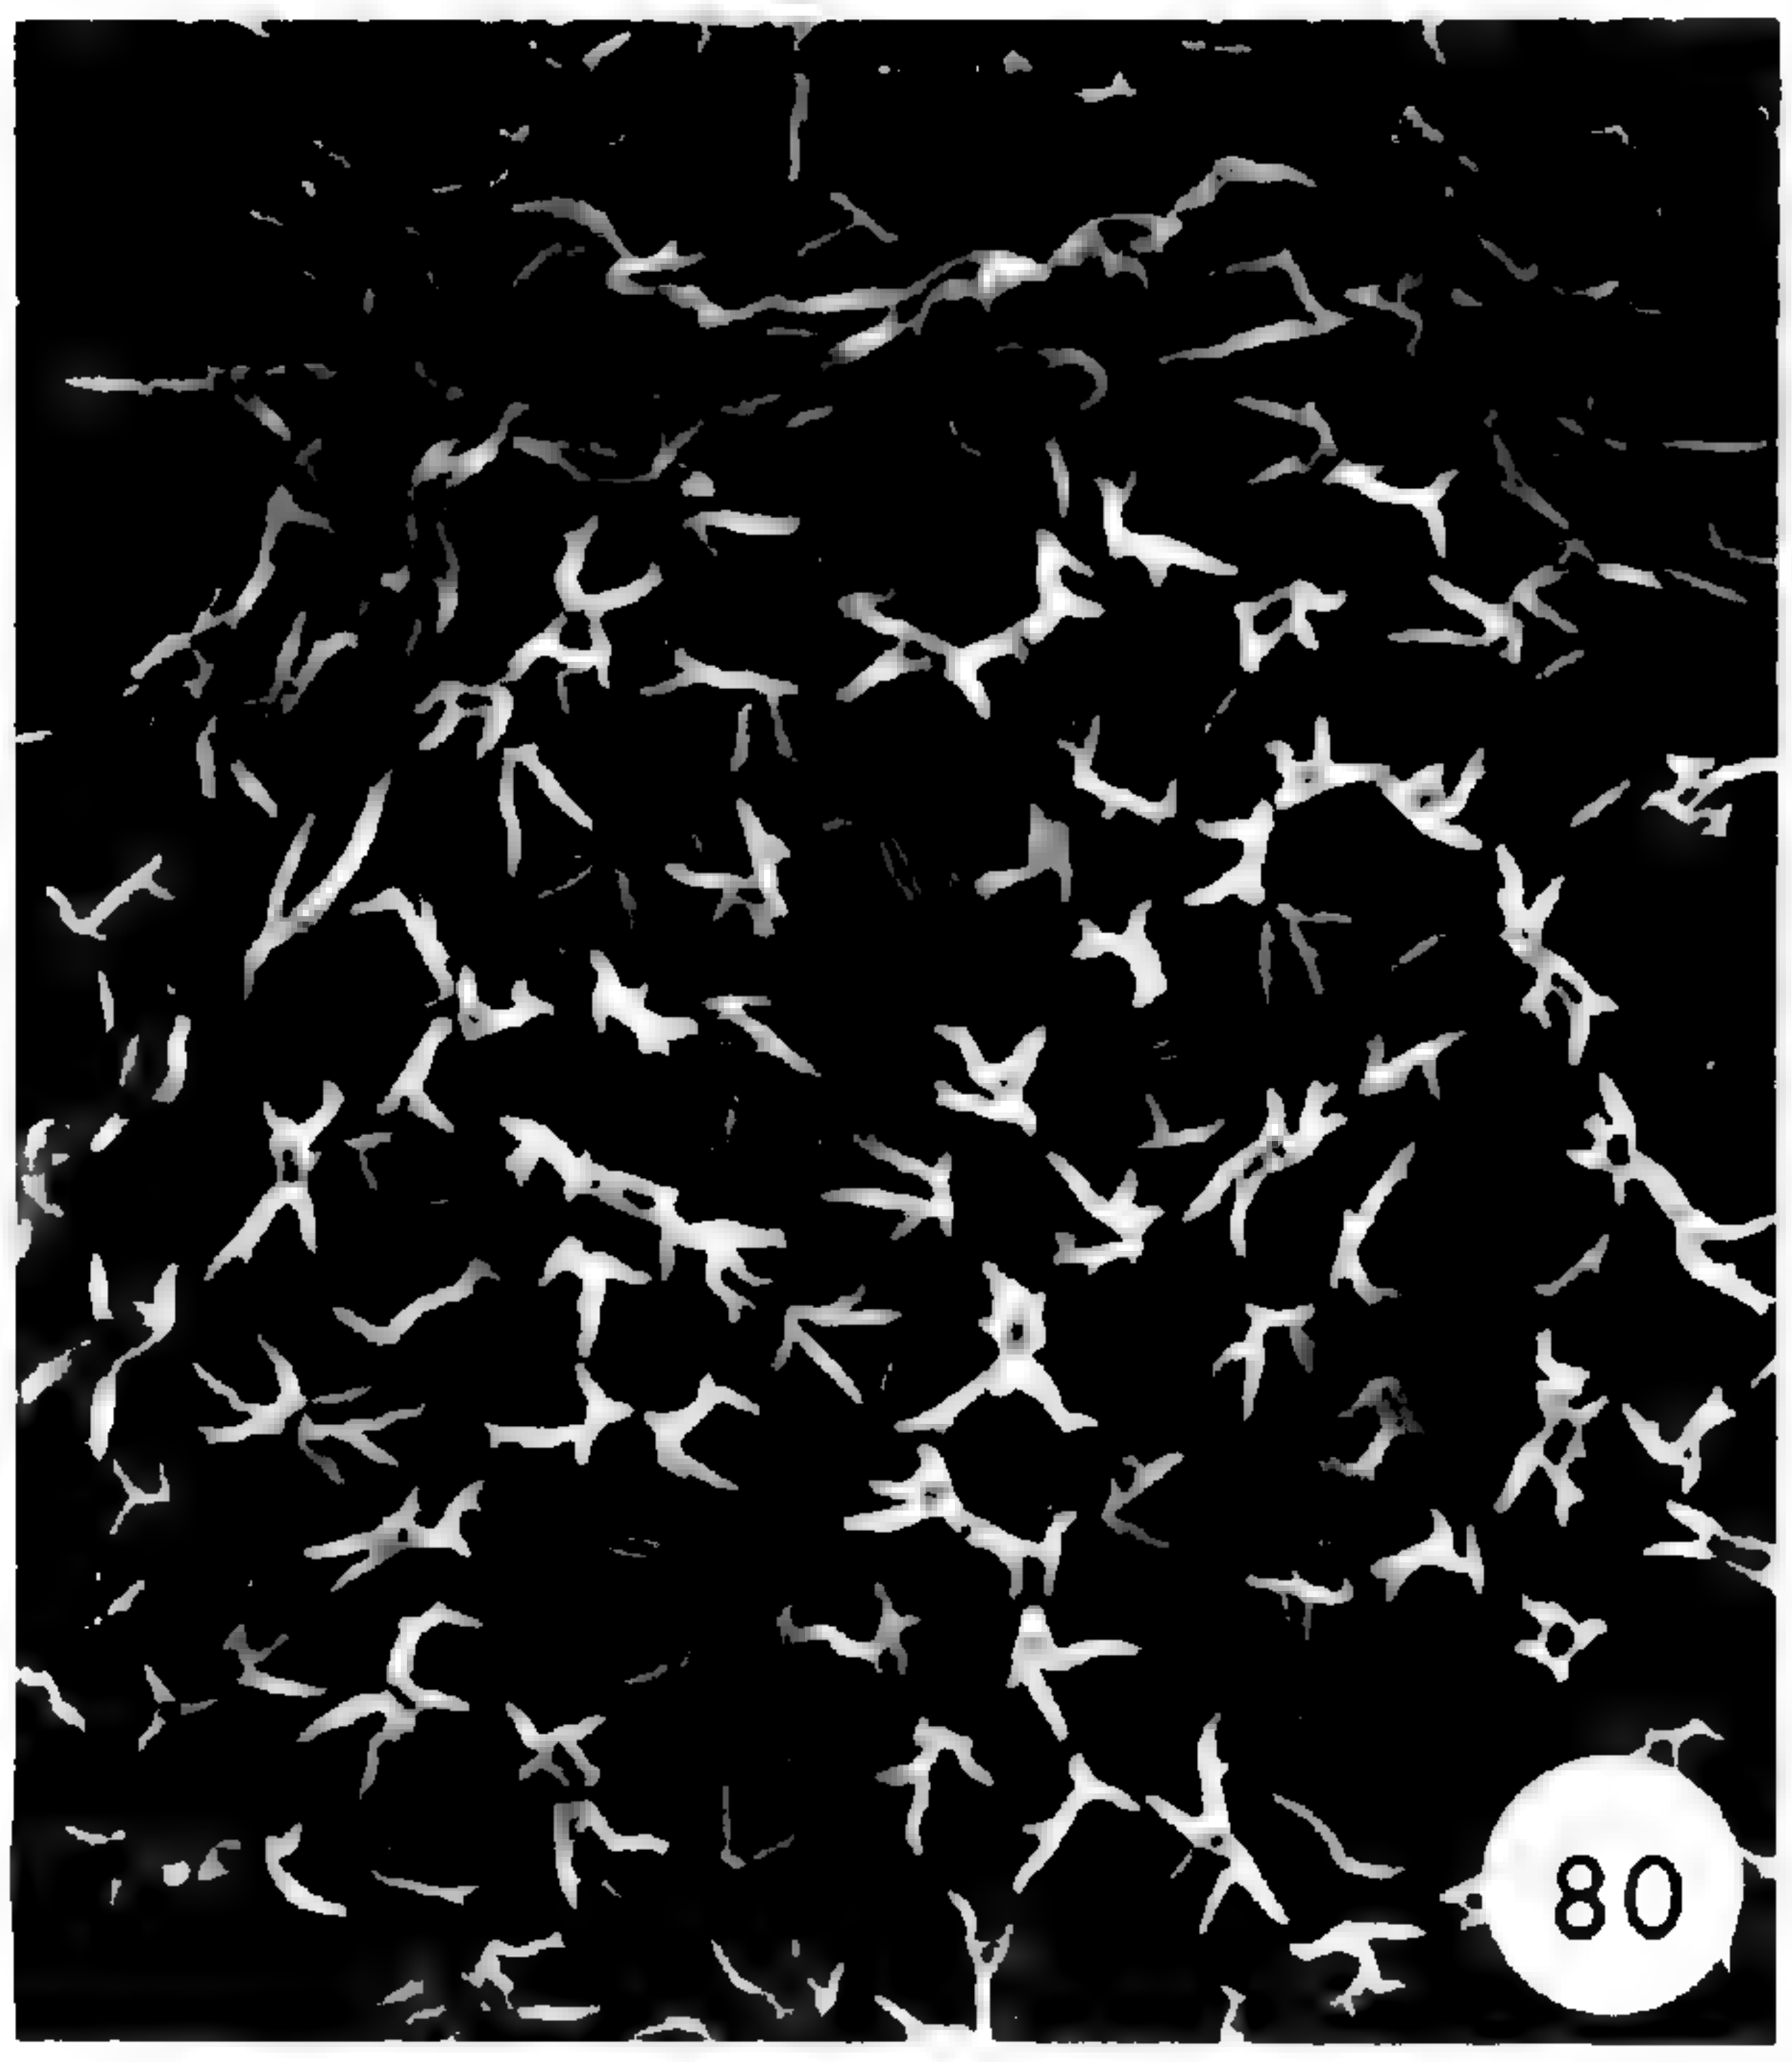
77



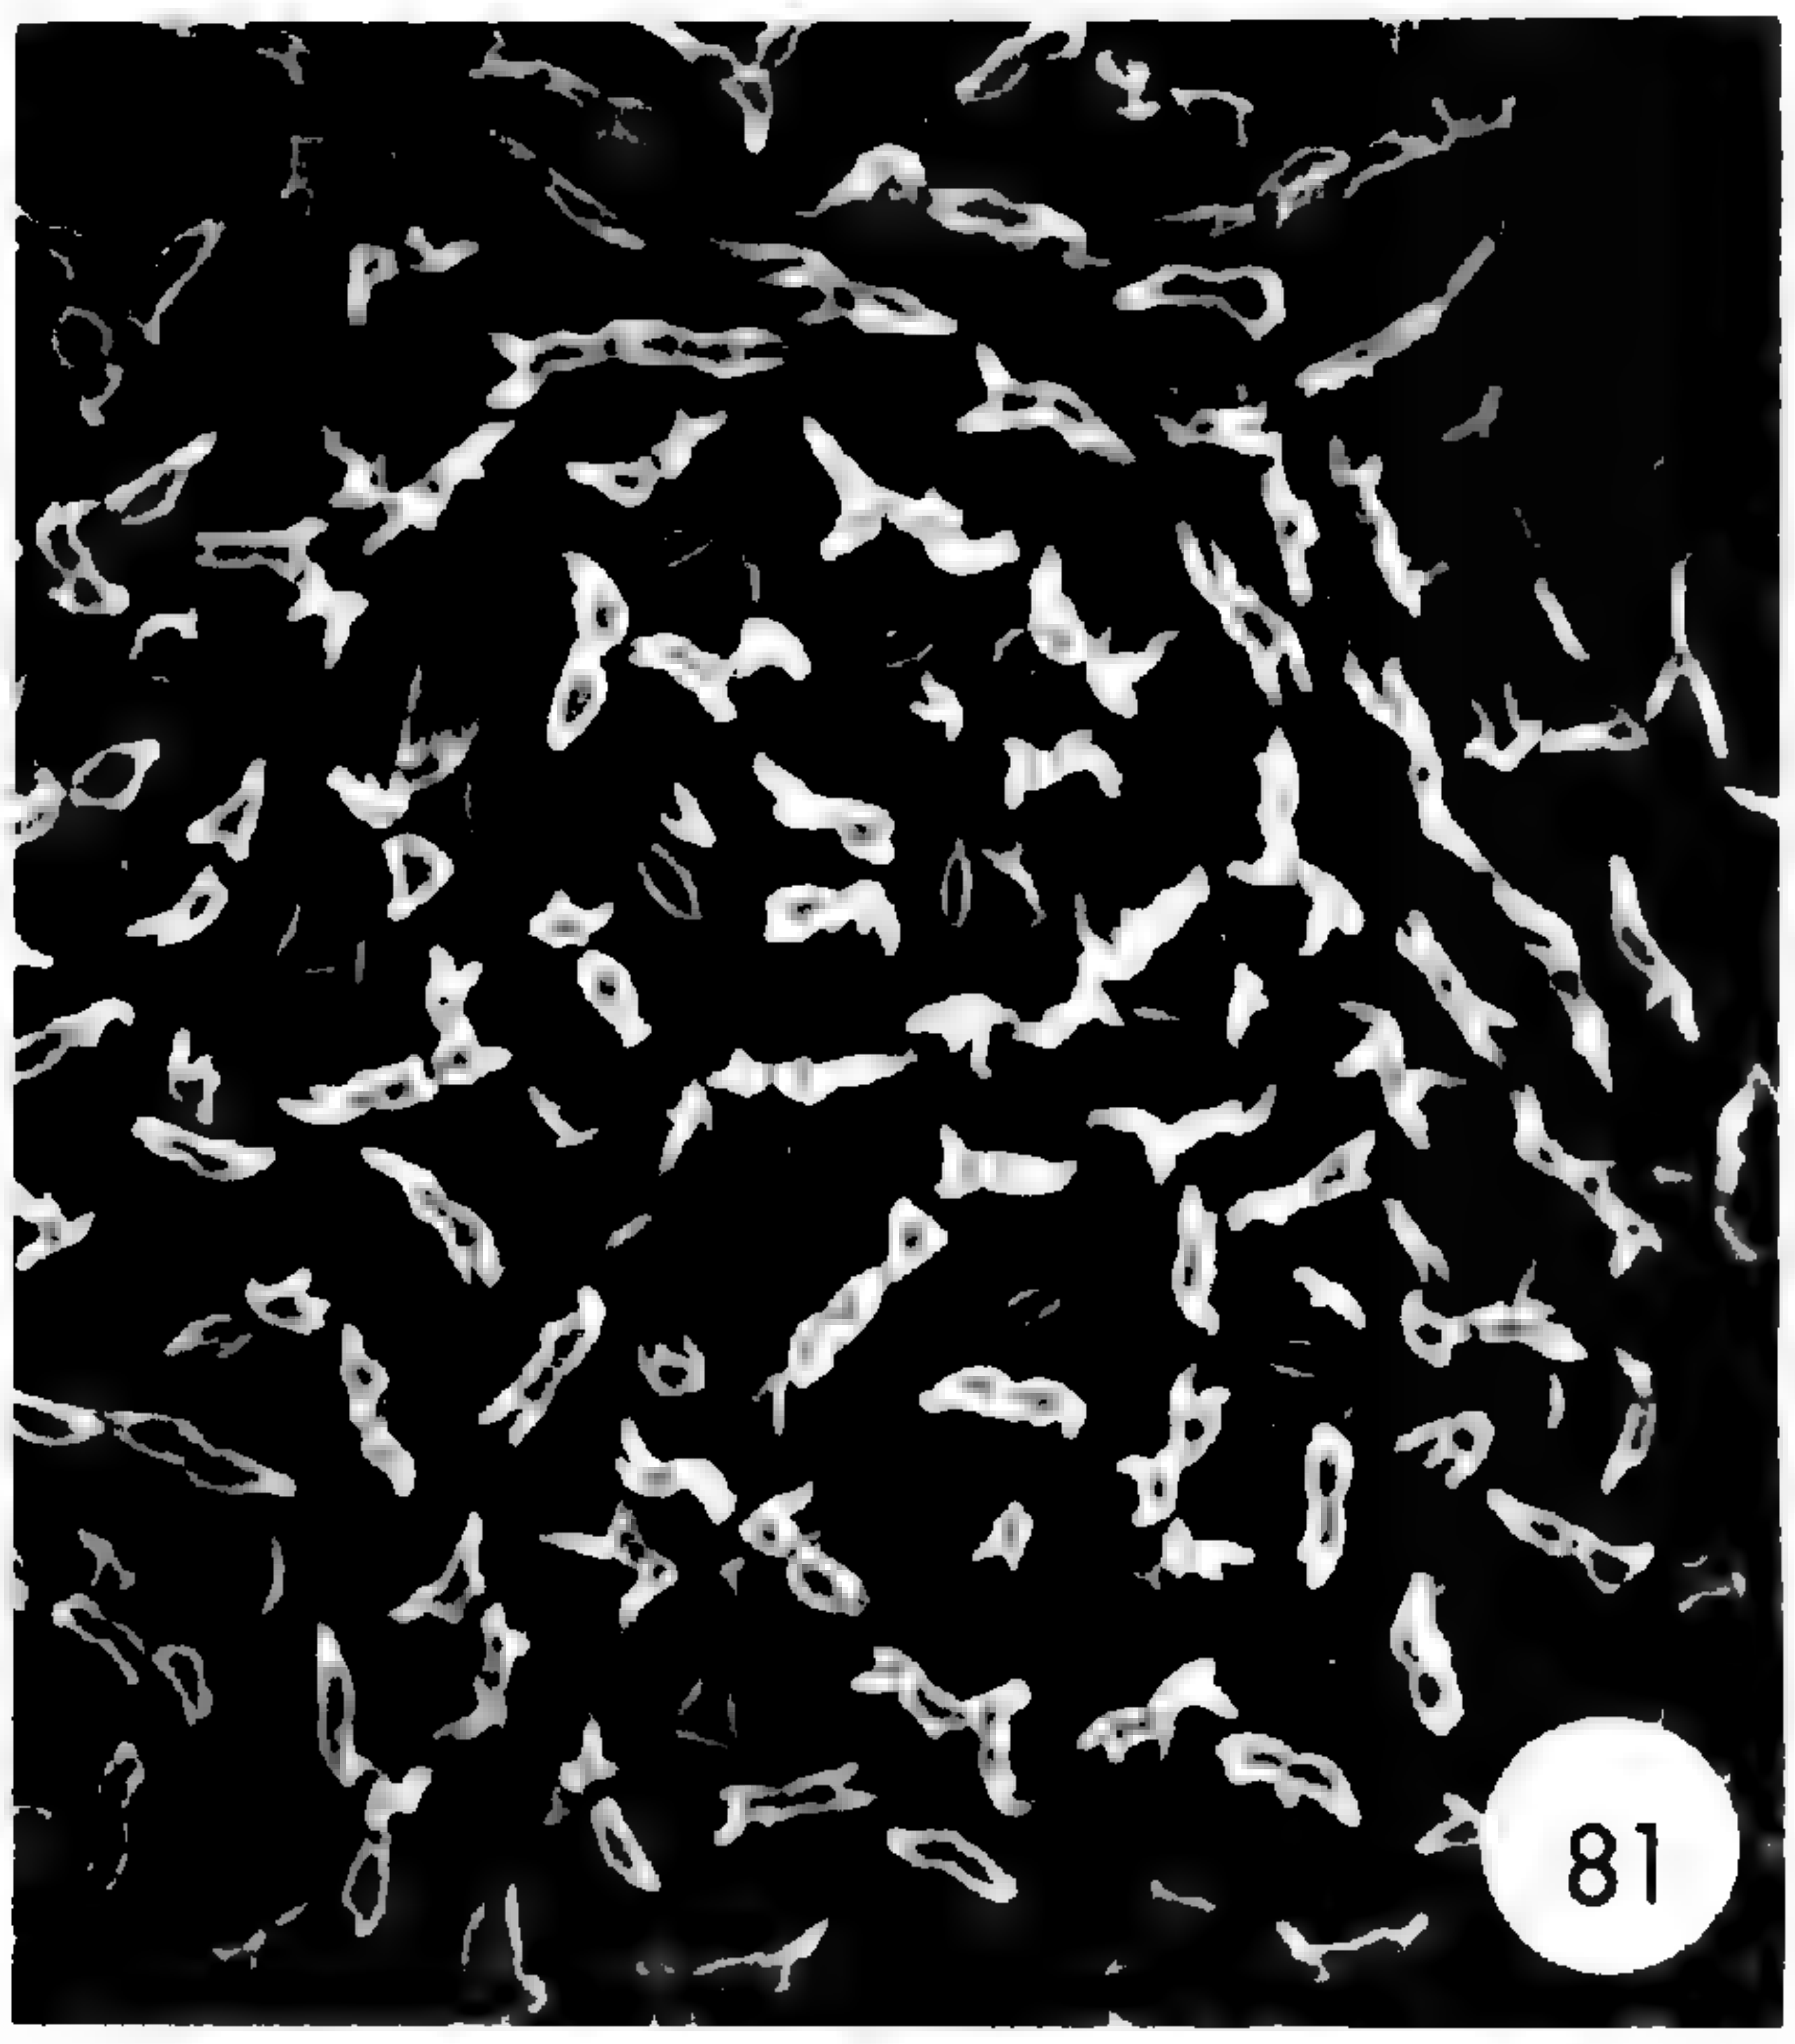
78



79



80



81

hair occur on the abaxial leaf surfaces of *Erythrina* species. The most common, and the only type found in sect. *Erythrina,* is a multicellular, two-armed hair (Fig. 14). This consists of several short basal cells, one or two longer cells forming the stalk, and one cell forming each of the arms, which may be 1,000 μm or more in length. Two-armed hairs are present on the young leaves of most species in sect. *Erythrina* and in species of other sections as well, but in many species they are deciduous and are absent from fully expanded leaves. In the other species, the hairs are retained on mature leaves and form a dense tomentum.

Multiple-branched, dendritic hairs (Fig. 15) are restricted to sect. *Erythraster.* They occur in all species of that section and are found on calyces, inflorescence branches, and on leaves. Each branch of the dendritic hair is 50–100 μm long and is formed by a single cell. The dendritic hair has about 8–12 branches and extends up to 300 μm above the surface of the epidermis.

"Glandular" Hairs. Multicellular, uniseriate hairs occur sporadically on leaf surfaces of many *Erythrina* species (Figs. 22, 23). They appear to be glandular, but what substance these hairs secrete, if any, is not known. They are squat, rounded hairs about 50 μm long and comprised of five or six cells. Observed with a microscope, they glisten with a translucent amber color.

Unicellular Hairs. The most common type of multicellular hair in *Erythrina* is formed by a rounded or elliptic, thin-walled cell which loses its cytoplasm and collapses at leaf maturity or upon drying (Fig. 16). These I refer to as "balloonlike" hairs. They occur in several sections of *Erythrina.* Long, flat, ribbonlike hairs 500 μm or more in length are found particularly along the principal veins of the leaf in some species (Fig. 17). This type of hair is predominant in the Mexican sects. *Breviflorae* and *Leptorhizae.*

Epidermal Sculpturing: Papillae and Lamellae. The remaining types of *Erythrina* trichomes are considered separately from hairs because they are more integrally a part of the foliar epidermis. These are papillae and lamellae, which I refer to collectively as "epidermal sculpturing."

Papillae are single-celled, fingerlike trichomes. Each papilla is formed by the protrusion of an epidermal cell above the leaf surface. Papillae are up to 40 μm tall and 15 μm in diameter (Figs. 18, 19). Papillae and the epidermal surface between them are usually covered with epicuticular wax platelets. Under low magnification, a leaf surface with papillae appears covered with whitish granules. Krukoff (Krukoff & Barneby, 1974) termed such leaf surfaces "farinose-ceriferous" or "granular-ceriferous," but the "granules" he described are wax-covered papillate cells, not individual particles of wax.

Papillae similar to the ones found in *Erythrina* occur on leaf surfaces in many groups of plants, but the structures I have termed "lamellae" have not to my knowledge been reported from leaf epidermis of any angiosperm besides *Erythrina.* Lamellae, like papillae, are formed by protrusions of epidermal cells, but in lamellae the cells are joined edge-to-edge to form continuous "walls" one cell thick that stand above the surface of the leaf (Figs. 20, 21). Leaf surfaces with lamellae are also usually covered with epicuticular wax.

Lamellae occur in several species of sect. *Erythrina.* In these species the lamellae are discontinuous; each lamella is composed of several to twenty cells standing edge-to-edge. The lamellae form a dense, discontinuous network with a characteristic pattern when observed at low magnification (Fig. 34). Krukoff (Krukoff & Barneby, 1974) referred to leaves with wax-covered lamellae as "reticulately ceriferous."

A unique pattern of lamellae occurs only in the Asian sect. *Suberosae* (Figs. 24–27). The lamellae are tall (50 μm) and continuous. Parallel rows of several lamellae, each leaning at a different angle with respect to the leaf surface (Fig. 25), are joined to form an open network of interconnected polygons (Fig. 24). Shorter lamellae extend into the center of the polygons. The distribution of the polygons is associated with the vascular tissue of the leaf. *Erythrina suberosa* (Figs. 26, 27) has both polygon-forming lamellae and two-branched hairs.

Trichome characters are generally quite constant within a species and are useful taxonomic markers, often allowing species identification from

sterile material. In contrast, presence or absence of epicuticular wax is variable within populations and is not a useful marker. As will be seen in the discussion of the hybrids below, epicuticular wax is evidently a simply inherited trait. Krukoff (Krukoff & Barneby, 1973) separated the Mexican species *Erythrina americana* Miller and *E. coralloides* A. DC. (sect. *Erythrina*) solely on the basis of presence or absence of epicuticular wax. This trait is variable and is not well correlated with geographic distribution. For this and other reasons, *Erythrina coralloides* is here considered a synonym of *E. americana.*

Inheritance of Leaf-Surface Characters in Interspecific Hybrids

Each of the six plates comprising Figures 28–75 illustrates the leaf surface features of a single F_1 hybrid and its two parents. On each plate, the female parent is illustrated on the left, the male parent on the right, and the hybrid in the center. Each horizontal row of photographs is a comparison of the three individuals at equal magnification (indicated by the bar in the left-hand photograph). Table 18 summarizes the features present in the parents and hybrids.

Four of the six hybrids illustrated were derived from the same genetic individual as female parent, *Erythrina guatemalensis* PT 700018001 and WA 74c1453. It is particularly instructive to note the pattern of inheritance in the hybrids produced from the combination of this genome with those of four different species: *E. berteroana*, *E. chiapasana*, *E. abyssinica*, and *E. senegalensis.*

Erythrina guatemalensis has well-developed papillae on the abaxial leaf surface, each composed of a single epidermal cell; the male parent *E. berteroana* has well-developed lamellae, each composed of about 4–5 cells forming a "wall-like" structure. The F_1 hybrid has lamellae intermediate in length between the two parents, composed of 2–3 cells, but these are lower in stature and less developed than the epidermal sculpturing of either parent (Figs. 37–45).

Erythrina guatemalensis lacks hairs on mature leaf surfaces. The male parents *E. chiapasana* and *E. abyssinica* have dense covering of two-armed hairs. The hybrids derived from these males with *E. guatemalensis* as female also possess two-armed hairs, but at a much lower density than in the male parents (Figs. 46–51, 52–60). *Erythrina senegalensis* has scattered balloonlike hairs, and these are also inherited in the F_1 hybrid *E. guatemalensis* × *E. senegalensis* (Figs. 61–69). The male parents *E. chiapasana* and *E. senegalensis* lack epicuticular wax; this trait is present in the female *E. guatemalensis* and in the hybrids. (Other individuals of *E. chiapasana* than the one used in this cross do have epicuticular wax.)

Similar patterns of inheritance are exhibited by the other F_1 hybrids, for example, *Erythrina chiapasana* × *E. berteroana* (Figs. 28–36). The female parent *E. chiapasana* has a dense covering of hairs and lacks lamellae and epicuticular wax. The male parent *E. berteroana* lacks hair but possesses lamellae and wax. The F_1 hybrid has scattered hairs, lamellae reduced in stature, and epicuticular wax.

In the interspecific hybridization that produced *Erythrina lysistemon* × *E. speciosa*, the male parent possesses two-armed hairs, which are lacking in the female parent; hairs are present in the F_1 hybrid, but again, at a rather lower density than in the male parent (Figs. 70–75).

These results demonstrate that it is possible to confirm hybridity in the progeny by examination of leaf epidermal characters. Many of the hybrids possess characters present in the male parent but absent in the female parent. There is no evidence

of matrocliny or female-dominant inheritance in the *Erythrina* hybrids.

The results, although preliminary, also suggest a difference in the genetics of inheritance of hairs on the one hand, and papillae and lamellae on the other. Hairs are inherited in the hybrids as discrete characters—that is, they are fully formed and of normal size, although they occur at low densities, in crosses between hairy and hairless parents. The formation of hairs may thus be controlled by a single gene or supergene, with modifiers controlling density of the hairs. On the other hand, in crosses between papillate (or lamellate) and nonpapillate parents, papillae (lamellae) may be present but they are much reduced in stature. This suggests that the stature of papillae and lamellae are continuously variable, typical of morphometric traits, and controlled by many genes, each of small effect.

This suggestion requires confirmation by analysis of segregation in the F_2 generation.

The variation in the four F_1 hybrid siblings derived from a single cross, *Erythrina crista-galli* × *E. guatemalensis*, is illustrated in Figures 76–87. The female parent has an irregular network of low lamellae less than 10 μm tall and lacks epicuticular wax. The male parent has a dense covering of unicellular papillae up to 40 μm tall and has epicuticular wax. The F_1 hybrids exhibit a narrowly segregating array of these characters: they have papillae and/or lamellae intermediate in form and stature between the two parents. Some F_1s resemble the female parent more closely and some resemble the male parent. All the F_1s have epicuticular wax, evidently derived from the male parent. (Other individuals of *E. crista-galli*, besides the one used in this cross, do possess wax.)

The leaf epidermis of three F_1 siblings derived from the cross *Erythrina crista-galli* × *E. fusca*, together with their parents, are illustrated in the two plates comprising Figures 88–99. Also included on these plates are photos of *E. dominguezii*, a species that, based on floral characters, may be a stabilized derivative of hybridization between *E. crista-galli* and *E. fusca* (see discussion of hybrid flowers below). The male parent *Erythrina fusca* has a very unusual epidermal surface with deep and irregularly sized and shaped cavities, knobs and protrusions, appearing under SEM much like the surface of a limestone cavern. The stomata are at the bottom of the cavities.

The F_1 hybrids vary somewhat in surface configuration, but none of them possess either the regular network of lamellae present in *E. crista-galli* or the complex, irregular cavity structure of *E. fusca*. Two of the F_1s have scattered low papillae and one is nearly flat on the abaxial surface. All three F_1s have epicuticular platelets, which are not present in either of the parents.

Erythrina dominguezii (Figs. 93, 99) has scattered balloonlike hairs, not present in *E. crista-galli* or *E. fusca*. Otherwise, the epidermal surface on *E. dominguezii* has no distinctive features. Low

epidermal convolutions similar to the lamellae of *E. crista-galli* are visible at high magnification (Fig. 99) but these are not organized into a regular reticulate pattern.

FLORAL FEATURES: INHERITANCE IN INTERSPECIFIC HYBRIDS

The inheritance of floral morphology and color was examined in the hybrids that flowered by November 1984. These included the hybrids within sect. *Erythrina* and the intersectional hybrid *Erythrina crista-galli* × *E. fusca.*

Materials and Methods

Fresh flowers of the hybrids and parents were fixed in FAA, which preserved their three-dimensional shape, and later measured, described, and photographed, each hybrid together with its par-

graphed at the time of collection. Herbarium vouchers are deposited at Missouri Botanical Garden (MO).

Results

Hybrids within Sect. Erythrina

Inflorescence and Flower Orientation. Species of sect. *Erythrina* all have erect inflorescences, but they differ in the arrangement of the flowers on the inflorescence axis (congested or open), length of the axis, and orientation of the flowers (ascending, horizontal, or descending). These traits are generally intermediate in the hybrids (e.g., Figs. 100–102). In *Erythrina guatemalensis*, the female parent, the flowers are horizontal on an open inflorescence. In *E. folkersii*, the male parent, the flowers descend to nearly vertical on a congested inflorescence. The F_1 hybrid is intermediate in both these traits.

Floral Characters. A comparison of floral characters of the hybrids and their parents within sect. *Erythrina* is summarized in Table 19. The flowers are illustrated in Figures 103–110.

In all characters—color, indumentum, shape, and morphometric dimensions—the F_1 hybrids are intermediate between the two parents. The F_1 siblings from a single cross vary to some extent. There is no evidence of matrocliny or maternal dominance.

Subjectively, some of the hybrids resemble the male parent more closely than the female parent. This is evident in the progeny of the reciprocal hybridizations between *Erythrina guatemalensis* and *E. macrophylla* (Figs. 107, 108). The vestiture and shapes of the calyces of the hybrids are

intermediate and variable, but in both reciprocals the hybrids resemble the male parent somewhat more than the female.

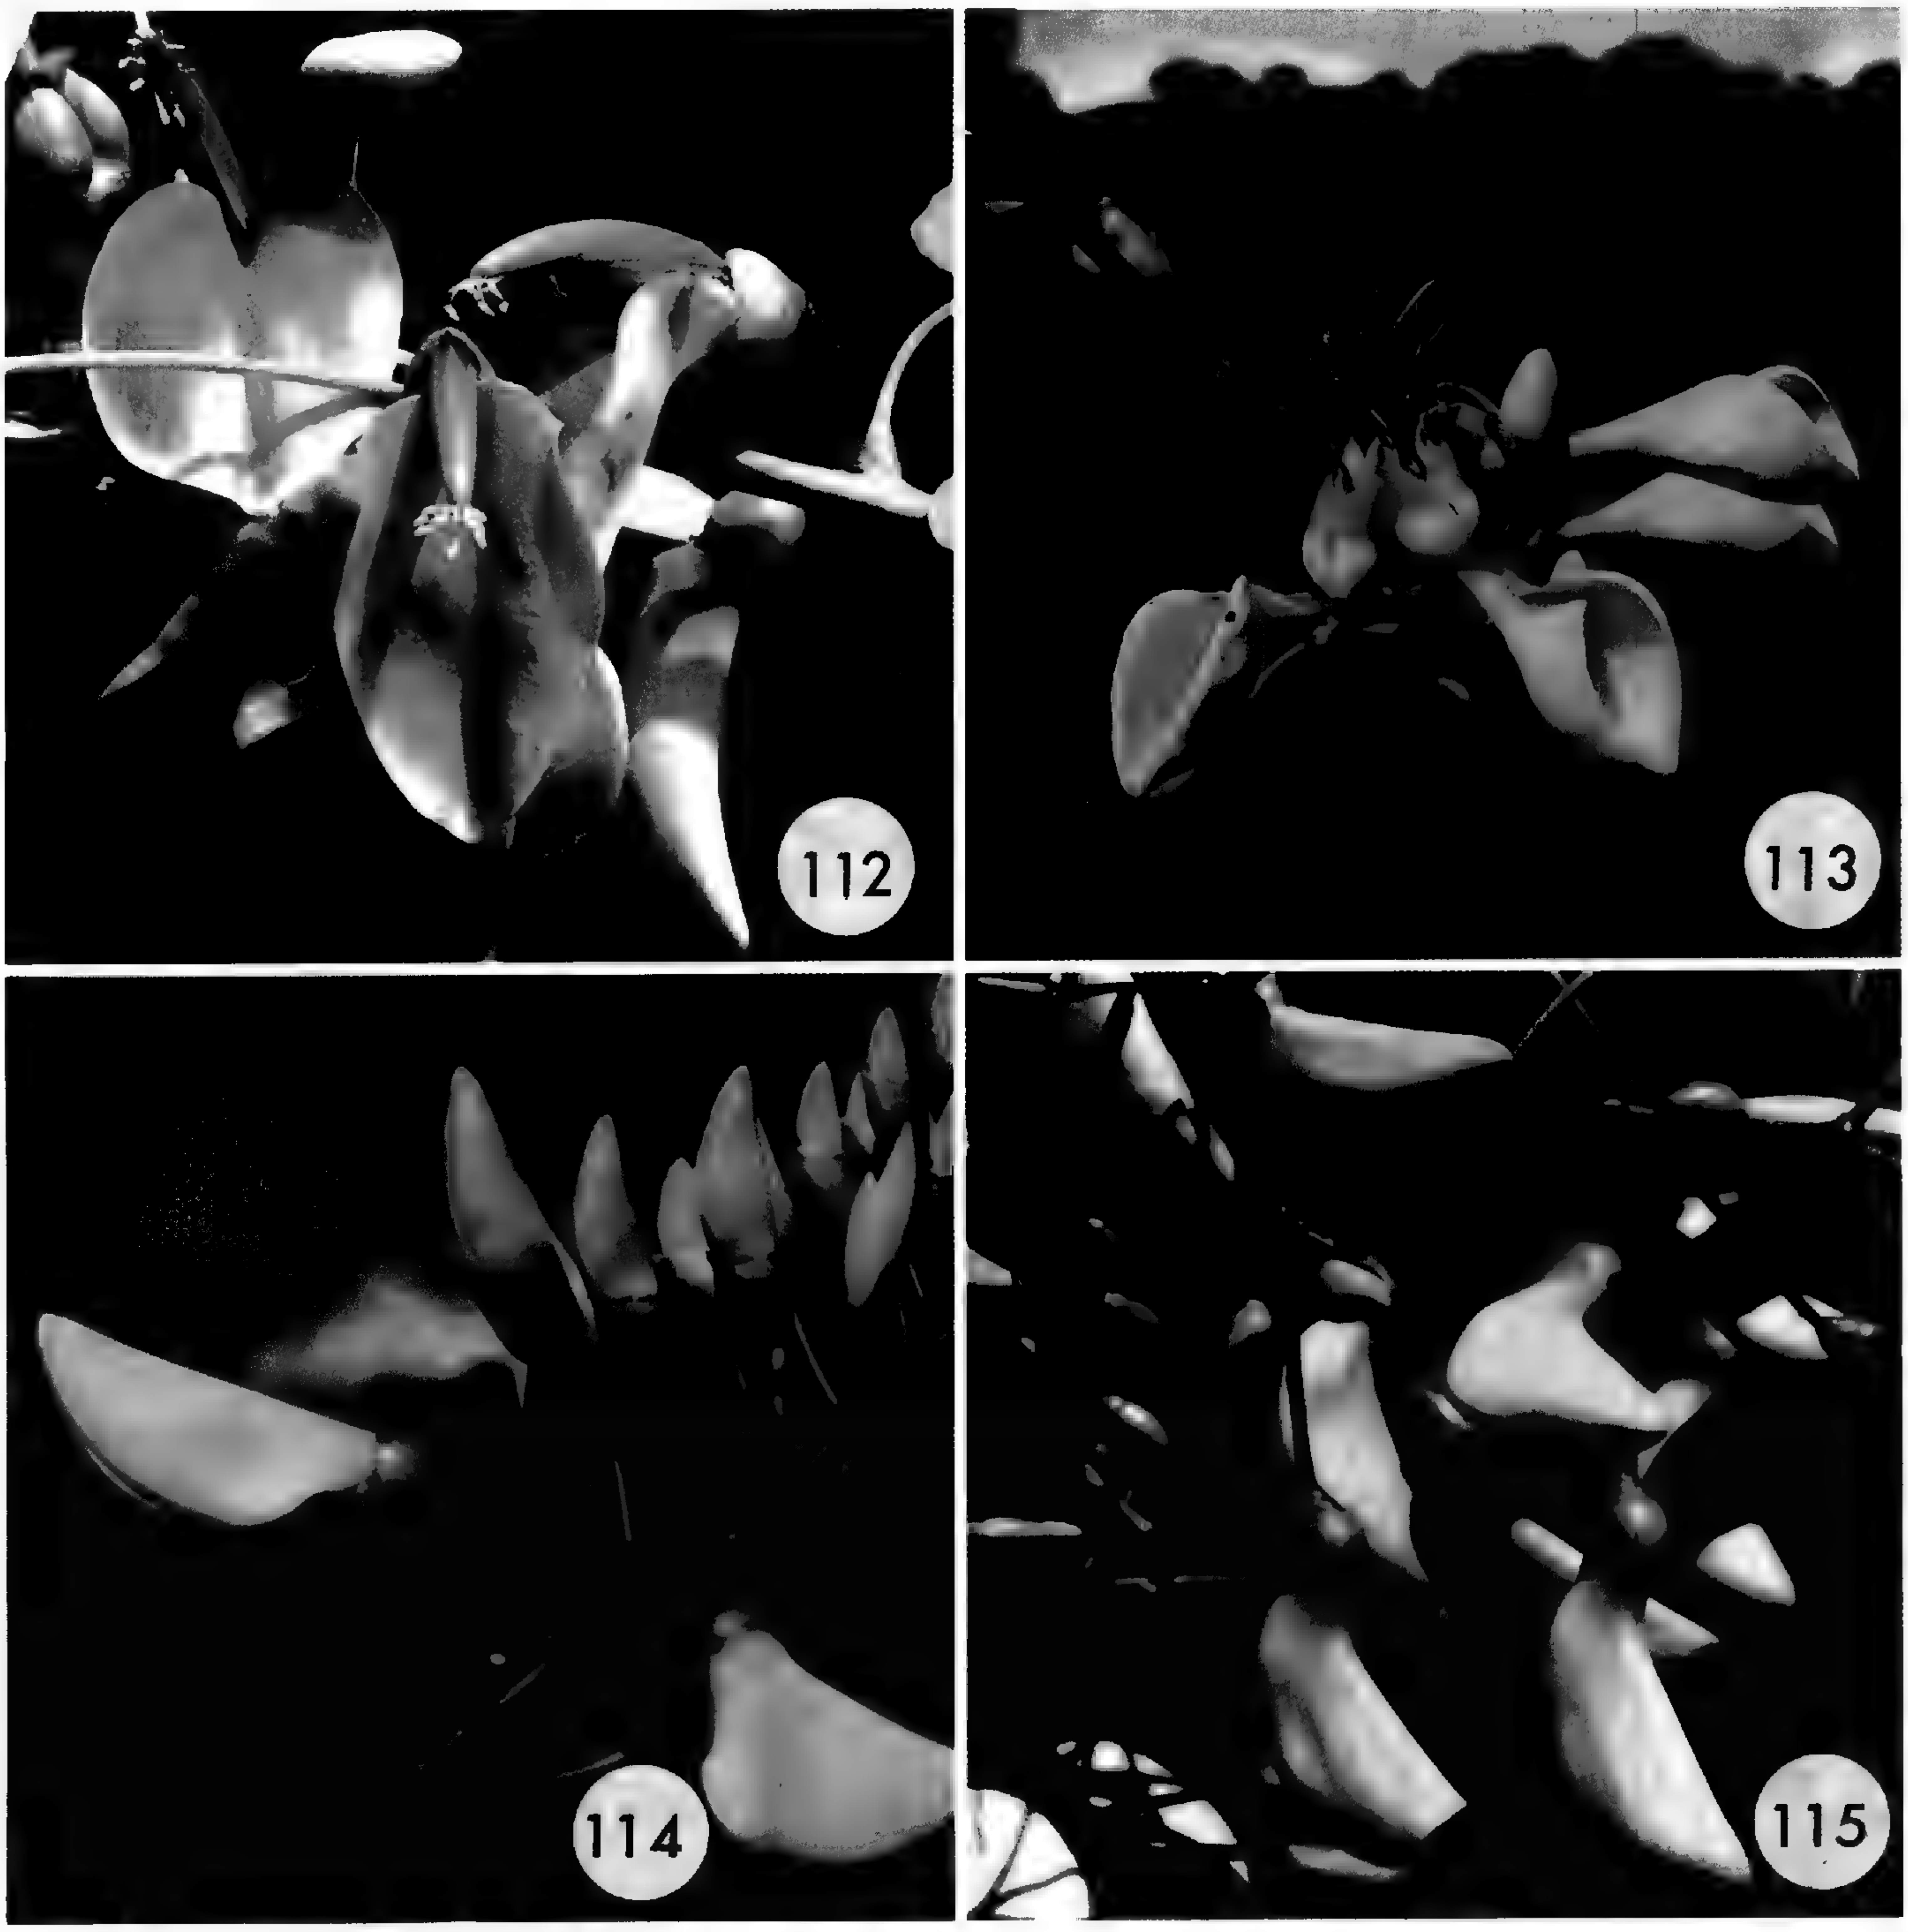
In crosses involving species with tomentose and glabrous calyces, the hybrids are tomentose, but sometimes sparsely so. In color values and morphometric dimensions, the hybrids are generally intermediate between the two parents.

The flower of the hybrid *Erythrina macrophylla* × *E. berteroana* is intermediate between the two parents, and it closely resembles a third recognized species, *E. atitlanensis* (Fig. 111, Table 20). The principal difference is that the calyx of the F_1 hybrid is somewhat longer than that of *E. atitlanensis.* The natural distribution of *Erythrina atitlanensis* is confined to a small area near Lake Atitlan in western Guatemala, and it is geographically and ecologically intermediate between *E. macrophylla* and *E. berteroana.* The possibility that the form known as *E. atitlanensis* represents either a hybridizing population or a stabilized species of hybrid origin will be discussed below.

Flowers of Erythrina crista-galli × E. fusca

The inflorescence and flowers of this intersectional hybrid and its parents are illustrated in Figures 112–117 and described in Table 21. A third species, *E. dominguezii,* is included in the illustrations and descriptions for reasons discussed below.

The morphometric dimensions and proportions of the floral parts of the two parental species are relatively similar, considering the total range of



FIGURES 112–115. *Inflorescences in natural position of* Erythrina crista-galli × E. fusca, *its parents, and* E. dominguezii.—*112.* E. crista-galli, *WA 74p840.*—*113.* E. fusca, *WA 74s99.*—*114.* E. crista-galli × E. fusca, *PT 840231001.*—*115.* E. dominguezii, *PT 740234001.*

variation of these traits in the genus *Erythrina*, but the way in which these parts are arranged and the overall appearance of the flowers are very different. The flower of *E. crista-galli* is resupinate (inverted from the usual position, with the standard below the keel) and the red standard is flattened out, an unusual trait in *Erythrina*. The orange standard of *E. fusca* is reflexed from the clawed base, exposing the reproductive parts, and is broadly folded down the middle.

The flower of the F_1 hybrid *E. crista-galli* × *E. fusca* is different from either parent. The hybrid flower is semicleistogamous, with the standard tightly folded over the wings, keel, and reproductive parts. In this semicleistogamous form, in the orientation of the flowers and the inflorescence, and in the pale pink-orange color of the corolla standard, *E. crista-galli* × *E. fusca* bears a striking resemblance to *E. dominguezii* (Figs. 114–117). Certainly the hybrid resembles *E. dominguezii* more closely in overall appearance than either of its parents. The dimensions of the floral parts are not identical in the F_1 hybrid and in *E. dominguezii* (Fig. 117, Table 21). The overall similarity between the two could be a coincidence, but it is so striking and so unexpected that it raises the possibility that *Erythrina dominguezii* is in fact a hybrid derivative of *E. crista-galli* and *E. fusca*. The distribution of *E. dominguezii* is geographically intermediate but ecologically distinct from *E.*

crista-galli and *E. fusca.* This will be discussed in greater detail in Section 6.

Conclusions: Inheritance of Phenetic Traits in Interspecific Hybrids

The results of the morphological studies of the F_1 hybrids clearly demonstrate that the progeny are indeed of hybrid origin. Almost universally, the F_1 progeny meet the criterion of intermediacy, and frequently they possess traits present in the male parent but absent in the female parent. Matrocliny is not indicated in *Erythrina* hybrids. Some of the F_1 hybrids closely resemble forms occurring in natural populations and recognized as species.

SECTION 6. NATURAL HYBRIDIZATION AND HYBRID SPECIATION

The Mexican state of Chiapas has great geographical diversity and complexity and a very large flora for an area its size. Climate ranges from semidesert to rainforest, and elevation from sea level to over 4,000 m. The flora of Chiapas contains more than 8,000 plant species and 13 major vegetational formations recognized by Breedlove (1981).

Chiapas, together with adjacent western Guatemala, is also the center of diversity of *Erythrina* sect. *Erythrina.* Eleven species are known to occur in the state, and six of these are endemic or shared only with western Guatemala. Although they are not found in abundance or in large populations, species of *Erythrina* occur in virtually every vegetation type in Chiapas except the upper belts of the cloud forest and elfin forest on the highest peaks.

In common with the usual pattern of distribution in *Erythrina*, the Chiapas species of the genus are mostly allopatric. However, at some localities, particularly at the margins of distribution of the species, different species do come into contact, and there natural hybrids are formed.

One phenomenon that has apparently occurred with *Erythrina* in Chiapas and perhaps elsewhere is spontaneous hybridization in man-made populations. Throughout Mesoamerica many species of *Erythrina* trees are used by the local populace as "living fenceposts." Erythrinas take root readily from woody cuttings and the trunks are ideal posts for stringing barbed wire. Extensive fencerows of the plants line roads and fields in many areas.

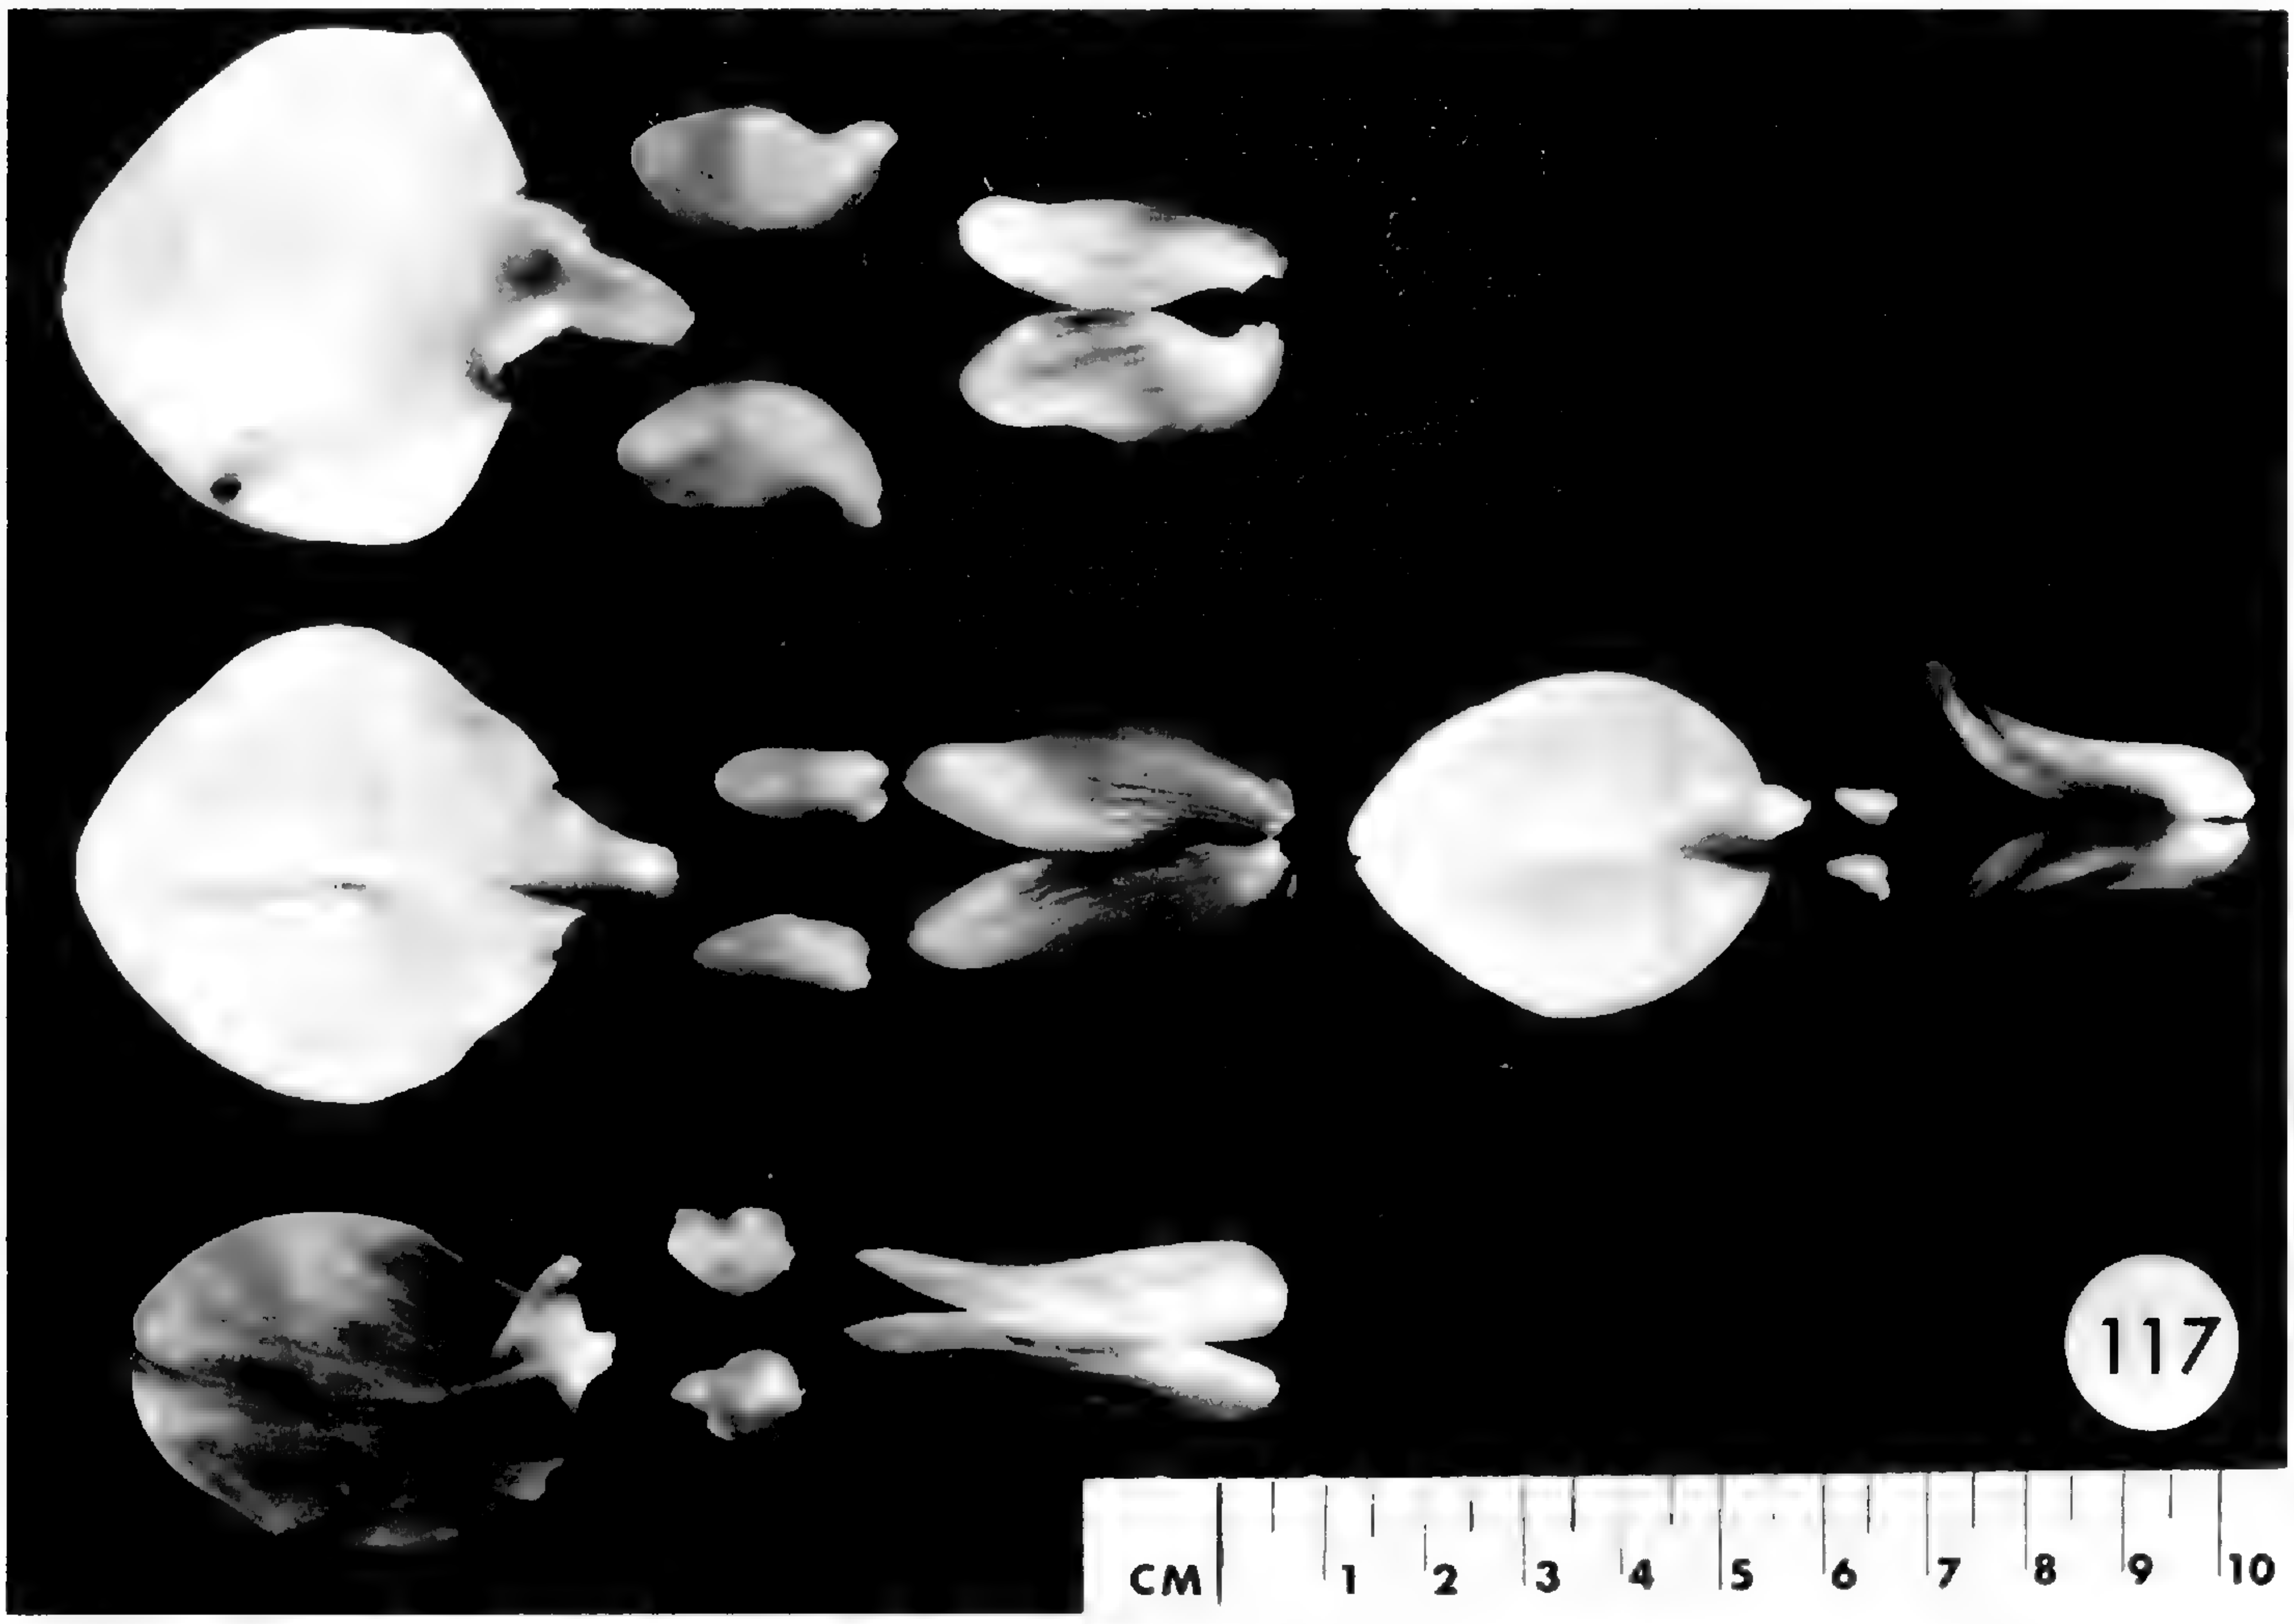

FIGURE 117. *Dissected petals of* Erythrina crista-galli × E. fusca, *its parents, and* E. dominguezii *(each flower, left to right: standard, wings, keel). Top:* E. crista-galli, *WA 74p840, female parent. Center left:* E. crista-galli × E. fusca, *PT 840231001. Center right:* E. dominguezii, *PT 740234001. Bottom:* E. fusca, *WA 74s99, male parent.*

Sometimes two species are cultivated together, and hybrids, apparently produced spontaneously in situ, are occasionally found in these fencerows.

An analysis of hybridizing populations involving three species of *Erythrina* in central Chiapas, *Erythrina chiapasana*, *E. goldmanii*, and *E. pudica*, is presented below. Distributions of these species and their hybrid populations are shown in Figure 118.

Erythrina chiapasana × *E. goldmanii*

Erythrina chiapasana is a tree of the pine–oak forests of the Central Plateau of Chiapas, occurring primarily above 1,500 m. *Erythrina goldmanii* inhabits the dry tropical deciduous forests of the Central Depression of Chiapas, formed by the highland-rimmed valley of the Río Grijalva. At El Sumidero National Park a few km north of the city of Tuxtla Gutierrez, where the Río Grijalva cuts through the limestone of the Central Plateau on its way to the Atlantic Ocean and forms a spectacular 800-m-deep canyon, the two species occur parapatrically and a hybrid zone is found about 2 km wide and extending about 300 m along an elevational gradient (Fig. 119).

Throughout their respective distributions, *Erythrina chiapasana* and *E. goldmanii* exhibit some intraspecific variation, but the two species are readily distinguishable morphologically. The leaves of *E. chiapasana* are densely tomentose with two-armed hairs on the abaxial surface (Fig. 120). The leaves of *E. goldmanii* are glabrous or nearly so at maturity and are aculeate along the midvein and primary veins of the abaxial surface (Fig. 122). The calyx of *E. chiapasana* is green to reddish, densely puberulent, and truncate at the margin without a prominent tooth on the carinal side; the corolla standard is dark red. The calyx of *E. goldmanii* is broader, dark purple brown to nearly black, glabrous, and provided with a prominent apical tooth on the carinal side; the corolla standard is usually pale red.

At El Sumidero both species are at the altitudinal and geographical limits of their ranges. Only individuals with the "pure" *E. chiapasana* phenotype are found in the oak-dominated forest at the plateau summit above 1,100 m; only individuals

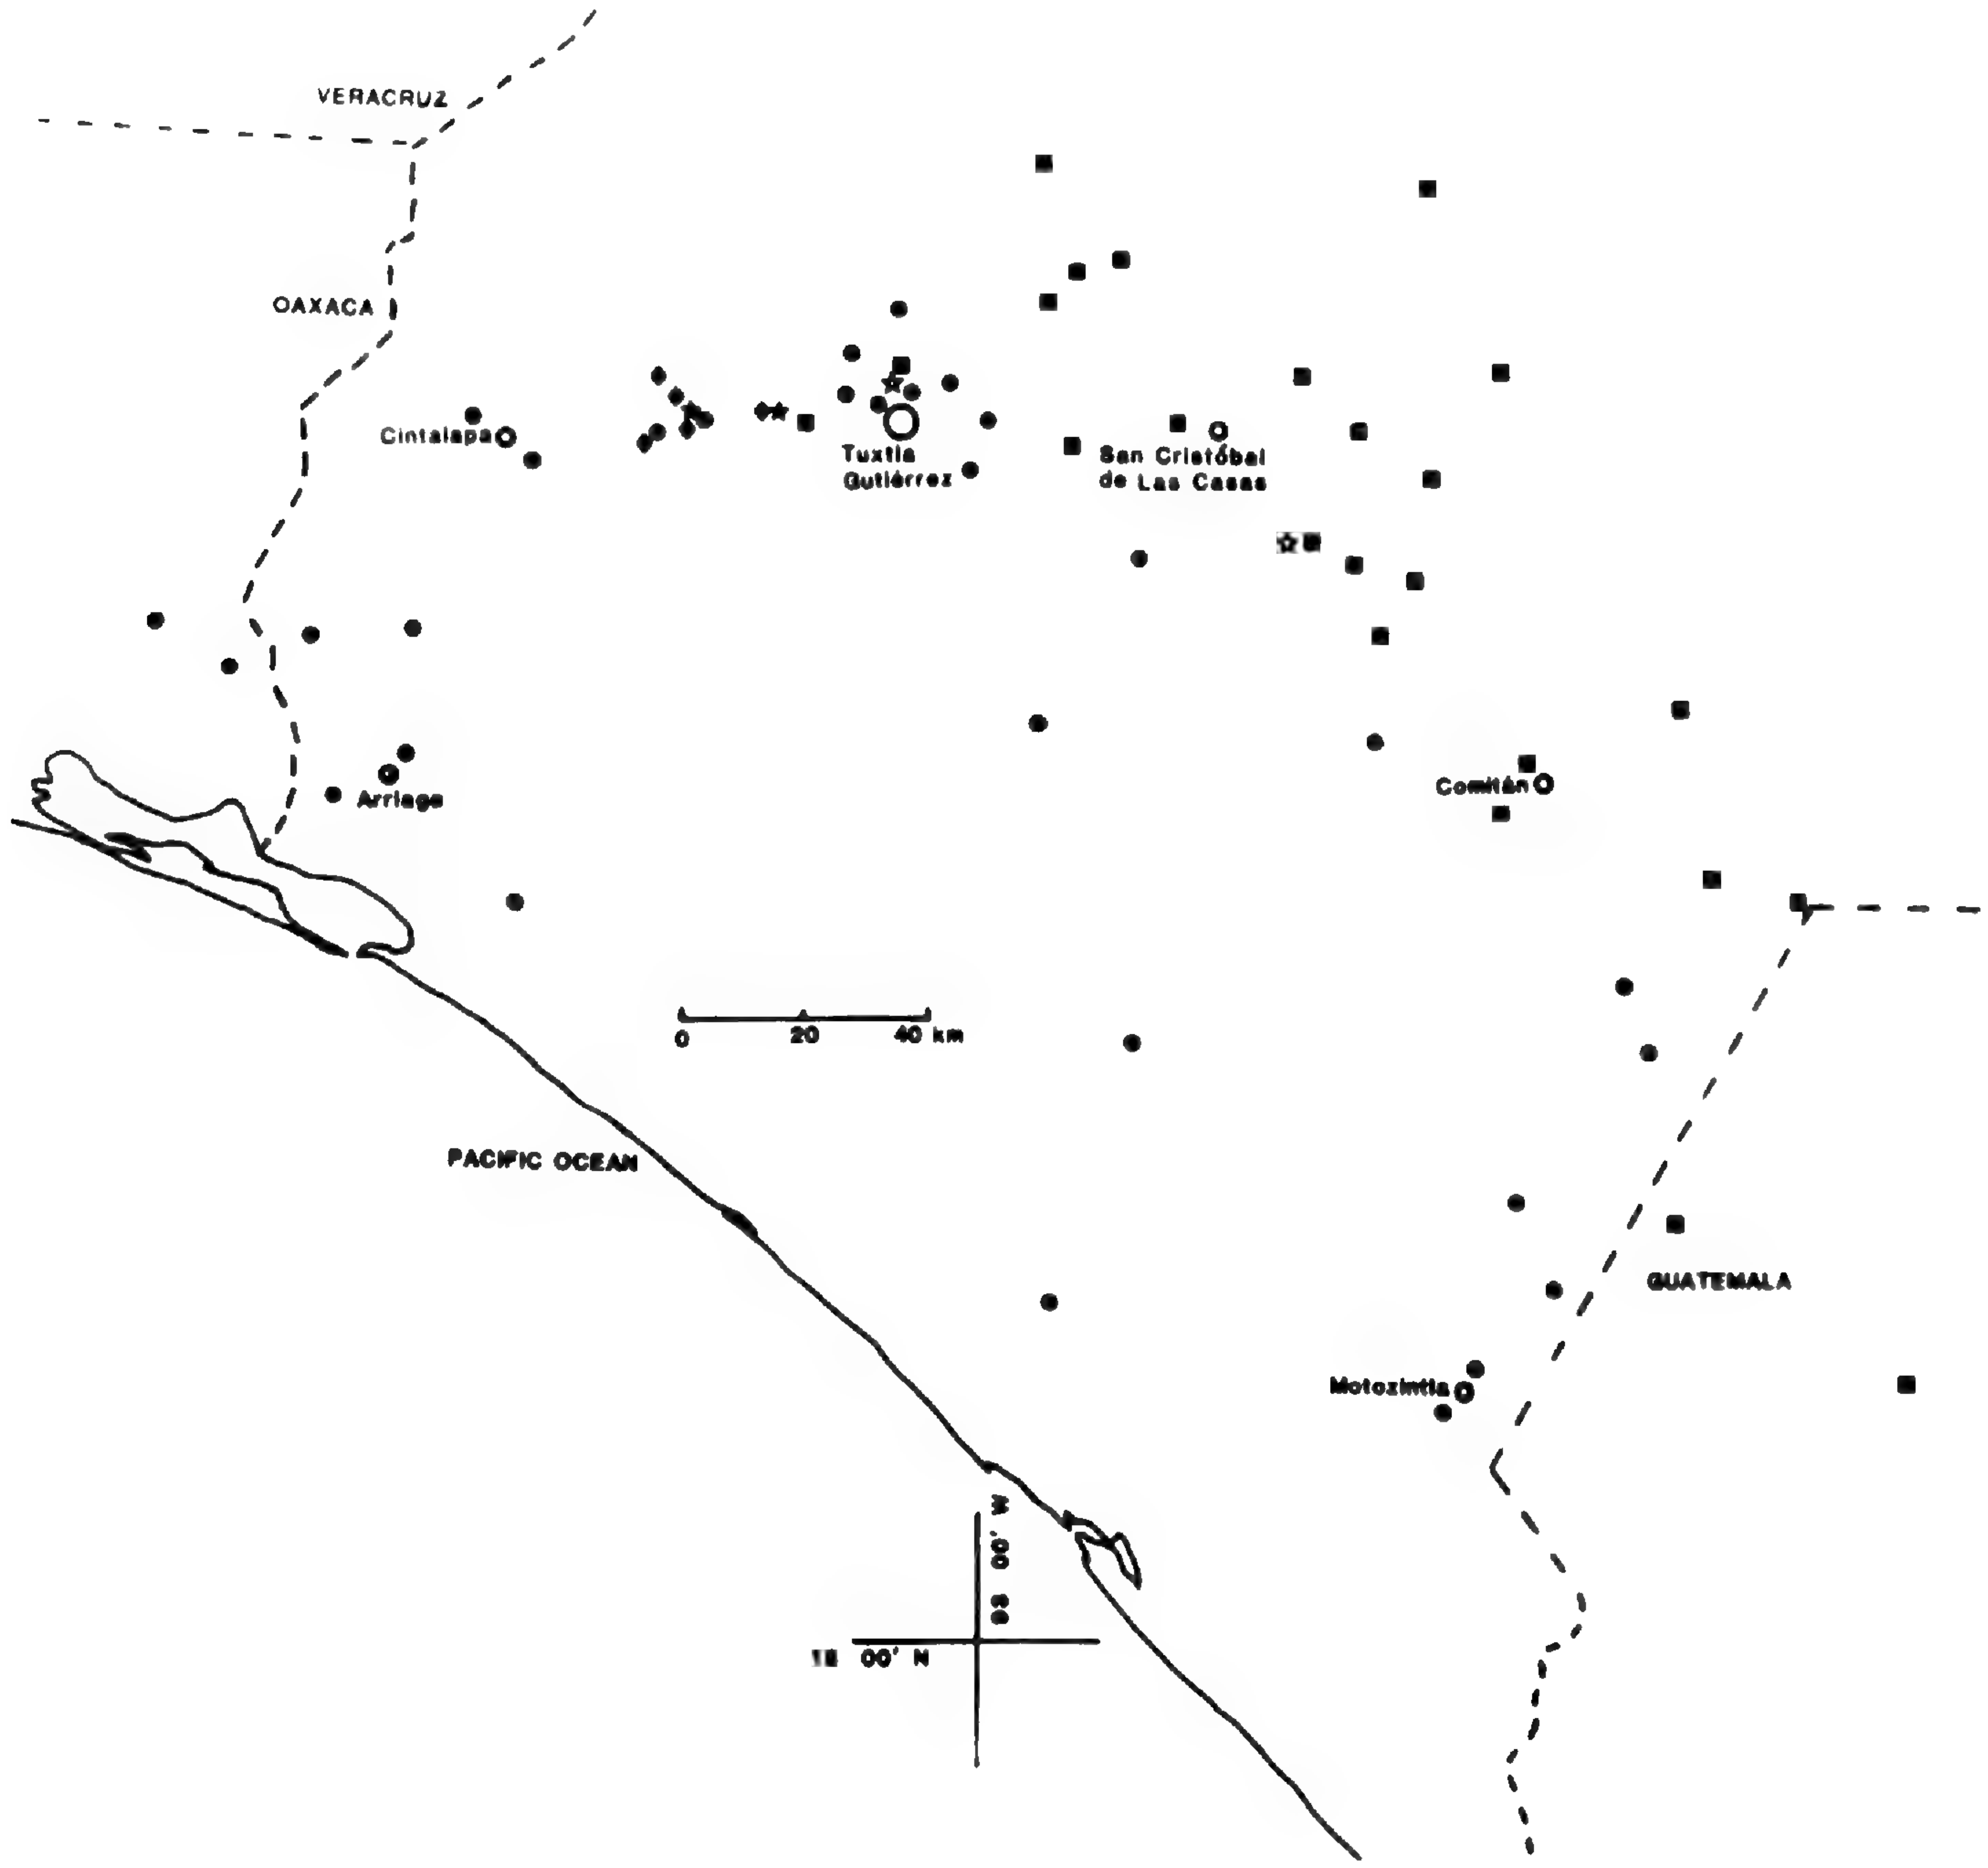

FIGURE 118. *Distribution of* Erythrina chiapasana, E. goldmanii, E. pudica, *and hybrid populations in Chiapas, Mexico. Squares*—E. chiapasana; *circles*—E. goldmanii; *diamonds*—E. pudica; *open stars*—E. chiapasana × E. goldmanii; *solid stars*—E. goldmanii × E. pudica.

with the "pure" *E. goldmanii* phenotype are found in the dry scrub forest below 800 m. In the transition zone near the top of the escarpment between 800 m and 1,100 m there are plants with intermediate phenotypes, or displaying in one individual various combinations of traits of both species. Some individuals, for example, have leaves that are sparsely tomentose on the abaxial surface and are also aculeate on the midvein (Fig. 121). Others have flowers with characters intermediate between the two species, or with various combinations of parental traits such as a puberulent, dark purple-brown calyx with an apical tooth (Fig. 123). Both parental types are also present in the transition zone.

This pattern of variation in the intermediate zone at El Sumidero establishes with reasonable certainty that the population is a hybrid swarm of *Erythrina chiapasana* × *E. goldmanii.* The intermediacy of the traits in this population resembles the patterns of inheritance expressed in the experimentally produced hybrids as discussed in Section 5.

As indicated in Section 4, I attempted to synthesize hybrids between *Erythrina chiapasana* and *E. goldmanii* in the field at El Sumidero using the same techniques of controlled hand-pollination employed in the experimental gardens in Hawaii. Hybrid fruits in both reciprocal crosses were obtained, but the fruit of *Erythrina chiapasana* ♀ × *E. goldmanii* ♂ was destroyed in a brush fire. The reciprocal *E. goldmanii* ♀ × *E. chiapasana* ♂ produced one mature hybrid seed. The F_1 was viable and is now growing in cultivation in Hawaii

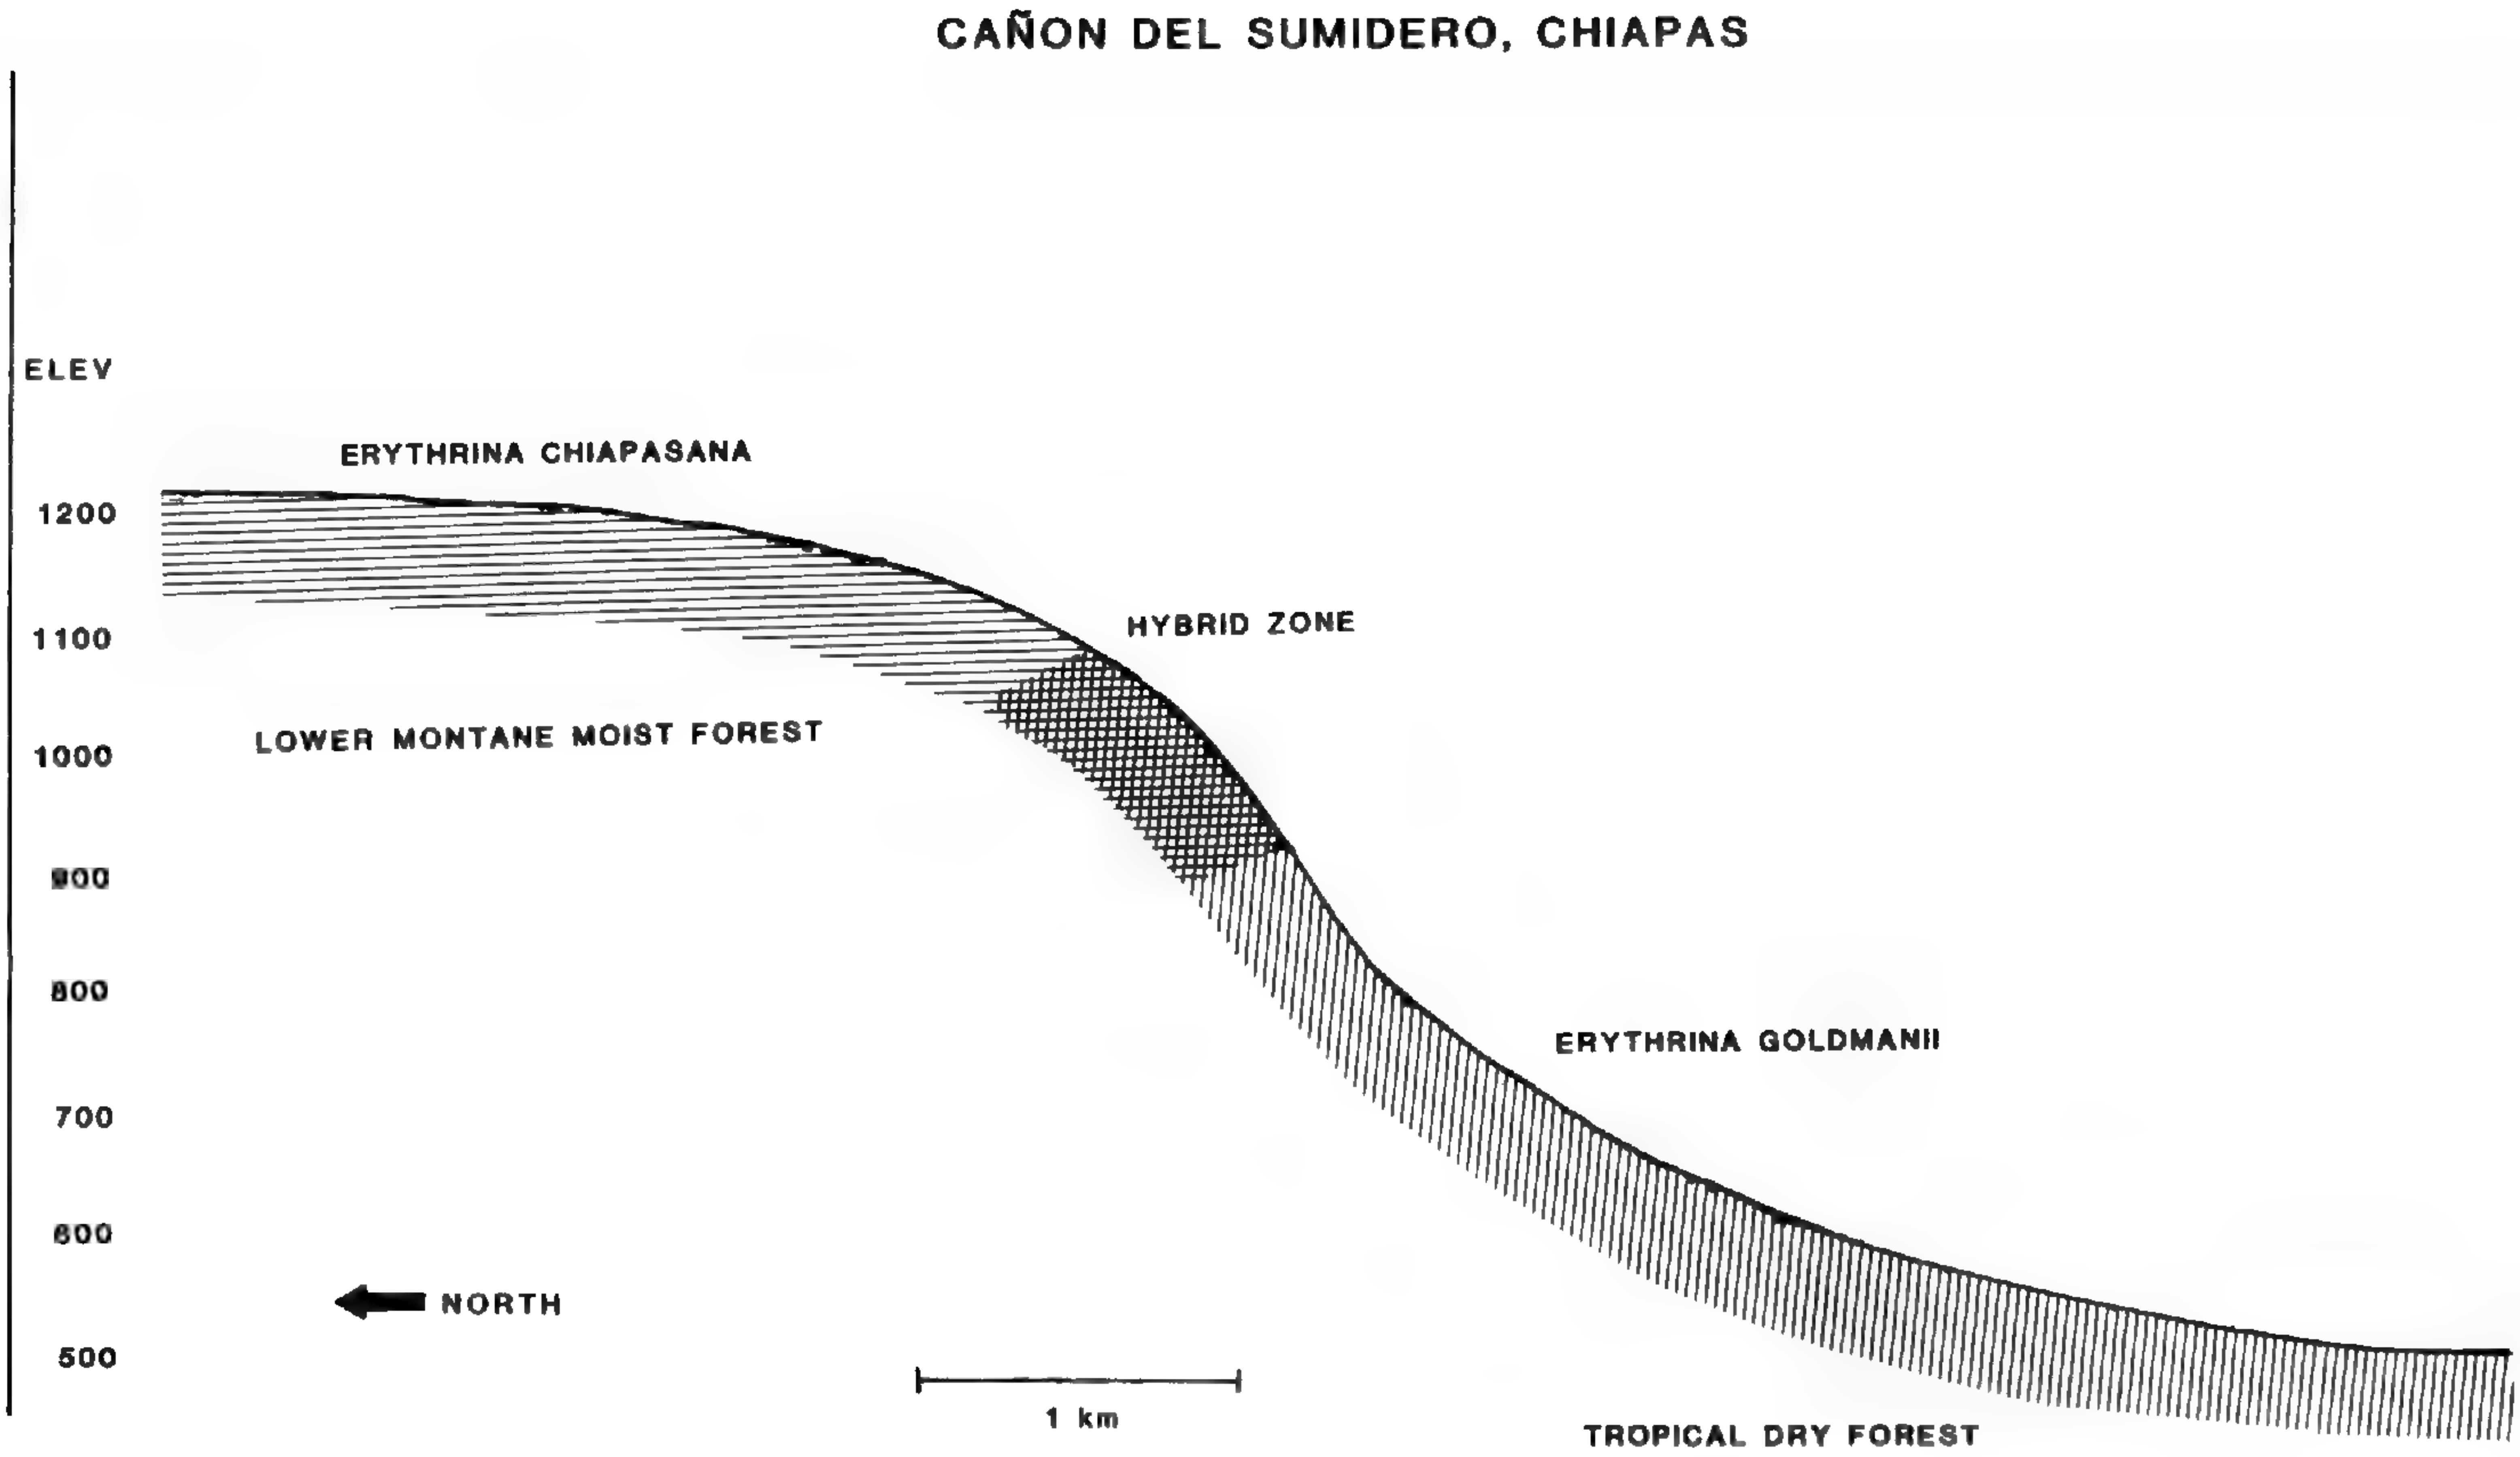

FIGURE 119. *Cross section of slope at El Sumidero, Chiapas, Mexico, showing distribution of* Erythrina chiapasana, E. goldmanii, *and hybrid zone.*

alongside accessions of both parental strains (Table 11). When this artificial hybrid flowers it will be possible to compare it with specimens of the putative natural hybrids from El Sumidero.

As discussed in a separate paper (Neill, 1987), the hummingbird *Heliomaster constantii* pollinates *Erythrina chiapasana* and *E. goldmanii* at El Sumidero and is therefore implicated as the agent directly responsible for interspecific gene flow in the hybridizing *Erythrina* population.

Erythrina goldmanii × *E. pudica*

Erythrina pudica is a locally endemic species that is restricted to the dry valley of the Río de La Venta, a tributary of the Río Grijalva, at the western end of the Central Depression of Chiapas. This is an unusual species, with the flowers drooping to nearly parallel with the erect axis of the inflorescence (Fig. 126). The calyx is truncate without an apical tooth and covered with a dense grayish tomentum; the corolla is very pale pink or orange-pink.

In the vicinity of Ocozocuautla, Chiapas, at the eastern margin of its small range, *Erythrina pudica* occurs sympatrically with *Erythrina goldmanii.* In disturbed scrub forest small hybrid populations are found, with individuals of both parental species as well as intermediates (Figs. 124–126).

Along the highway 5 km east of Ocozocuautla are living fencerows of *Erythrina* containing both *E. goldmanii* and *E. pudica,* and occasional intermediate and evidently hybrid individuals occur there. These intermediates are similar in appearance to the trees occurring in the adjacent natural hybrid populations. The fencepost hybrids are very likely the progeny of other fencepost trees that received interspecific pollen from foraging hummingbirds moving down the line of mixed species fenceposts. The hybrid seed thus probably germinated directly below its female parent and grew up to become part of the fencerow itself.

Erythrina berteroana × *E. folkersii*

On the Atlantic coastal plain of northern Chiapas and adjacent states the natural vegetation has been almost entirely destroyed and replaced with pastures. There, as elsewhere in Mesoamerica, the pastures and roadsides are commonly lined with living fencerows of *Erythrina* trees. On the Atlantic plain the most frequently used species are *E. berteroana* and *E. folkersii,* which are both native to the region.

Trees morphologically intermediate between *Erythrina berteroana* and *E. folkersii* in shape and vestiture of the calyx and orientation of the flower occur in northern Chiapas. None of the intermediates set seed. Pollen stainability from four collections of the intermediates (Alexander's stain; 500 grains per sample: *Neill 5533, 5540, 5543, 5544*) was 73.2% (range 60.9–86.1%), an unusually low figure for *Erythrina*. These individuals are almost certainly hybrid *Erythrina berteroana* × *E. folkersii*. The reason for the low level of stainable pollen and lack of fruit set is not known; the experimentally produced hybrids within sect. *Erythrina* (Section 4) all had very high pollen fertility.

These intermediates closely match the type specimen of *Erythrina caribaea* Krukoff & Barneby as well as other collections determined by Krukoff as this species. Despite a protracted search, I never found this form occurring in a natural population and never found any seed set on the fencepost trees. It seems reasonable that *Erythrina caribaea* is in fact a hybrid *E. berteroana* × *E. folkersii* and probably occurs only as a cultivated fencepost tree.

HYBRID SPECIATION

In this paper it has been demonstrated that diploid *Erythrina* species are interfertile, that the hybrids are viable and fertile, and that hybridization sometimes occurs in natural populations. What has not yet been shown is the validity of the final hypothesis set forth in the introductory chapter: that hybrid speciation has taken place in *Erythrina*, that some distinct forms recognized as species are stabilized derivatives resulting from hybridization of two parental species, and that this process has been an important element in the evolutionary history of the genus.

Direct and unequivocal evidence relating to this hypothesis is difficult to obtain. Phylogenies based on molecular data of the taxa involved, including studies on isoenzymes and on nucleic acid restriction sites, might in the future provide such evidence. The best evidence available at present is the morphological congruence between certain artificially produced hybrids and certain naturally occurring forms that evidently are stabilized and self-perpetuating populations.

In considering the hypothesis of hybrid speciation, there is no reason to assume that the stabilized derivatives, especially if they became stabilized several generations or more after the original hybridization event, should be precisely intermediate between the parental species or should resemble closely the F_1 hybrids. A limited number of F_1 hybrids is, however, generally the only material available for comparison.

In *Erythrina* some of the artificial F_1 hybrids do resemble naturally occurring forms recognized as species, according to the results of the morphological studies presented in Section 5. *Ery-*

FIGURE 123. *Flowers of* Erythrina chiapasana, E. goldmanii, *and hybrid from a population at El Sumidero, Chiapas, Mexico. Left:* E. chiapasana, Neill 5455. *Center top:* E. chiapasana × E. goldmanii, Neill 5493. *Center bottom:* E. chiapasana × E. goldmanii, Neill 5466. *Right:* E. goldmanii, Neill 5495.

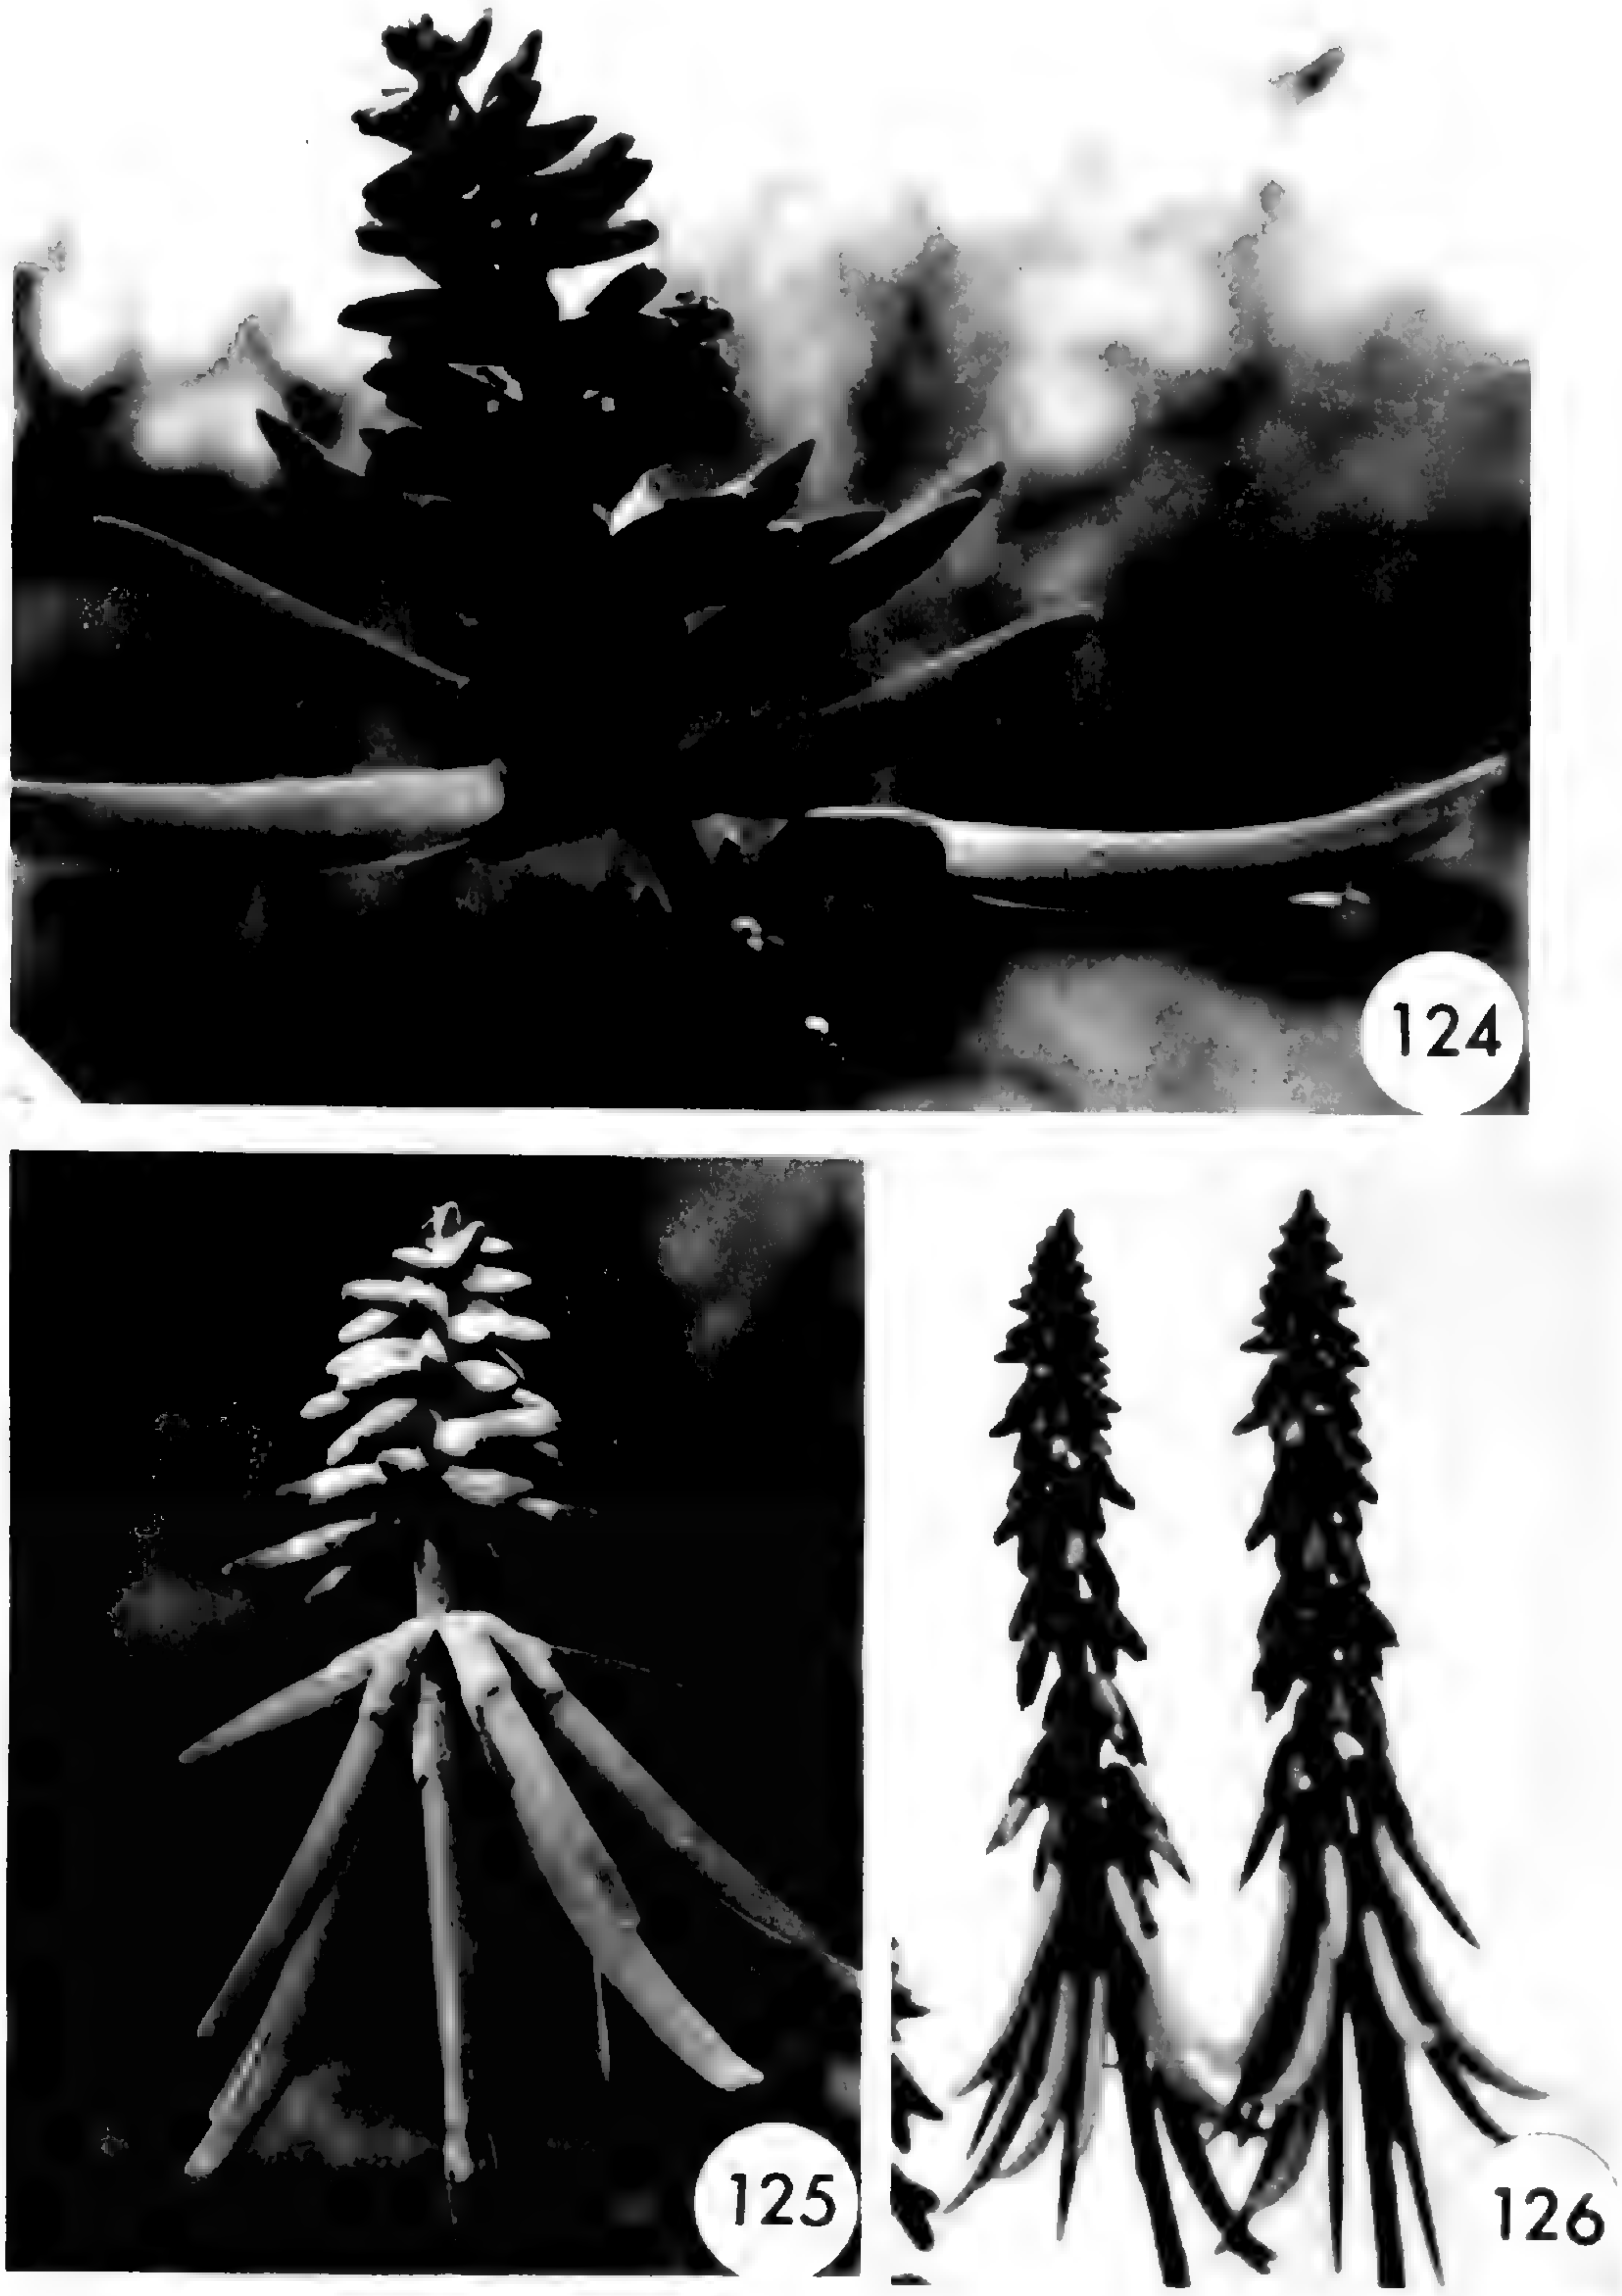
thrina macrophylla × *E. berteroana* bears a close resemblance to *E. atitlanensis*, and *E. crista-galli* × *E. fusca* resembles in certain features *E. dominguezii*. Field studies, which would be valuable for determining whether hybrid speciation could have occurred, were not conducted in either of these situations. The known geographical and ecological distribution of the taxa involved is outlined below.

Erythrina macrophylla is distributed throughout the highlands of Guatemala and western El Salvador, growing in the pine–oak forests above 1,500 m elevation. *Erythrina berteroana*, the most widespread species in sect. *Erythrina*, is common in the Pacific coastal plain of Guatemala and on the lower slopes of the volcanic range that lead up from the plain to the highlands. The intermediate known as *Erythrina atitlanensis* is known only from the vicinity of Lake Atitlan on the southern edge of the highlands. In terms of geography and elevational distribution, *E. atitlanensis* is precisely intermediate between the putative parental species. If hybridization is really implicated in this case, *E. atitlanensis* could be merely an early generation segregate rather than a stabilized, self-perpetuating derivative. Based on comparison of herbarium specimens, the progeny cultivated in Hawaii grown from seed obtained from the population in Guatemala closely resemble the parents. Therefore stabilization of the hybrid form may have taken place.

The case of *Erythrina dominguezii* and its putative parental species *E. crista-galli* and *E. fusca* is more problematic because the three taxa are so morphologically distinct. They are also ecologically distinct. *Erythrina crista-galli* and *E. fusca* are both riparian or estuarine species. *Erythrina crista-galli* is common along the estuary of the Río de La Plata and its tributaries and along the coast of southern Brazil. The more tropical *E. fusca* is distributed widely throughout the Amazon basin and south along the coast of Brazil. The ranges of the two species evidently do overlap in southern Brazil. The putative derivative *Erythrina dominguezii* also occurs in southern Brazil and westward through Paraguay and northern Argentina to eastern Bolivia, but it is an upland species of the dry Chaco forest and cerrado. *Erythrina dominguezii* would never have been suspected as a hybrid derivative of *E. crista-galli* × *E. fusca* were not its resemblance to the artificially produced F_1 so compelling. This situation appears to merit further investigation.

SUMMARY AND CONCLUSION

In the introduction, a set of five hypotheses was stated regarding the species relationships and evolutionary history of *Erythrina*: 1) The numerous species of sect. *Erythrina* can all cross freely with one another, producing fully fertile hybrids. The section forms a homogamic complex in which in-



FIGURES 124–126. *Inflorescences of* Erythrina goldmanii, E. pudica, *and hybrid from a population near Ocozocuautla, Chiapas, Mexico.*—*124.* E. goldmanii, Neill 5510.—*125.* E. goldmanii × E. pudica, Neill 5586.—*126.* E. pudica, Neill 5585.

ternal barriers to hybridization are absent. 2) The interfertile homogamic complex of sect. *Erythrina* extends, to a greater or lesser degree, to species in other sections and subgenera of *Erythrina*. Any diploid *Erythrina* species can hybridize with any other, but crosses between widely divergent taxa are generally difficult to obtain and the resulting F_1s may exhibit varying degrees of sterility. The genus as a whole may be characterized as a series of interfertile homogamic complexes with weak to moderate reproductive barriers between the complexes. 3) The widely foraging hummingbirds that pollinate species of sect. *Erythrina* are capable of effecting interspecific pollen flow between sympatric species of sect. *Erythrina*. 4) Sympatry at the local community level is rare among species of sect. *Erythrina*. Most species are restricted in geographic range and ecological amplitude and are allopatric, separated by habitat differences. However, sometimes different species do come into contact in nature, and then hybridizing populations are formed. 5) Patterns of distribution and phenetic variation in sect. *Erythrina* indicate that some distinct forms recognized as species are stabilized derivatives resulting from hybridization of two parental species. As a consequence of changing climates and dynamic geomorphological processes, and the consequent migration of vegetation types and mixing of floristic elements, formerly allopatric species may have come into contact a number of times. With the temporary breakdown of external isolating barriers, the interfertile species hybridized and the subsequent segregation and stabilization of hybrid derivatives have contributed to the proliferation of species of *Erythrina*.

The data presented in this paper have been marshalled in support of this set of hypotheses. The cytological studies (Section 3) and the experimental hybridization and self-compatibility trials (Section 4) present evidence in support of the first two hypotheses. In spite of the considerable morphological, ecological, and geographic differentiation of *Erythrina*, the species have retained a high degree of chromosomal (structural and genic) homology. Within sect. *Erythrina*, this homology, as evidenced by interspecific compatibility, is virtually complete: there is no detectable difference in the success of interspecific matings as compared with intraspecific matings. At greater taxonomic distances between the two parents (intersectional and intersubgeneric matings), mating success declines to some extent, but the number of successful "wide hybridizations" obtained in the experimental trials indicates that even the most morphologically and ecologically divergent of diploid *Erythrina* species have retained their ancestral chromosomal and genic homology and have not evolved substantial barriers to hybridization in concert with morphological differentiation. *Erythrina* forms a homogamic complex of interfertile species, or perhaps a series of homogamic complexes with weak to moderate barriers between the complexes. *Erythrina* shares this pattern of species relationships with many temperate-zone genera of trees and shrubs. The evidence from *Erythrina* suggests that the patterns of species relationships in predominantly or exclusively tropical groups of woody plants may not differ significantly from the patterns found in their better-known temperate-zone counterparts. Formation of homogamic complexes may be a common phenomenon in tropical woody plants and may be an important factor in the evolution of these taxa.

The patterns of inheritance of phenetic traits in the artificially produced hybrids (Section 5) confirm the true hybrid nature of these plants and demonstrate that matricliny, a potential complicating factor in the inheritance of these traits and in the interpretation of hybridization patterns, is not indicated in *Erythrina* hybrids. The patterns of inheritance in the artificial hybrids reveal the patterns to be expected in the detection and analysis of natural hybridization: for morphometric characters, a rather narrowly segregating array of intermediate types among the hybrids; and for discrete characters such as trichomes, possessed exclusively by either the female or male parent, the inheritance of the character in some of the hybrid offspring, the character being often reduced in size or density.

Evidence for the third hypothesis, concerning the pollination of sect. *Erythrina* by relatively specialized, widely foraging hummingbirds and the relation of this pollination system to *Erythrina* breeding systems, is presented in a separate paper (Neill, 1987). The pollination studies indicate that interspecific pollen flow and potential natural hybridization are likely to occur among sympatric species of sect. *Erythrina*.

Evidence for the fourth and fifth hypotheses, concerning natural hybridization and hybrid speciation in *Erythrina*, is presented in Section 6. Natural hybridization was detected among several co-occurring species of sect. *Erythrina* in Chiapas, Mexico, at the geographical center of diversity of the section. The natural hybrids display the same patterns of inheritance of phenetic traits as the artificial hybrids described earlier. The evidence for hybrid speciation itself is somewhat more equivocal. As stated in the introduction to this paper, the final hypothesis is historical and cannot be tested directly, but can be inferred only by drawing on information obtained by testing the first four.

The information presented throughout this paper does make plausible the hypothesis of hybrid speciation in *Erythrina*. Moreover, the research reported here provides a unique base of information for further studies of species relationships and the evolutionary history of *Erythrina*, as a model of evolutionary processes in flowering plants that may be common to many tropical woody genera. Perhaps the most incisive research that could be carried out at this point in the continuing biosystematic investigation of *Erythrina* would entail studies of isoenzymes and particularly of nucleic acid restriction sites among the taxa, as well as the inheritance of these molecular character states in the hybrids of known origin, followed by the construction of phylogenies combining molecular data with the presently available evidence on morphological and biogeographic patterns and the data from crossing experiments. The collection of *Erythrina* species and hybrids now available in cultivation at the

Hawaiian botanical gardens provides an ideal resource for such studies, and it is my hope that my colleagues specializing in chemosystematics and molecular phylogenetics do take advantage of this resource to investigate further the patterns of evolution in this interesting genus.

APPENDIX I. *Species, sections, and subgenera of* Erythrina. *All recognized taxa in* Erythrina *are included in this list. I do not recognize infraspecific taxa in* Erythrina. *Proposed taxonomic changes are anticipated here, prior to their formal designation. The numbering sequence of Krukoff & Barneby (1974) is followed for reference to that work, and because the numbers were used to designate the hybrids. There are gaps in the number sequence because of reduction of species to synonymy. Species reduced to synonymy since Krukoff & Barneby (1974) are indicated at the end of this list.*

  - 108. *Erythrina melanacantha* Taubert ex Harms

Species reduced to synonymy since Krukoff & Barneby (1974):

Erythrina caribaea Krukoff & Barneby
= *E. berteroana* Urban × *E. folkersii* Krukoff & Mold.
Erythrina coralloides A. DC. = *E. americana* Miller
Erythrina insularis F. M. Bailey = *E. vespertilio* Benth.

The first two reductions to synonymy are proposed for the first time in this paper. The third reduction follows Krukoff's treatment in his post-1974 publications on *Erythrina.*

APPENDIX II. Erythrina *hybridization trials. This appendix summarizes the results of the interspecific hybridization trials for each species combination. For many of the species combinations, more than one accession was employed as the male and/or female parents. The identity of the individual parents is presented in Tables 11–13 only for the successful trials resulting in viable hybrid plants.*

The hybridization trials are grouped into five categories:

I. *Narrow hybridizations within sect.* Erythrina.
II. *Narrow hybridizations, excluding sect.* Erythrina.
III. *Intersectional hybridizations: female parent in sect.* Erythrina.
IV. *Intersectional hybridizations: male parent in sect.* Erythrina.
V. *Intersectional hybridizations: excluding sect.* Erythrina.

In categories III–V, the number in parentheses after the species name refers to the section to which the species belongs (see Table 1). An asterisk indicates a wide (intersubgeneric) hybridization.

Hybrid # = a number assigned to each hybrid combination, made up from the numbers assigned to the parental species as listed in Krukoff & Barneby (1974)
Pol = number of flowers hand-pollinated in the hybrid combination
Frt = number of pollinations producing mature fruits
Sds = total number of normal-sized seeds produced in the hybrid combination
Ger = number of seeds that germinated
Liv = surviving progeny; number of live F_1 plants in the hybrid combination

APPENDIX III. *Sources of cultivated* Erythrina *used as parentals in successful interspecific hybridizations. (W): Accession obtained from known wild populations; (NW): Accession obtained from cultivated source, or otherwise not from a known wild population.*

Vouchers (from plants cultivated in Hawaiian gardens) are deposited at MO. Location of voucher from original wild collection of seed is indicated here if known.

Erythrina abyssinica Lam. PT 770034001
Kenya: Nairobi. *E. Taylor 17.* (NW)

Erythrina abyssinica Lam. PT 731006002
Kenya: Nairobi, cultivated tree in yard of Cunningham van Someren. (NW)

Erythrina americana Miller WA 75c1171
Mexico: Mexico City, cultivated tree. *L. S. Ayres s.n.* (Waimea received as cutting from Los Angeles State & County Arboretum # 565874) (NW)

Erythrina berteroana Urban PT 730311001
Guatemala: Suchitepequez. Nahualate, Finca El Salvador. *B. A. Krukoff 1973-13* (NY). (W)

Erythrina berteroana Urban PT 700044001, -002
Panama: Canal Zone. Tree cultivated at Summit Gardens. *W. S. Stewart s.n.* (NW)

Erythrina berteroana Urban WA 74s864
Guatemala: Suchitepequez. Municipio Chicacao. *B. A. Krukoff 1968-508* (NY). (W)

Erythrina berteroana Urban WA 78s564
Panama: Canal Zone. Between Madden Dam and Chilibre. *J. Folson 3661* (MO). (W)

Erythrina caffra Thunb. WA 74c1456
South Africa: Cape Province, Grahamstown, elev. 2,400 ft. *Roy Bayliss s.n.* (Waimea received as cutting from Foster Garden # 69.265) (W)

Erythrina chiapasana Krukoff PT 721005001
Guatemala: Huehuetenango, near La Estancia. *B. A. Krukoff 1969-68* (NY). (W)

Erythrina chiapasana Krukoff PT 730710001
Guatemala: Huehuetenango, near La Estancia. *B. A. Krukoff 1973-16* (NY). (W)

Erythrina crista-galli L. PT 740283001
Paraguay: near Asunción. *Conrad & Die 2191.* (W)

Erythrina crista-galli L. WA 74p840
South Africa. Cultivated tree; seed received from Wm. J. Tijmens, Univ. of Stellenbosch. (Waimea received as live plant from PT 72s352) (NW)

Erythrina falcata Benth. PT 750086001
Argentina. Thays Botanical Garden, cultivated tree. *E. Pingitore s.n.* (NW)

Erythrina folkersii Krukoff & Mold. PT 700010001
Guatemala: Izabal, at junction of road to Puerto Barrios and Mathias Calves. *B. A. Krukoff 1969-109* (NY). (W)

Erythrina fusca Lour. PT 740230005, WA 74599
Guatemala: Escuintla. *B. A. Krukoff 1972-12* (NY). (W)

Erythrina guatemalensis PT 700018001, WA 74c1453
Guatemala: Alta Verapaz, along Cobán–Salama road, near Santa Cruz, elev. 1,280 m. *B. A. Krukoff 1969-195* (NY). (W) Note: The tree at Waimea Arboretum WA 74c1453 was grown from a cutting taken from PT 700018001, so the two accessions are genetically identical.

Erythrina guatemalensis Krukoff PT 720999002
Guatemala: Huehuetenango, near Barillas. *B. A. Krukoff 1969-200* (NY). (W)

Erythrina guatemalensis Krukoff PT 750419001
Guatemala: Huehuetenango, near Barillas. *B. A. Krukoff s.n.* (W)

Erythrina herbacea L. PT 75c1103
California: Los Angeles State & County Arboretum # 54s1201, cultivated. (NW)

Erythrina herbacea L. WA 76s187
Florida: Miami, Fairchild Garden, cultivated. (NW)

Erythrina humeana Sprengel WA 74p1382
South Africa: locality unknown. *D. Millington s.n.* (NW)

Erythrina latissima E. Meyer PT 750281004
South Africa: Natal. Cultivated tree at Pine Town Gardens. *Ian Whitton 750401.* (NW)

Erythrina lysistemon Hutchinson PT 750280002, -003
South Africa: Natal, Durban. *Ian Whitten s.n.* (1975) (W)

Erythrina macrophylla A. DC. PT 750420002, WA 75s1136
Guatemala: Sololá, near Godinez. Elev. 6,145 ft. *B. A. Krukoff 1975-4* (NY). (W)

APPENDIX III. *Continued.*

Erythrina perrieri R. Viguier WA 74s857
Madagascar: Maintirano, near Bekopaka. *Fred Meyer s.n.* (W)

Erythrina salviiflora Krukoff & Barneby PT 721000002
Guatemala: Suchitepequez, Municipio Chicacao, Finca El Naranjo. Elev. 1,070 m. *B. A. Krukoff 1969-58* (NY). (W)

Erythrina senegalensis A. DC. WA 74s100

THE BIOSYSTEMATICS OF *LUDWIGIA* SECT. *MICROCARPIUM* (ONAGRACEAE)[1]

Ching-I Peng[2]

ABSTRACT

Ludwigia *sect.* Microcarpium *is a polyploid complex of 14 species distributed primarily in the southeastern United States. Several of the species are variable and taxonomically difficult; the boundaries of many are blurred by intermediate forms. Relationships among the species are often reticulate and in some cases difficult to specify precisely. Data from the study of meiosis in artificial and natural hybrids were used to analyze relationships among the species. Among diploid (*$n = 8$*) species,* L. linearis *and* L. linifolia *are similar in morphology but differ chromosomally by one reciprocal translocation.* F_1 *hybrids between them are vigorous, have 47–48% stainable pollen, and produce moderate quantities of viable seeds. Another diploid,* L. microcarpa, *is morphologically and genetically distinct from* L. linearis *and* L. linifolia. *Hybrids between* L. microcarpa *and either other diploid are vigorous but produce only 6% stainable pollen and no viable seeds. They formed mostly univalents at meiotic metaphase I, with up to three sometimes heteromorphic bivalents. The fourth diploid,* L. stricta, *has not been studied biosystematically. The eight morphologically distinct tetraploid (*$n = 16$*) taxa can be crossed in any combination, producing fertile offspring with complete association of their 16 bivalents. No extant diploids are believed to have been involved directly in forming the tetraploids of sect.* Microcarpium. Ludwigia alata, *a hexaploid (*$n = 24$*), is morphologically similar to the tetraploids, and chromosome pairing in experimental hybrids suggests that it originated after hybridization between a tetraploid and* L. microcarpa *or populations ancestral to that species. Two chromosome numbers are present in the* L. curtissii *complex (*L. simpsonii, $n = 24$*;* L. curtissii, $n = 32$*). The hexaploid complement of* L. simpsonii *appears to include three different diploid genomes, one of which is identical with that of* L. microcarpa. *Present data are not sufficient to determine if the diploid* L. linearis–L. linifolia *lineage was involved in parentage of the hexaploid* L. simpsonii, *but morphological evidence suggests it was not. It is highly probable, however, that the octoploid* L. curtissii *was derived after hybridization between the diploid* L. linearis–L. linifolia *lineage and the hexaploid* L. simpsonii.

Ludwigia contains some 82 species, which are classified into 23 sections (Raven, 1963; Ramamoorthy, 1979; Ramamoorthy & Zardini, 1987). It is the only member of the monotypic tribe Jussiaeeae and is the fourth largest genus in Onagraceae (after *Epilobium*, *Oenothera*, and *Fuchsia*). It has existed since at least the Eocene (Eyde & Morgan, 1973), and increasing evidence suggests it represents the earliest surviving evolutionary offshoot of the family (review in Ramamoorthy & Zardini, 1987; Eyde, 1981), or, in cladistic terms, the "sister group" of all other genera of the family. Study of this genus is therefore critical to understanding the overall evolutionary pattern in Onagraceae, a subject to which Peter H. Raven and his associates have devoted much time and energy over the past 30 years.

Thirteen species of *Ludwigia* are restricted to the Old World, 59 to the New World, and 10 are common to both hemispheres (Ramamoorthy,

---

[1] *This study was part of my doctoral studies at Washington University, St. Louis, Missouri. I am indebted to Peter H. Raven for suggesting and supporting this project and to the Biology Department of Washington University and the Missouri Botanical Garden for facilities and research space. A Graduate Fellowship from the Division of Biology and Biomedical Sciences, Washington University made possible my study in the United States. Financial support was provided also by the U.S. National Science Foundation, most recently grant DEB-8518906 to Peter H. Raven. I thank Gerrit Davidse, Peter Goldblatt, Peter C. Hoch, and Porter P. Lowry II for valuable suggestions, comments, and criticisms; David Dille for data and living plants of* Ludwigia *sect.* Microcarpium; *Steven Seavey, Warren Wagner, and Hiroshi Tobe for interesting discussions; David Boufford and Emily Wood for their help in the field and their encouragement of my study; Jychian Chen, who assisted me in the field; James Hunt, who identified the wasps that visited* Ludwigia; *Donovan S. Correll, Clark Cowan, Robert K. Godfrey, and John Popenoe, who supplied living material of* Ludwigia; *Bruce Carr, who helped with the cytological analysis; James Henrich and Emily Colletti for aid in the greenhouse; Ji-Yui Guo for aid in preparing figures; John Myers for preparing the maps; Gloria Hoch who typed the manuscript; and, finally, my wife, Wanling, for assisting in the field, preparing line drawings, and for supporting my work, without which my dissertation could not have been completed.*

ANN. MISSOURI BOT. GARD. 75: 970–1009. 1988.

1980). Most sections are tropical and subtropical, but *Ludwigia* also has several well-developed temperate offshoots, particularly in North America (Raven & Tai, 1979).

Most native North American *Ludwigia* species have four sepals, four stamens, pluriseriate and free seeds with narrow raphes, and a herbaceous habit (Raven, 1963). With a few exceptions they are confined to the Atlantic and Gulf coastal plains of the United States. The 23 haplostemonous species represented here are placed in three sections: sect. *Ludwigia*, with 4 species (Munz, 1944, 1965; Raven, 1963); sect. *Dantia*, with 5 species (Schmidt, 1967); and sect. *Microcarpium*, a diverse group of 14 species (Table 1), which constitutes the subject of this study.

Section *Microcarpium* was selected for the present study because it represents a diverse polyploid complex (Raven & Tai, 1979) in which abundant natural hybridization occurs and in which the relationships among species are not clear. In a comparative study of the reproductive structures in *Ludwigia*, Eyde (1978) considered sect. *Microcarpium* as "remarkably diverse," at least with respect to surface-cell orientation of the seeds. The fact that several polyploid species were reported to have two different chromosome numbers (Raven & Tai, 1979) may reflect either difficulties in identification or their diverse genetic backgrounds. Duke (1955) noted the varying degree of intergradation exhibited between North Carolina *Ludwigia* species, and he suspected one population to be of hybrid origin between two species of sect. *Microcarpium*. A critical study of herbarium material has revealed many specimens exhibiting various intermediate morphological characteristics. Two such natural hybrids, *L. lanceolata* × *L. pilosa* and *L. suffruticosa* × *L. pilosa*, have even been given specific and varietal names (*L. simulata* Small and *L. suffruticosa* Walter var. *pubens* Torrey & A. Gray, respectively). Conclusive evidence of intergradation among species, however, can only be obtained through experimental hybridization.

Schmidt's (1967) work in establishing the phylogenetic relationships among species belonging to *Ludwigia* sect. *Dantia* has proved helpful in the study of sect. *Microcarpium*. Both of these sections were grouped, along with the monotypic East Asian section *Miquelia*, in the "*Microcarpium* complex" on the basis of reproductive structures and overall evolutionary patterns in *Ludwigia* (Eyde, 1981). Schmidt (1967) demonstrated through artificial hybridization and cytological observations of hybrid microsporocytes in sect. *Dantia* that hybrids between plants of different ploidy levels consistently exhibited typical "Drosera-type" chromosome pairing; i.e., homologous genomes in the F_1 generations always formed bivalents and nonhomologous genomes remained unpaired.

Schmidt (1967) also studied two naturally occurring intersectional hybrids. Meiotic observations of the hybrid between *L. palustris* ($n = 8$; sect. *Dantia*) and *L. glandulosa* ($n = 16$; sect. *Microcarpium*) revealed very little association between chromosomes, with 0–3 weakly joined bivalents. The other natural hybrid examined, involving *L. simpsonii* ($n = 24$, cited as *L. curtissii* by Schmidt; sect. *Microcarpium*) and *L. repens* ($n = 24$; sect. *Dantia*), yielded 48 unpaired chromosomes at meiosis. These observations suggest that in the related sect. *Microcarpium*, "Drosera-type" chromosome pairing also occurs. This characteristic is helpful in studying genetic relationships among species in such a polyploid complex.

The purpose of the present study was to determine the evolutionary relationships of the taxa comprising sect. *Microcarpium*. Toward this end I have considered extensive cytological evidence from my experimental hybridizations. This has been supplemented with data on morphology, pollination biology, crossing relationships, geographical distribution, and field observations of morphological variation and habitat preference. In addition, more than 7,000 herbarium specimens have been examined.

MATERIALS AND METHODS

Specimens were collected from wild populations and were propagated from seeds or clonal transplants in the experimental greenhouse at the Missouri Botanical Garden (with the exception of some strains that were obtained as seeds from the Kew Seed Bank). Members of sect. *Microcarpium* can be cloned easily from their vegetative parts and cultivated in the greenhouse by standard procedures. Parental seeds usually germinated readily one or two weeks after they were sown. However, it took one or two months or even longer for some of the hybrid seeds to germinate. Plants of sect. *Microcarpium* normally flower the first year.

In an insect-free greenhouse, several flowers of each parental strain were (1) artificially self-pollinated to test for self-compatibility, (2) left alone to test for self-pollination, and (3) emasculated and left alone to test for apomixis. Plants of all species studied were found to be self-compatible and nonapomictic. Except for a few species, in which selfing is prevented physically, members of sect. *Microcarpium* are capable of mechanical self-pollination.

All experimental crosses were therefore made by first emasculating the ovulate parent before self-pollination could occur, and then applying pollen from the pollen parent to its stigmas. Generally, several different parental strains were used in each cross; in a given trial all pollen parents were from the same population. The seeds resulting from successful hybridizations were sown early the following spring. Usually six seedlings of each artificial hybrid were randomly selected and transplanted into five-inch pots. A few of the F_2 families were also grown to maturity. About five to six months were required to produce a flowering hybrid after germination.

Flower buds to be examined for meiotic behavior were fixed in a 3:1 mixture of 95% ethanol and glacial acetic acid and stored in the refrigerator. Prior to staining, the buds were hydrolyzed for 5–8 minutes at 60°C using a 1:1 mixture of concentrated HCl and 95% ethanol. They were then squashed in FLP orcein (Jackson, 1973). Somatic chromosome counts for some of the parental strains were obtained from actively growing root tips pretreated for three to four hours in 8-hydroxyquinoline, then fixed as above for at least ten minutes. The root tips were then hydrolyzed in 1 N HCl for 8–10 minutes at 60°C and squashed in the FLP orcein. Semipermanent slides were prepared and preserved in the freezer. Cytological observations were made using a Zeiss Universal Large Research Microscope. All analyzable chromosome configurations (mostly diakinesis or metaphase I) were documented with camera lucida drawings or photomicrographs using Kodak Panatomic-X film. Negatives and drawings are deposited at the Institute of Botany, Academia Sinica, Taipei.

Fertility of greenhouse parental individuals, experimental hybrids, and suspected naturally occurring hybrids was estimated by determining the percentage of stainable pollen using the malachite green-acid fuchsin-orange G stain of Alexander (1969), which stains pollen walls green and cytoplasm red. Pollen grains with uniformly red cytoplasm were scored as fertile; partially stained or unstained grains were considered sterile. In many hybrids, however, and especially those of heteroploid crosses, the stainable pollen grains differ substantially in size, and some probably are not functional, as was suggested by Uhl (1976). At least 200 tetrads (when pollen shed as tetrads) or 400 single grains (when pollen shed singly) per plant were scored.

Seeds of members of sect. *Microcarpium* are so small (ca. 0.4–0.7 mm long) that studying the shapes and orientations of their surface cells under a dissecting microscope is very difficult. However, they are transparent enough to be examined under a light microscope. Photographs of seeds were taken with strong back illumination using Kodak Panatomic-X film. Polarized light was sometimes used.

Herbarium specimens prepared from all experimental plants, both parental and hybrid (with the exception of the very small individuals such as those which did not develop much further than the cotyledonous stage), are deposited at MO. Experimental hybrids are designated by a formula consisting of the acronym (Tables 3–15; Figs. 5, 21) for the two parents, connected by the multiplication sign (×), with the ovulate parent listed first.

DIAGNOSTIC FEATURES

Discussion of the morphological features is limited to those useful in delimiting members of sect. *Microcarpium* and in recognizing hybrids. A more complete discussion of morphological variability in this group can be found in Peng (in press). Characters that are functionally related to the pollination biology will be examined in more detail later in this paper. Some relevant diagnostic characters are summarized in Table 1.

HABIT

Plants of this section are all erect perennial herbs about 15–100 cm tall. They produce sprawling, leafy stolons along the surface of the ground in winter, although some species may also send out stolons in the summer while they are still flowering. In *Ludwigia suffruticosa*, however, underground rhizomes with scalelike leaves are also produced.

FLOWERS

The flowers have four sepals, four stamens, and a four-loculed ovary. Only *L. linearis*, *L. linifolia*, and *L. stricta*, all diploid, consistently have four yellow petals. The only other diploid species, *L. microcarpa*, and tetraploid, hexaploid, and octaploid species are apetalous. Vestigial petals are, however, occasionally present in normally apetalous species, especially *L. curtissii*. Loss of petals apparently represents the derived status, which is reflected in the fact that all polyploid species lack petals. Absence of petals does not in itself indicate autogamy, however, since nectary discs on top of the ovaries of all species produce various amounts of nectar that is fed on by insects. Furthermore, in the apetalous species—*L. alata*, *L. suffruticosa*, *L. pilosa*, and *L. sphaerocarpa*—the sepals are either cream-colored or yellow and are quite showy.

One aspect of the floral morphology of particular

TABLE 1. *Some characters of* Ludwigia *sect.* Microcarpium.

Taxon	Chromosome Number	Petals Present (+) or Absent (−)	Pollen Shed Singly (S) or as Tetrads (T)	Seed Surface Cell Shape and Orientation[a]

L. suffruticosa Walter	$n = 16$	−	S	I

[a] Letter codes I, P, T indicate seeds with surface cells more or less isodiametric, in columns parallel elongate to the seed length, and transversely elongate to the seed length, respectively.

[b] Flowers with 1–3 (sometimes 4) vestigial petals sometimes observed.

[c] Seed surface cells elongate parallel to the seed length are predominantly exhibited by the subglabrous populations, whereas cells elongate transversely to the seed length are prevalent in more strigillose populations.

[d] Seed surface comprised of a mixture of cells both parallel and transversely elongate to the seed length. Sometimes the orientation of these columnar cells is irregular.

interest in *L. linearis* is the presence in the anthers of transverse septa composed of tapetum and parenchyma which divide the sporogenous tissue into packets (Eyde, 1977; Tobe & Raven, 1986). This character is shared only by an unrelated South American species, *L. latifolia* (Benth.) Hara, and five other genera of Onagraceae.

POLLEN

Pollen morphology of Onagraceae has been studied intensively by Ting (1966), Brown (1967), Skvarla et al. (1975, 1976, 1978), and Praglowski et al. (1983). Unique palynological features of the family include: protruding papillose apertures; mechanisms of tetrad and polyad cohesion; the fine structure of the exine; and viscin threads, which are extensions of the exine that tend to bind the grains together in masses. Pollen of sect. *Microcarpium* is quite uniform, being characterized by isopolar grains frequently with prominent colpal extensions and with a psilate exine (Praglowski et al., 1983). Most species shed pollen in tetrads, although in *L. alata*, *L. curtissii*, *L. microcarpa*, *L. simpsonii*, and *L. suffruticosa* grains are shed singly (in monads), a characterisic found sporadically in other species of *Ludwigia* (Praglowski et al., 1983). Pollen shed as monads is thought to be the ancestral condition in *Ludwigia* (Praglowski et al., 1983), but in view of the relationships suggested by Eyde (1977, 1978, 1981), the monad pollen in sect. *Microcarpium* was probably derived secondarily from tetrad pollen. In any event, this character, along with the seed-surface cell pattern, is useful in distinguishing closely related species like *L. alata* ($n = 24$; monads) and *L. lanceolata* ($n = 16$; tetrads), which have different chromosome numbers but are otherwise difficult to distinguish. It is also highly helpful in detecting natural hybrids when their suspected parents differ in this character.

CAPSULES

Fruit anatomy of *Ludwigia* has been studied by Eyde (1978), who reported that the fruit wall in *L. alata* is thickest in the placental radii, contrasting markedly with the fruit wall in sect. *Dantia* and in most other species of sect. *Microcarpium*. The shape, size, and vestiture of capsules are very

FIGURES 1–4. Photographs of seeds of some members of *Ludwigia* sect. *Microcarpium.*—1. *L. lanceolata,* Florida: Highlands Co., *Peng 4183* (MO).—2. *L. glandulosa* subsp. *glandulosa,* Florida: Santa Rosa Co., *Dille 412* (MO).—3. *L. alata,* Florida: Wakulla Co., *Morar 11* (FSU).—4. *L. sphaerocarpa,* South Carolina: Jasper Co., *Dille 348* (MO). Scale bar = 0.4 mm.

diverse within sect. *Microcarpium.* Capsule shape ranges from obpyramidal to subcylindrical, oblong-obovate, turbinate, or subglobose, and length ranges from 1 to 12 mm. In *L. alata* and *L. lanceolata,* the capsules are narrowly to markedly four-winged. The surface vestiture ranges from glabrous to strigillose or hirtellous. These characters are of paramount importance in distinguishing the species and detecting hybrids. Furthermore, the lengths of persistent bracteoles at or near the capsule base is often a diagnostic character in species delimitation and hybrid recognition.

SEEDS

The seeds are small, 0.4–0.7 mm long, and are cylindric, ellipsoid, reniform, or ovoid in shape. Their surface cells are diverse in shape and orientation (Eyde, 1978). They are either more or less isodiametric (Fig. 1) or are in parallel columns that are predominantly either elongate parallel (Fig. 2) or transversely elongate (Fig. 3) to the seed length, with minor variation on the two ends and areas near the raphe (Table 1). Like capsule morphology, seed-surface pattern provides excellent diagnostic characters for identifying the species and detecting natural hybrids.

In *L. sphaerocarpa* the seed-surface cells (Fig. 4) are less regularly oriented than in the other species. They are arranged in columns both transversely elongate and parallel to the seed length, with the former alignment often dominant in the central part of the seed. In this species, it is also not uncommon to have some seeds with variously oriented cells, a pattern that supports the suggestion of a hybrid origin for *L. sphaerocarpa* (see below).

REPRODUCTIVE BIOLOGY

Raven (1979) thoroughly reviewed reproductive biology of Onagraceae. Two-thirds (56 of 82) of all species in *Ludwigia* modally self-pollinate, and of the 26 that modally outcross, most accomplish that by separation of the stigma and anthers (Raven, 1979; Ramamoorthy & Zardini, 1987). There are no known instances in *Ludwigia* of protandry, protogyny, or male sterility, such as are found in other genera of Onagraceae (Raven, 1979). In nine species of *Ludwigia,* however, outcrossing is reinforced by genetic self-incompatibility, which occurs in about a quarter of all outcrossing species in the family (Raven, 1979).

All members of sect. *Microcarpium* are genetically self-compatible perennials that are mostly facultatively autogamous. Shortly after the flowers open in the morning, the anthers dehisce and the stigma becomes receptive. The anthers spread and are held away from the stigma shortly after anthesis, but in most species, petalous or apetalous, the anthers arch over a few hours later and attach firmly to the sticky stigma, thus effecting self-pollination.

Self-pollination, as well as cross-pollination, however, can also be achieved by insect vectors without having the anthers attached to the stigma mechanically. Bumble bees, honeybees, wasps, moths, and ants were observed visiting populations of *L.*

pilosa in the field (Peng, 1984). Raven (pers. comm.) also observed numerous wasps attracted by flowers of *L. sphaerocarpa*. The presence of plentiful confirmed natural hybrids (see below) suggests substantial cross-pollination by insects in the field.

CYTOLOGY

The first cytological study of a member of sect. *Microcarpium* was made by Gregory & Klein (1960) who, in the course of investigating the meiotic chromosomes of several onagraceous genera, recorded five counts for four species (cited as five species). These authors were the first to document polyploidy in the genus. One diploid population of *L. linifolia* that they studied was subsequently examined mitotically by Kurabayashi et al. (1962), who called attention to the fact that the chromosomes of *Ludwigia* and those of tribe Epilobieae are the smallest in Onagraceae, and also that they may differ conspicuously in size within a single genome. The proximal ends of the chromosome arms are heavily pycnotic and appear even in interphase nuclei as very distinct and definite chromocenters.

Based on a review of the literature and the study of 302 individuals from 282 naturally occurring populations from throughout the range of the genus, Raven & Tai (1979) presented a comprehensive chromosome number report for 38 of the 45 species of *Ludwigia* exclusive of sect. *Myrtocarpus* sensu lato. The basic chromosome number for the genus was established as $x = 8$ with no aneuploidy but extensive polyploidy. In my description of a new species of sect. *Microcarpium*, *L. ravenii* (Peng, 1984), I reported $2n = 32$ for this species, which has been misidentified as *L. pilosa* in the past. *Ludwigia stricta*, a Cuban endemic, is here reported as a diploid, with $n = 8$. Through these efforts, chromosome counts are now available for all taxa recognized in sect. *Microcarpium*. Section *Microcarpium* is shown to be a diverse polyploid complex, with four diploids, eight tetraploids, two hexaploids, and an octoploid. *Ludwigia alata*, *L. curtisii*, and *L. suffruticosa*, reported as having more than one chromosome number (Raven & Tai, 1979), will be discussed below.

In the present paper, I am reporting 78 more counts representing 75 populations of 14 species and one additional subspecies in sect. *Microcarpium* (Table 2). The chromosome number of *L. stricta* is here reported for the first time. These, along with 69 previously reported counts by Raven & Tai (1979), constitute our present knowledge of cytology of sect. *Microcarpium*. Because several taxonomic changes have been made, including a new combination (Peng, 1986), and because a new species, *L. ravenii*, has recently been recognized (Peng, 1984), I have checked the identification of voucher specimens cited by Raven & Tai (1979) and included these previously published counts in Table 2, using the currently accepted names. All counts are gametic except those indicated by "$2n =$ ". Original counts reported by Raven & Tai (1979) are indicated by asterisks; those reported by others are accompanied by references.

Raven & Tai (1979), while reporting two chromosome numbers for *L. alata*, stated that "Chromosome counts are now available for all taxa except . . . *L. stricta* . . . and, if it is distinct from *L. alata*, *L. lanceolata* Ell." Indeed, the last two species are similar in many aspects, especially in sharing obpyramidal capsules with winged corners, which is the key character in recognizing this species pair. However, upon examination of microscopic characters, such as seed surface architecture and the way pollen grains are shed, characters which previously have not been used by monographers (Munz, 1944, 1965), it has become clear that the two are distinct species. *Ludwigia alata* consistently sheds pollen singly (Praglowski et al., 1983) and has seed-surface cells in parallel columns transversely elongate to the seed length (Fig. 3), whereas *L. lanceolata* sheds pollen as tetrads (Praglowski et al., 1983) and invariably has nearly isodiametric seed-surface cells (Fig. 1). Their seeds differ in size and shape as well. Furthermore, these differences are correlated with chromosome number. Based on the 15 counts available (Table 2), *L. alata* is hexaploid with $n = 24$, whereas *L. lanceolata* is tetraploid with $n = 16$. The only exception is a specimen collected from Collier Co., Florida (*Raven 18672*), which Raven & Tai (1979) correctly identified as *L. alata* and reported to have $n = 16$. In order to verify this report, the same population was sampled again in 1980 (*Peng 4242*). Plants from this population yielded a count of $n = 24$. It seems likely, therefore, that the reported count of $n = 16$ resulted from confusion or interchange of samples. The questionable count has therefore been omitted from Table 2.

For *L. suffruticosa* there are 11 chromosome counts available at present, ten with $n = 16$, and one with $n = 24$ for a collection (*Raven 18651*) from Hillsborough Co., Florida (Raven & Tai, 1979). Four other populational counts obtained from the same county consistently show $n = 16$. It is possible that plants with $n = 24$ have arisen

[a] Chromosome number here determined for the first time.

directly from tetraploids by fusion of an unreduced gamete from one parent with a normal gamete from the other, as Raven & Tai (1979) postulated. Meiosis was normal (Raven & Tai, 1979), and pollen from the voucher specimen was fully viable as judged by staining results. The count of $n = 24$ should be reconfirmed and investigated further if additional individuals are located; it is omitted from Table 2.

Ludwigia curtisii is another species Raven & Tai (1979) reported as having two chromosome numbers. They considered this species, along with *L. simpsonii* and *L. spathulifolia,* to comprise a single species complex, within which diagnostic characters such as capsule size and leaf shape (Munz, 1944, 1965) were not correlated with chromosome numbers. The present study, however, indicates that *L. simpsonii* is specifically distinct from *L. curtissii* and that *L. spathulifolia* should be treated as a variant of *L. curtissii* with slightly larger capsules.

In addition to being high polyploids (hexaploid and octoploid), plants of this complex are unique among species of sect. *Microcarpium* in having the capsules split along four longitudinal lines opposite the loculi at maturity (Peng & Tobe, 1987). Capsules from other species in sect. *Microcarpium* dehisce either by separation of the walls from the indurate nectary disc (Munz, 1944, 1965; Raven, 1963) or by irregular disintegratoin of the fruit wall (Peng & Tobe, 1987). Technical characters, such as the way pollen grains are shed and seed-surface cell shape and orientation, are not useful in distinguishing these taxa; they have both pollen grains shed singly and seed-surface cells in parallel columns transversely elongate to the seed length. They have turbinate or slightly broadly turbinate capsules 1.5–4.5 mm long and are extremely variable in cauline leaf shape, which ranges from obovate to spatulate-oblanceolate, narrowly oblanceolate, or sublinear. No consistent correlation was found between leaf shape and capsule size. When plants of distinct leaf shape and capsule size were collected and cultivated in an experimental greenhouse, the leaf shapes tended to converge and become spatulate-oblanceolate, but the capsule sizes remained constant.

Based on counts from 30 populations, including seven reported by Raven & Tai (1979), differences in chromosome number are indeed correlated with mature capsule size. All plants with $n = 24$ have mature capsules 1.5–2(–2.5) mm long, while all plants with $n = 32$ have mature capsules (2–)2.5–4(–4.5) mm long. The morphology of plants with $n = 24$ fits very closely the description of *L. simpsonii,* whereas the morphology of plants with $n = 32$ clearly corresponds to that of *L. curtissii* (including *L. spathulifolia*).

Compared with plants with $n = 32$, plants with $n = 24$ have generally diminutive floral parts: shorter bracteoles, sepals, stamens, and ovaries. Further, plants with $n = 24$ rarely exhibit vestigial petals, whereas those with $n = 32$ frequently have 1–3 caducous petals on at least some flowers. Vegetatively, plants with $n = 24$ are erect to ascending, or sometimes are prostrate and rooting at the nodes. They are pale green with slender stems often much branched from below or above. The leaves are sometimes quite small, tending to be opposite or subopposite at the lower nodes. By contrast, plants with $n = 32$ are usually dark green or sometimes purplish, have stouter erect stems branched above, and leaves usually alternate throughout.

Although *L. simpsonii* and *L. curtissii* frequently are sympatric, they are ecologically distinct and seldom actually intermix. Plants with $n = 24$ tend to grow along roadsides with other weeds in moist sandy soil. Plants with $n = 32$ grow far from roadsides in black muck and often in deep standing water, often mixed with tall grasses or sedges.

In view of this evidence, *L. simpsonii* is considered a hexaploid with $n = 24$, and *L. curtissii* (including *L. spathulifolia*) an octoploid with $n = 32$.

A collection from Clay Co., Florida (*Raven 18690*) was originally identified as *L. pilosa* and determined to be tetraploid with $n = 16$ (Raven & Tai, 1979). A more detailed morphological study reveals that this is best treated as *L. ravenii* (Peng, 1984). Nearly all previous collections of *L. ravenii* were initially identified as *L. pilosa* by their respective collectors: the two species are similar in being densely hirtellous, a distinct character not shared by any other member of sect. *Microcarpium. Ludwigia ravenii* may be distinguished readily from *L. pilosa* by having oblong-obovoid capsules and seed-surface cells predominantly in parallel columns transversely elongate to the seed length, and by having shorter sepals, filaments, and styles. Furthermore, unlike *L. pilosa,* which is nearly always hirtellous on the lower half of the style and between the lobes of the nectary disk, all 28 collections of *L. ravenii* are completely glabrous in these areas.

Among the voucher specimens for *L. glabrous* ($n = 16$, Raven & Tai, 1979), a collection from Fort Bend Co., Texas (*Raven 19398*), with short capsules and seed-surface cells in parallel columns transversely elongate to the seed length, has been placed under subsp. *brachycarpa* in Table 2. Another collection (*Raven 19405*) from the same county is preserved in two duplicate specimen sheets: one of them (FLAS) belongs to subsp.

brachycarpa; the other (DS), however, is a mixture of two plants of subsp. *L. glandulosa* with one of subsp. *brachycarpa*. This is arbitrarily placed under subsp. *brachycarpa* in Table 2; both taxa have the same chromosome number.

The following collections counted by Raven & Tai (1979) as $n = 16$ are considered to represent hybrid populations of *L. pilosa* × *L. sphaerocarpa* and have been excluded from Table 2: Florida: Highlands Co., *Raven 18683* (as *L. pilosa*); Clay Co., *Raven 18680* (as *L. sphaerocarpa*); Columbia Co., *Raven 18634* (as *L. sphaerocarpa*). South Carolina: Beaufort Co., *Raven 18716* (as *L. sphaerocarpa*); Colleton Co., *Raven 18718* (as *L. sphaerocarpa*).

EXPERIMENTAL HYBRIDIZATION

An extensive artificial hybridization program was carried out among members of sect. *Microcarpium* with the following objectives: (1) to determine chromosome homologies and relationships of taxa with the same and with different ploidy levels; (2) to study whether chromosome repatterning has played a role in the diversification of the species; (3) to study the genetic isolating mechanisms that may have permitted preservation of the genetic integrity of the taxa; and (4) to examine the variation pattern generated by hybridization, which is useful in studying natural hybrid populations.

Over 1,000 reciprocal crosses have been made among the 12 species and one additional subspecies of sect. *Microcarpium*. *Ludwigia ravenii* and *L. stricta* were not included because living plants were not available at the time these studies were conducted. Most of the attempted crosses resulted in seed set. Some of the failures probably resulted from damage by the sharp forceps used to emasculate the flowers and to transfer the pollen to these usually small-flowered plants. In these cases, additional attempts were made using either the same or different parental strains, and seed set was usually obtained. The only consistent failure occurred in some crosses involving *L. microcarpa* as pollen parent. This species is the smallest in

stature and in flower size and has the shortest style and smallest pollen grains among members of sect. *Microcarpium*. The few ovulate parents that failed to set seed in these crosses were of taxa with styles 3–6 times longer than those of *L. microcarpa*. Rather than genetic disharmony, it is likely that these failures were due to the improbability of small grains containing sufficient food reserves to support pollen tube growth through long styles (review in Lee, 1978), since the reciprocal crosses using shorter-styled *L. microcarpa* as ovule parent invariably set seeds.

As all plants in sect. *Microcarpium* are self-compatible and modally autogamous, self-pollination sometimes interfered with the hybridizations, especially in crosses involving a small-flowered ovulate parent. Part of the seed set may thus reflect a small to moderate amount of self-pollination despite regular emasculation. The seedlings resulting from self-pollination, however, can almost always be distinguished from those resulting from hybridization by the leaf color or shape, or even by growth rate, when both types of seedlings were grown together.

The strains utilized in the crossing experiments are presented in Table 3. The results of the artificial hybridizations are summarized in Figure 5 and indicate three more or less interfertile groups in sect. *Microcarpium*: (1) all the tetraploid taxa plus *L. alata*, a hexaploid; (2) *L. linearis* and *L. linifolia*, both diploid species; and (3) the *L. curtissii* complex (hexa- and octoploids). Data on the percentages of stainable pollen in hybrids (Table 4) support this interpretation.

The crossing results will be discussed in the following order: (I) the diploid group (including *L. linearis*, *L. linifolia*, and *L. microcarpa*); (II) the *L. pilosa* group (including all tetraploids and a single hexaploid, *L. alata*); (III) the *L. curtissii* complex (including *L. curtissii* and *L. simpsonii*); (IV) crosses between the diploid group and the *L. pilosa* group; (V) crosses between the diploid group

and the *L. curtissii* complex; and (VI) crosses between the *L. pilosa* group and the *L. curtissii* complex.

HYBRIDS WITHIN THE DIPLOID GROUP (*LUDWIGIA LINEARIS, L. LINIFOLIA,* AND *L. MICROCARPA*)

These interspecific crosses resulted in significant seed set except for a few cases in which *L. microcarpa* was pollen donor. As suggested earlier, these failures were probably due to the inability of the small pollen grains of *L. microcarpa* to grow through the long styles of *L. linearis* and *L. linifolia*. Four hybrid combinations were obtained (Table 5) and grown to flowering.

Meiotic analysis and pollen stainability

Meiosis was normal in the examined natural populations of the diploid parental strains. The chromosomes regularly formed eight bivalents, with no univalents or multivalents observed. In the reciprocal crosses between *L. linearis* and *L. linifolia*, meiotic configurations ranged from eight bivalents to four bivalents and eight univalents; a ring or chain quadrivalent was observed in 11 of the 29 cells examined. In a single cell, a hexavalent was observed; trivalents were observed occasionally. In the translocation heterozygote, chiasma frequency and quadrivalent frequency are interdependent to a certain extent, as McCollum (1958) suggested. If chiasmata are formed in each of the four paired arms of the cross-shaped configuration at pachytene, then the four chromosomes form a ring at metaphase I; progressively lower numbers of chiasmata will give a chain of three plus a univalent, two bivalents, or four univalents. The observation of the quadrivalent in meiosis of the diploid hybrid indicates that the strains of *L. linearis* and *L. linifolia* hybridized differ by at least one reciprocal translocation, which may help to account for the inviability in about half of the pollen in the hybrid. This is the first demonstration of a reciprocal translocation in *Ludwigia*. The interpretation of the single cell recorded as having a hexavalent is uncertain, and the observation should be confirmed.

The reciprocal hybrids between *L. linearis* and *L. linifolia* produced many aborted seeds. However, *L. linearis* has the highest number of seeds per capsule (about 700) among species of sect. *Microcarpium*. F_1 plants resulting from reciprocal crosses involving *L. linearis* and *L. linifolia* were also very fecund, and their output of viable seeds per capsule was therefore quite substantial, although reduced. An F_2 family of nearly 100 plants was grown for each of the reciprocal crosses. Some 25% of these plants died in the seedling stage, and another 25% were very weak. About 10–15% of the F_2s flowered. Pollen stainability of the seven F_2 plants examined ranged from 1 to 52% (1, 7, 10, 15, 22, 32, 52%). None of the F_2s that survived were as vigorous and floriferous as the F_1 plants.

In diakinesis and first metaphase of *L. microcarpa* × *L. linearis* and *L. microcarpa* × *L. linifolia* univalents predominated. The bivalents ranged from 0 to 3, the rest being univalents. Heteromorphic bivalents were observed in at least a few cells. The paired chromosomes were sometimes held together by a matrix connection instead of by a chiasma. However, a maximum of three true bivalents, held together by chiasmata, were observed in a few cells. The few paired chromosomes did not always line up in the equatorial plane, more often being randomly placed like univalents. Micronuclei were present at the tetrad stage. Pollen grains were shed both singly and as (loose) tetrads. Their sizes varied. The stainability was 0% in *L. microcarpa* × *L. linearis* and 6% in *L. microcarpa* × *L. linifolia*, which seemed to accord with the fact that no or one bivalent(s) were observed in the former and two or three were observed in the latter.

Morphology of the hybrids

Reciprocal hybrids between *L. linearis* and *L. linifolia* resembled each other morphologically. They were vigorous and floriferous. In overall habit and capsule shape they were more similar to *L. linearis*. In floral details, however, the hybrids were intermediate between the parents. For example, the divided sporogenous tissue in the anthers, which is characteristic of *L. linearis*, also appeared in the hybrids, although the packets were fewer and shallower. Seed set was variable from capsule to capsule, but was generally fairly high.

Ludwigia microcarpa, a small, highly autogamous herb with minute, apetalous flowers and obovate-spatulate to spatulate leaves, differs from both *L. linearis* and *L. linifolia* in nearly every morphological aspect. Hybrid combinations between *L. microcarpa* and *L. linearis* and those involving *L. microcarpa* and *L. linifolia* were vigorous and morphologically intermediate between the parents. Both produced small flowers with four yellow petals and reached the maximum height of the taller parents. Hybrids between *L. microcarpa* and *L. linearis* were about 70 cm tall and had very narrowly elliptic leaves, whereas those between *L. microcarpa* and *L. linifolia* were about 35 cm tall and had oblanceolate to narrowly obovate leaves. Neither hybrid set fruit—the ovaries simply withered.

HYBRIDS WITHIN THE *LUDWIGIA PILOSA* GROUP

Parental strains of this group consisted of one hexaploid species, *L. alata* ($n = 24$), and seven tetraploid entities ($n = 16$). All interspecific reciprocal crosses attempted invariably yielded abundant seed. As many hybrid combinations as greenhouse space and time allowed were grown (Fig. 5; Tables 6, 7). Hybrid seedlings were nearly always vigorous. Occasionally a few plants assumed stunted growth or exhibited some morphological abnormality. These are considered to represent chance combinations of disharmonious genotypes from the two parents. For each hybrid combination, only the healthy F_1 individuals were grown to maturity for study.

Meiotic analysis and pollen stainability

Meiosis was normal in all parental strains of the tetraploid species as well as in *L. alata*, the only hexaploid in this group. From diakinesis to metaphase I, 16 and 24 bivalents, respectively, were invariably observed in these taxa; no univalents or multivalents were detected. Disjunction and microspore formation also appeared to be normal. The pollen stainability of the parental strains was 95–100%.

As all the hybrids between tetraploid taxa exhibited a similar pattern of meiotic behavior, the data for these are pooled and discussed together. Hybrids between the tetraploid taxa and *Ludwigia alata* (hexaploid) were likewise similar with respect to meiotic behavior; these data will also be treated as a group.

(1) Hybrids between tetraploid taxa (Table 6)

In very many cases, meiosis in these hybrids appeared normal, exhibiting 16 bivalents from diakinesis to metaphase I. The majority of cells exhibited complete chromosome pairing, but 2–6 (very rarely 8–10) univalents were often encountered in prepared slides. In many cases these univalents appeared to have resulted from precocious separation of the bivalents (probably because no chiasmata developed). This was suggested by their shapes and nonrandom locations on the metaphase plates. Nevertheless, meiotic anaphase I was generally regular, and no micronuclei were observed in the tetrad stage. Occasionally bivalents had a slightly stretched or attenuated appearance. This stretching may result from a failure of terminal chiasmata to disjoin properly (Grant, 1952). A few cells with 2–3 bivalents associated side by side were seen. This association is apparently not due to chiasmata but rather to the "sticky" matrix bands typical of the "pseudobivalents" in hybrids of other taxa (e.g., *Bromus*, Walters, 1954).

Despite the few meiotic irregularities observed, the pollen stainability of the tetraploid hybrids was generally high (Tables 4, 6). Of the 17 hybrid combinations examined, 6 had estimated pollen stainabilities of 95–98%. With a few exceptions, most other hybrids exhibited 75–87% stainable pollen.

Two hybrids failed to flower in the closed greenhouse: *L. glandulosa* subsp. *brachycarpa* × *L. lanceolata* and *L. sphaerocarpa* × *L. glandulosa* subsp. *glandulosa*. These were then moved to an open, netted greenhouse. Here, the hybrids between *L. sphaerocarpa* × *L. glandulosa* subsp. *glandulosa* produced a single flower; its pollen stainability was not studied. The hybrid *L. glandulosa* subsp. *brachycarpa* × *L. lanceolata* was very vigorous and produced many flowers two

months after transfer. Its pollen stainability was estimated to be only 56%, significantly lower than one would expect, since this plant has as much chromosome pairing (13–16 pairs) as other hybrids that exhibited 75–98% stainable pollen.

Jones (1976) noted that environmental factors may exert considerable influence on production of presumably normal stainable pollen. She found that plants of some *Aster* species moved out from the greenhouse to the field consistently yielded significantly reduced fractions of normal pollen. Whether this is the case for *L. glandulosa* subsp. *brachycarpa* × *L. lanceolata* remains to be confirmed by growing them in a closed experimental greenhouse. It is also possible that the low observed pollen stainability is the result either of genic interaction between the parents or of the pronounced meiotic irregularities discussed earlier. However, the present sample size is not large enough to establish that hybrids from the cross *L. glandulosa* subsp. *brachycarpa* × *L. lanceolata* indeed exhibit a higher degree of meiotic irregularity than other hybrids.

Reciprocal hybrids between tetraploid taxa generally exhibited similar values for pollen stainability (Tables 4, 6). Different values were obtained for the reciprocal crosses between *L. lanceolata* and *L. pilosa* (96% and 75%), but different strains of *L. pilosa* were used in these crosses.

These data suggest that the tetraploid species in sect. *Microcarpium* in general have high chromosome homology, and complete pairing is frequently observed in almost all interspecific hybrids. The few meiotic irregularities occasionally observed (a few univalents, slightly attenuated bivalents, and sticky bivalents) have little effect on the hybrid fertility (as estimated by pollen stainability). This was further substantiated by abundant seed sets of all the hybrids.

A small family of vigorous F_2 individuals was reared for two randomly selected hybrids: *L. pilosa* × *L. glandulosa* subsp. *glandulosa* (17 plants) and *L. lanceolata* × *L. suffruticosa* (19 plants). These populations were small, owing to the limited space and time available to handle them. They generally received less care than the F_1s. Therefore, the several plants that were weak or died may not necessarily reflect F_2 weakness or breakdown. For example, the organic potting soil that was used was easily spoiled since all pots were continuously kept in standing water and were sprayed with insecticide periodically. Had the potting soil not been changed as needed, the plants might have remained vegetative, become weak, or even died.

All F_2s that did grow were vigorous. In the cross *L. pilosa* × *L. glandulosa* subsp. *glandulosa*, the only individual that flowered was quite unlike either the parents or the F_1s in morphology but had 91% stainable pollen. In *L. lanceolata* × *L. suffruticosa*, about 10 F_2 individuals flowered, some of which resembled the intermediate F_1s, whereas others were similar to *L. lanceolata*. Pollen stainability was quite different from plant to plant, ranging from 1% to 97% (1, 12, 51, 63, 74, 97%) in the six plants studied. Meiosis of an F_2 individual (pollen stainability not assessed) was nearly normal. Complete chromosome pairing was nearly always exhibited, although 2–4 univalents were occasionally seen. Some of the univalents were formed as a result of precocious disjunction of the bivalents.

(2) Hybrids between tetraploid taxa and hexaploid species (Table 7)

The hexaploid *L. alata* ($n = 24$) was crossed reciprocally to nearly all of the tetraploid ($n = 16$) taxa. All crosses resulted in vigorous, floriferous, pentaploid hybrids. Meiosis in the F_1 individuals typically exhibited a maximum of 16 bivalents and 8 scattered univalents, although exceptional configurations of 17 bivalents and 6 univalents were observed in *L. alata* × *L. lanceolata* (one cell), *L. alata* × *L. sphaerocarpa* (four cells), and *L. pilosa* × *L. alata* (one cell). One or two trivalents were seen occasionally in diakinesis and metaphase I of the following hybrids: *L. alata* × *L. glandulosa* subsp. *glandulosa* (one trivalent in two cells; two trivalents in one cell), *L. alata* × *L. lanceolata* (one trivalent in four cells; two trivalents in one cell), *L. alata* × *L. sphaerocarpa* (two trivalents in one cell), and *L. polycarpa* × *L. alata* (one trivalent in two cells; two trivalents in one cell). Groups of 2–4 bivalents (often of similar shape and size) "sticking" to one another sidewise were observed in meiotic metaphase but not in diakinesis. These associations were obviously not a result of chiasmata formation. Eight univalents would normally be expected in these hybrids. Observations of additional univalents at metaphase I either represent precociously separated bivalents or chromosomes which have no homologue. Present observations suggest that in most cells which had more than eight univalents, these "extras" are often precociously separate bivalents, judged by their shapes and locations.

Pseudobivalents (Walters, 1954) composed of two univalents held together by matrix bands were seen at least in a few metaphase I cells. One to six (rarely to ten) bivalents of stretched appearance were also seen occasionally. Some metaphase I cells in *L. alata* × *L. suffruticosa* were peculiar in having attenuated ends on the bivalents. Lagging univalents were uniformly found in meiotic anaphase I and II of all hybrids, and micronuclei occurred in nearly all the sporads.

Pollen stainability was in the range 43–71%, rather high for pentaploid hybrids exhibiting the above meiotic irregularities. All F_1 plants produced some aborted and some viable seeds in the plump capsules. An F_2 family (*L. glandulosa* subsp. *glandulosa* × *L. alata*) of 32 vigorous plants was grown and many individuals probably flowered but were not studied in detail. One morphologically intermediate plant was examined, however, and had 31% stainable pollen.

Morphology of the hybrids

Because of an apparently chance distribution of dominance between parents, some hybrids are likely to possess some characters of one parent, some of the other, and some (due to incomplete dominance or polygenic inheritance) that are intermediate (Stace, 1975). The net result is that hybrids are nearly always intermediate in overall morphology between the two parents. This is the situation within sect. *Microcarpium*. Genomic interaction resulting in a new character state has not been observed in these plants. With the exceptions of *L. glandulosa* subsp. *glandulosa* × *L. polycarpa* and *L. sphaerocarpa* × *L. glandulosa* subsp. *glandulosa*, all hybrids were very vigorous and flowered over a period of at least a month. Even in these two exceptional hybrids, if additional seeds were sown, or if different parental strains were crossed, vigorously growing hybrids would, I believe, be expected. This is because of the occurrence of a natural hybrid population of *L. sphaerocarpa* × *L. glandulosa* subsp. *glandulosa*. As there are very many naturally occurring hybrid populations between members of the *L. pilosa* group, it is valuable to discuss the morphology of artificial hybrids between these taxa. Since all reciprocal hybrids resembled each other, the discussion of characters that follows is limited to crosses in only one direction.

(1) Tetraploid hybrids

Ludwigia glandulosa subsp. *glandulosa* × *L. polycarpa*. These were dwarfs 5–20 cm in height at maturity, with an ascending habit. Despite their abnormal appearance, all produced a few flowers, set plump capsules with abundant seeds, and survived in the experimental greenhouse for two consecutive years. In general they were intermediate in vegetative and reproductive features, especially in shapes and sizes of floral parts and capsules. Like their parents, the hybrids shed pollen grains as tetrads and had seed-surface cells in parallel columns elongate to the seed length.

Ludwigia glandulosa subsp. *glandulosa* × *L. glandulosa* subsp. *brachycarpa*. The intermediacy of these hybrids was apparent in capsule size (4.5–5.5 mm long) and seed surface, which exhibited a mixture of columnar cells elongate and transversely elongate to the seed length (Fig. 6).

Ludwigia lanceolata × *L. pilosa*. The parents did not differ in seed-surface cell pattern or in the way their pollen grains were shed. The hybrids showed intermediate morphology in all aspects. Diagnostic characters include hirtellous pubescence and oblong-obpyramidal, 4-angled, unwinged capsules.

Ludwigia lanceolata × *L. polycarpa*. The hybrids were morphologically intermediate between the parents. Diagnostic characters include the 4-angled capsules and seed-surface cells (Fig. 7) basically similar in orientation to those of *L. polycarpa* (Table 1) but arranged in shorter columns. Some of them appeared more or less isodiametric in shape.

Ludwigia lanceolata × *L. sphaerocarpa*. The hybrids were again intermediate. The obpyramidal capsules were puberulent and very slightly winged, and the seed surface was composed of some more or less isodiametric cells and numerous, variously oriented short columnar cells (Fig. 8).

Ludwigia lanceolata × *L. suffruticosa*. The hybrids were generally intermediate in morphology. The stems were much branched as in *L. lanceolata*, but with a slightly congested and branched terminal inflorescence. The lower margins of sepals, bracteoles, and peduncles were slightly hirtellous. The capsules were weakly 4-winged and the seed-surface cells were subisodiametric as in both parents. Pollen grains were shed singly as in *L. suffruticosa*.

Ludwigia pilosa × *L. glandulosa* subsp. *glandulosa*. These hybrids were similar to *L. glandulosa* subsp. *glandulosa* in having subcylindric capsules, which were, however, somewhat shorter (5–5.5 mm long). Otherwise the plants were intermediate in general appearance, pubescence, and shape and size of floral parts. Seed-surface cells (Fig. 9) were predominantly columnar and elongate to the seed length like those of *L. glandulosa* subsp. *glandulosa* (Fig. 2). Yet few columnar cells were transversely elongate or oblique to the seed length. Some subisodiametric cells characteristic of *L. pilosa* were also present.

Ludwigia pilosa × *L. sphaerocarpa*. The hybrids were intermediate in pubescence (being densely strigillose) and shape and size of floral parts. Seed surface pattern (Figs. 10, 11, 12) was irregular and variable within the same capsule. A small yellow petal was observed in a single flower. Vestigial

petals, however, occur occasionally in both parental species.

Ludwigia pilosa × *L. suffruticosa*. The hybrids were intermediate in leaf shape and habit, were similar to *L. pilosa* in being hirtellous, and resembled *L. suffruticosa* in having a congested inflorescence. Fruiting specimens were not studied.

Ludwigia pilosa × *L. glandulosa* subsp. *brachycarpa*. The hybrids were similar to *L. pilosa* × *L. glandulosa* subsp. *glandulosa* in general, although they were less robust and had shorter subcylindric capsules 3–3.5 mm in length. The plants were strigillose. Their seed surface was composed predominantly of columnar cells, which were transversely elongate to the seed length (Fig. 13) as in *L. glandulosa* subsp. *brachycarpa*. Some more or less isodiametric cells typical of *L. pilosa* were also present, however. Also, columnar cells that were either parallel to the seed length or randomly oriented were observed.

Ludwigia polycarpa × *L. pilosa*. Hybrids were morphologically intermediate. Diagnostic features included the overall strigillose pubescence and the cubic-turbinate capsule with long bracteoles. These plants exhibited seed-surface cell patterns similar to those of *L. pilosa* × *L. glandulosa* subsp. *glandulosa* (Fig. 9).

Ludwigia sphaerocarpa × *L. glandulosa* subsp. *glandulosa*. The hybrids were not as vigorous as other hybrid combinations involving members of this group. The plants were reddish and less than 20 cm high. They were glabrous except for the fruits, which were sparsely and minutely strigillose. Only a single individual flowered, which later set plump capsules oblong in outline. Seed-surface cell pattern was basically similar to that of *L. glandulosa* subsp. *glandulosa*, but with some irregularities.

Ludwigia glandulosa subsp. *brachycarpa* × *L. lanceolata*. These hybrids were morphologically intermediate between the parents. The plants were nearly glabrous. The capsules were about 3 mm long, elongate obpyramidal, minutely strigillose on the sepal margins, and weakly winged on the angles. The bracteoles were short (about 1.2–1.5 mm long) and, as in *L. glandulosa* subsp. *brachycarpa*, the seed surface (Fig. 14) consisted mostly of columnar cells elongate transversely to the seed length. Some cells were arranged parallel to the seed length. Isodiametric cells, as characteristic of *L. lanceolata*, were uncommon.

(2) Pentaploid hybrids

Ludwigia alata × *L. glandulosa* subsp. *glandulosa*. These hybrids were similar to *L. alata* in habit, leaf shape, and in having winged capsules. Intermediate characters included capsule shape (elongate obpyramidal) and pollen grains shed singly and as tetrads. The seed surface in the hybrid consisted mainly of columnar cells elongate transversely to the seed length, as in *L. alata*, although the cells were much smaller and were sometimes more nearly isodiametric than on seeds of that species (Fig. 15). Columnar cells elongate parallel to the seed length and similar to those of *L. glandulosa* subsp. *glandulosa* were also observed.

Ludwigia alata × *L. lanceolata*. The parental species were themselves very similar in floral morphology and habit. The hybrids can be identified only by seed surface (Fig. 16), which consists of a mixture of columnar cells elongate transversely to the seed length, as in *L. alata*, and more or less isodiametric cells characteristic of *L. lanceolata*. Pollen grains were shed singly as in *L. alata*.

Ludwigia alata × *L. pilosa*. These hybrids were generally intermediate. They were neither glabrous as in *L. alata* nor hirsute as in *L. pilosa*, but were minutely villous all over. The capsules, like those of *L. alata*, were winged. Seed-surface cell pattern (Fig. 17) was similar to that of *L. alata* × *L. lanceolata*. Pollen grains were shed mostly as tetrads, although single grains were seen occasionally.

Ludwigia alata × *L. polycarpa*. With their winged capsules, the hybrids were more similar to *L. alata* in general appearance. They had the minutely strigillose leaf margins characteristic of *L. polycarpa*, however. Conspicuously intermediate characters include: sepal shape, seed surface

pattern in which columnar cells were randomly oriented (Figs. 18, 19), and pollen grains shed as loose tetrads.

Ludwigia alata × *L. sphaerocarpa*. These hybrids were similar to *L. alata* in habit and in having winged capsules. However, they shed pollen grains as loose tetrads, and their capsules were strigillose, both intermediate character states. Seed-surface cell pattern is not of diagnostic value here, as both parents were similar in this respect.

Ludwigia alata × *L. suffruticosa*. These hybrids generally resembled *L. alata*. The flowers were loosely arranged along the apices of the stems, and the capsules were winged and glabrous. The seed-surface cell pattern was intermediate between that of the two parents, being similar to that shown in Figure 16. The hybrids shed pollen grains singly, as did both parents.

In summary, artificial hybrids between members of the *L. pilosa* group were easily produced and were nearly always vigorous and floriferous. Morphologically, F_1 plants were more or less intermediate between the parents. The only character that exhibited some consistent degree of dominance is the winged capsules of *L. alata*. When tetraploid species with rounded capsules were crossed with *L. alata*, the resultant hybrids invariably had distinctly winged capsules. In contrast, when *L. lanceolata*, a tetraploid with winged capsules, was crossed with tetraploid species having rounded capsules, the F_1 individuals usually exhibited intermediate capsule shape—their capsules were 4-angled or at most slightly winged. Therefore, it seems that in hybrids involving *L. alata*, the apparent dominance of the winged-capsule character may be due to a multiple dose of genetic information received from this hexaploid.

The single most important diagnostic character for hybrids within the *Ludwigia pilosa* group is the shape and size of the capsules. Other diagnostic characters include overall pubescence, seed-surface pattern, and to some extent whether pollen grains are shed singly or as tetrads. This pollen character is of limited value, as most species in the *L. pilosa* group shed pollen as tetrads. When one of the taxa that do shed pollen singly was used as a parent, loose tetrads or a mixture of single and tetrad pollen grains were commonly found in the hybrids. This pattern was also clearly shown by the diploid hybrids *L. microcarpa* × *L. linearis* and *L. microcarpa* × *L. linifolia*. Similarly, hybrids between species that differ in their seed-surface pattern always showed a mixture of cell types or cells with intermediate shapes and/or of random orientation. Likewise, a hybrid resulting from crossing a hirtellous species with a glabrous species always showed minutely villous or strigillose pubescence. Examination of the above-mentioned diagnostic characters permits very accurate determination of the parentage involved in hybrids within the *L. pilosa* group.

HYBRIDS WITHIN THE *LUDWIGIA CURTISSII* COMPLEX

Two species, *L. curtissii* ($n = 32$) and *L. simpsonii* ($n = 24$), are included in this complex. Reciprocal hybridizations (Table 8) between them resulted in vigorous, floriferous F_1 individuals.

Meiotic analysis and pollen stainability

Meiosis was normal in both parental species. Diakinesis and metaphase I cells consistently revealed only bivalents. Multivalents were never observed despite the polyploidy of both parents. The two parents have pollen stainability of 97–100%.

Although reciprocal hybrids were made, meiosis was examined only in F_1s in which *L. curtissii* was the ovulate parent and *L. simpsonii* the pollen parent. Of the seven clear, analyzable cells, three were at diakinensis and four in metaphase I. They consistently showed a configuration of 24 bivalents and 8 univalents. Nearly all of the bivalents in the metaphase I cells were regularly rod-shaped, and were oriented on the equatorial plate. The eight univalents were scattered at random along a continuous bipolar spindle; some were probably lost at anaphase I and II, since micronuclei were observed in many sporads. In spite of the presence of scattered univalents, the hybrids produced 89% stainable pollen grains and a moderate number of viable seeds. Eleven F_2 plants grew up to flower. All of them branched profusely and set abundant fruits and seeds. The reciprocal F_1 hybrid, *L. simpsonii* × *L. curtissii*, had a similar value for stainable pollen (81%).

Morphology of the hybrids

Ludwigia curtissii and *L. simpsonii* are often difficult to distinguish; the only consistent diagnostic character available to separate them is the size of mature capsules. These of *L. simpsonii* are 1.5–2(–2.5) mm long, those of *L. curtissii* (2–) 2.5–4.5 mm long. Artificial hybrids between them had robust, erect stems up to 85 cm high and capsules about 2.5 mm long. Such plants are likely to be identified as *L. curtissii* in the field or the herbarium, although their capsule size is at the

lower limit for *L. curtissii*. The hybrid plants set plump capsules with moderate amounts of viable seed.

HYBRIDS BETWEEN THE DIPLOID GROUP AND THE *LUDWIGIA PILOSA* GROUP

Of the 42 hybrid combinations in which reciprocal crossing attempts have been made involving diploid taxa and members of the *L. pilosa* group (Fig. 5, Table 9), only three failed to result in seed set. These crosses involved the small-flowered *L. microcarpa* as pollen parent and one of the larger-flowered species as ovulate parent. Eight of the 39 successful crosses yielded offspring that did not germinate. Of these, 15 resulted in weak F_1 individuals that died soon after germination or remained sterile for the entire season. Only the remaining 15 hybrid combinations flowered successfully, but three of them were weak and died soon after anthesis. The 12 remaining combinations were vigorous and floriferous. Despite this, none of them set any seed. Their ovaries simply turned yellowish and dropped off or were somewhat persistent but shriveled after mechanical self-pollination.

The results of artificially hybridizing the different species of the above two groups ranged from seeds that were unable to germinate to vigorous and floriferous F_1 plants. A few general comments are appropriate here. First, the inability of hybrid seeds to germinate as observed in the present study is not necessarily a reliable indication of reproductive isolation. In some cases, seeds obtained from a particular cross did not germinate the first year, but additional seeds planted the following year did. Seed dormancy, however, is not characteristic of *Ludwigia*, at least of sect. *Microcarpium*. In a few rare cases, hybrid seeds were observed to germinate three or four months after they were sown. These would have been scored as germination failures if the experiments had been terminated after two months, as was generally done.

Second, on several occasions the majority of seeds failed to germinate or produced weak or stunted seedlings, although one or few vigorous and floriferous hybrid individuals grew to maturity. For example, only a single, healthy plant of *L. microcarpa* × *L. alata* was obtained from 18 seeds sown; none of the others germinated. Such failures to germinate are not mentioned in the above discussion, and records were not kept, because the seeds of *Ludwigia* species are very small, and usually 50–200 seeds were sown for each hybrid combination.

Third, weak or sterile hybrids could sometimes be brought to flower if they were grown very carefully or if alternative parental strains were utilized to vary the genetic composition of the hybrids (for examples see Table 9).

Meiotic analysis and pollen stainability

Cytological data are available for ten hybrid combinations. These include seven hybrids resulting from crosses between the tetraploid species and each of the three diploid species, including one reciprocal cross (Table 10), and three hybrids resulting from crosses between *L. alata* (hexaploid) and each of the three diploid species.

(1) Hybrids resulting from crosses between the diploid and tetraploid species

Crosses between diploids and tetraploids would normally be expected to form triploid hybrids. It is most interesting, therefore, that upon sowing 15 seeds resulting from crossing *L. linifolia* ($n = 8$) with *L. lanceolata* ($n = 16$), only 5 plants were obtained, all of which were tetraploid ($2n = 32$). That the diploid *L. linifolia* was used as the ovulate parent suggests that these $2n = 32$ plants were not simply the result of self-pollination in the tetraploid. This chromosome number was apparently produced by the union of an unreduced egg from the diploid *L. linifolia* with a normal sperm nucleus

TABLE 9. *Summary of crossing results between taxa of the diploid group and the* Ludwigia pilosa *group.*

L. linearis as female parent	
LIE b × ALA a	Seeds failed to germinate.
LIE a × LAN a	Plants weak, with reddish leaves, died soon after germination.
LIE a × PIL b	Seeds failed to germinate.
LIE b × POL c	Plants weak, barely flowered; no viable pollen.
LIE a × SPH c	F_1 hybrids vigorous and flowered (see Table 10).
LIE a × SUF b	Low germination percentage; weak plants died when ca. 4 cm high.
L. linearis as male parent	
ALA a × LIE a	F_1 hybrids vigorous and flowered (see Table 11).
BRA × LIE b	Formed a mat in 3-inch pots; remained sterile.
GLA a × LIE a	Plants sterile, about 10–30 cm high.
GLA a × LIE b	Plants sterile, about 5–30 cm high.
GLA a × LIE d	F_1 hybrids vigorous and flowered (see Table 10).
LAN a × LIE a	Died at cotyledon stage.
PIL b × LIE b	Formed 2–4 leaves and died.
POL c × LIE b	Seeds failed to germinate.
SPH c × LIE a	F_1 hybrids vigorous and flowered (see Table 10).
SUF c × LIE b	Some died in cotyledon stage; some produced a few pinkish leaves and soon withered.
L. linifolia as female parent	
LIF b × ALA a	Seeds failed to germinate.
LIF c × ALA b	Seeds failed to germinate.
LIF c × BRA	Cotyledons expanded a month after radicles had protruded; plants weak and died when ca. 1 cm high with 4–6 leaves.
LIF c × GLA c	Seeds failed to germinate.
LIF c × GLA b	Plants weak, mostly died 2–3 cm high; one plant barely flowered and showed 0% stainable pollen.
LIF b × LAN a	F_1 hybrids vigorous and flowered, but with an unexpected chromosome number of $2n = 32$ (see Table 10).
LIF c × PIL b	Very low germination percentage; 3 weak plants obtained, which died when ca. 1 cm high with about 10 leaves.
LIF b × POL c	Seeds failed to germinate.
LIF c × SPH c	Plants weak, sterile, about 5–7 cm high.
LIF b × SUF c	Five out of 20 seeds germinated; all very weak, died soon.
LIF c × SUF a	Numerous seeds germinated, but all died in 4–6-leaved stage.
L. linifolia as male parent	
ALA a × LIF c	F_1 hybrids vigorous and flowered (see Table 11).
BRA × LIF c	Plants remained small, died when ca. 2 cm high.
GLA b × LIF a	Plants weak, with reddish brown leaves, sterile.
LAN a × LIF b	Six out of 30 seeds germinated; all died in seedling stage.
PIL b × LIF b	F_1 hybrids vigorous and flowered (see Table 10).
PIL b × LIF c	Cotyledons reddish, soon withered.
POL c × LIF b	Died in cotyledon stage.
POL c × LIF c	Two weak plants barely flowered and soon died; 0% stainable pollen.
SPH c × LIF c	Plants with pinkish yellow leaves, 10–15 cm high, sterile.
SUF b × LIF b	Seeds failed to germinate.
L. microcarpa as female parent	
MIC a × ALA a	F_1 hybrids vigorous and flowered (see Table 11).
MIC a × GLA b	Plants healthy, flowered when 10–15 cm high.
MIC b × LAN a	Seeds failed to germinate.
MIC a × PIL b	Seeds failed to germinate.
MIC a × POL c	F_1 hybrids vigorous and flowered (see Table 10).
MIC c × SPH c	Plants flowered, but meiosis was not studied; 4% stainable pollen.
L. microcarpa as male parent	
ALA b × MIC a	Crosses failed to set seed.
GLA b × MIC a	F_1 plants healthy and flowered (see Table 10).
LAN b × MIC d	Plants recently grown; healthy, but have not yet flowered.
PIL c × MIC b	Crosses failed to set seed.
SPH a × MIC a	Very low germination rate; soon died.
SUF b × MIC a	Crosses failed to set seed.

[a] Hybrids with $2n = 32$, a number apparently produced by the union of an unreduced egg from the diploid (*L. linifolia*) with a normal sperm nucleus from the tetrapoloid (*L. lanceolata*).

from the tetraploid *L. lanceolata*. These plants are, following the terminology of Harlan & deWet (1975), Class I Polyploids. Diakinesis observed in one plant resulting from this cross clearly showed a configuration of 8II + 16I. Configurations at metaphase I, however, ranged from 6II + 20I to 8II + 16I, with two cells each exhibiting a single trivalent. The bivalents were apparently formed between chromosomes of the duplicated *L. linifolia* genome. This unexpected but significant finding suggests strongly that (a) chromosomes in the two genomes in the tetraploid *L. lanceolata* are not homologous and thus remained unpaired; and (b) the genome of *L. linifolia* does not pair with either of the genomes of the tetraploid species when true chromosome homologues are present.

The cytological behavior of all other hybrids generally followed a consistent pattern (Table 10). Although the number of bivalents formed was variable, it never exceeded eight, the haploid chromosome number of the diploid species. The number of bivalents ranged from three to seven in most hybrids, although values ranging from one to six were observed in *L. glandulosa* subsp. *glandulosa* × *L. microcarpa*. The configuration 8II + 8I was observed in only a single cell in *L. microcarpa* × *L. polycarpa*. However, in this metaphase I cell, two of the bivalents are in a somewhat perpendicular orientation to the other six bivalents and appear to be attached univalents. A single trivalent was seen in three of the 33 cells examined of the reciprocal hybrids between *L. linearis* and *L. sphaerocarpa*. One to three heteromorphic bivalents, in which the two chromosomes differed in shape or size, were observed on occasion. Attenuated bivalents and precociously separated bivalents were also seen in some cells. Pseudoassociation resulting from stickiness between two univalents, two bivalents, or one of each, was also observed in a few cases.

It is observed that the two to seven chromosome pairs observed in these diploid × tetraploid hybrids indicate that the diploid genome is homologous with only one of the tetraploid genomes.

The cytological abnormalities and the high proportion of univalents observed in these hybrids are reflected in the low pollen stainability. Six of the seven hybrids had less than 2% stainable pollen; only *L. microcarpa* × *L. polycarpa* had greater than 10% stainable pollen (Table 10), presumably due to chance events. In *L. microcarpa* × *L. polycarpa*, the pollen was shed as single grains and as tetrads, a combination of the characters seen in the two parental taxa. Most stainable pollen, however, was shed as single grains, an observation which cannot be explained at present.

(2) Hybrids resulting from crosses between the diploid and hexaploid species

All hybrids involving diploid and hexaploid taxa were made (Table 11). When *L. alata* was crossed to *L. linearis* and *L. linifolia*, the resulting hybrids typically exhibited a configuration of (1–2)III +

TABLE 11. *Meiotic configurations and pollen stainability in three hybrids resulting from crosses between the diploid and hexaploid species of* Ludwigia *sect.* Microcarpium.

Hybrid Combination	Modal Meiotic Configuration Observed	Number of Cells with Modal Configuration/ Total Number of Cells Examined	Pollen Stainability (%)
ALA b × LIE a	(1–2)III + (4–6)II + (21–16)I	7/12	1
ALA b × LIF c	1III + 6II + 17I	1/6	0
MIC a × ALA b	1IV + (7–10)II + (14–8)I	5/14	15

(4–6)II + (21–16)I in both diakinesis and metaphase I, although a configuration of 8II + 16I was occasionally seen. There is no unequivocal evidence to indicate whether the trivalents represent intergenomic homology in the hexaploid *L. alata* or associations between chromosomes of *L. alata* and those of *L. linearis* or *L. linifolia*. In metaphase I of many cells, one to three bivalents appeared to be attached univalents and were often observed away from the equatorial plate. Other cytological aberrations, including heteromorphic bivalents and elongate, attenuated bivalents, were very common. Normal rod or ring bivalents were infrequent.

In *L. microcarpa* × *L. alata* the modal meiotic configuration was 1IV + (7–10)II + (14–8)I, with maximum pairing of either 1IV + 10II + 8I or 11II + 10I. In the latter case, the quadrivalent was not seen, as it probably separated into two bivalents because of a lack of sufficient chiasmata to hold them together. Rings or chains of four chromosomes were more commonly seen in diakinesis than in metphase I. Trivalents were not noted. It is uncertain whether the quadrivalent indicated that, in addition to the difference in ploidy level, the two species differ by a reciprocal translocation, as the multivalent can also result from associations of one chromosome from *L. microcarpa* and three chromosomes each from one of the three genomes of *L. alata*.

The bivalents observed in the meiotic first metaphase of *L. microcarpa* × *L. alata* were typically normal, being ring- or rod-shaped. Attenuated bivalents were very seldom found. Heteromorphic bivalents or attached univalents were not observed. The reduced occurrence of cytological aberrations and the higher number of chromosome pairings in these hybrids probably account for their higher

pollen stainability (15%) than was observed in *L. alata* × *L. linearis* and the reciprocal hybrids of *L. alata* × *L. linifolia* (0–1%).

Morphology of the hybrids

In diploid species of sect. *Microcarpium*, the presence of petals appears to be dominant over the apetalous condition, judged from the consistent presence of petals in the petalous × apetalous hybrids. It is therefore of interest to examine this character in hybrids resulting from crosses between the petalous diploids and the apetalous polyploids. It was observed that all hybrids between diploids and tetraploids exhibited a variable number (0–4) of vestigial petals on different flowers of the same plant, whereas all hybrids between the diploids and hexaploids lacked petals completely.

When two of the diploid species *L. linearis* or *L. linifolia* were crossed to the tetraploid taxa, the resulting hybrids were somewhat intermediate in overall pubescence, leaf shape, capsule shape and size, sepal shape and size, and bracteole length. However, when *L. microcarpa*, the third diploid, was crossed with tetraploids, the F_1 hybrids were generally similar to their tetraploid parent in aspect but were diminutive in height and in leaf and flower size.

When all three of these diploids were each crossed to the hexaploid, *L. alata*, the resultant F_1 hybrids were more similar to *L. alata*, particularly in exhibiting its characteristic winged capsules. The hybrids *L. alata* × *L. linearis* and *L. alata* × *L. linifolia* resembled each other in their slightly narrower and longer capsules as compared with those of *L. alata*. Neverthelesss, *L. alata* × *L. linearis* had sparsely strigillose capsules, short sepals, and bracteoles shorter than the ovary, whereas *L. alata* × *L. linifolia* was completely glabrous, had elongate acuminate sepals, and had bracteoles longer than the ovary.

Hybrids between *L. microcarpa* and *L. alata* had small leaves and flowers, but were at least as robust and tall as *L. alata*. This is in sharp contrast to the situation in hybrids resulting from crosses between *L. microcarpa* and the tetraploid taxa (see above).

When diploid species (with pollen shed as tetrads) were crossed to hexaploid species (with pollen grains single), the resulting hybrids had single pollen grains only. Hybrids resulting from crosses between diploid species having single grains and tetraploid species having tetrad pollen showed a mixture of tetrad and single pollen in mature anthers. Crosses between diploids and tetraploids that both shed pollen as tetrads yielded hybrids that also produce tetrads. In the hybrid *L. linifolia* × *L. lanceolata*, however, where unreduced gametes of the diploid *L. linifolia* united with normal pollen of the tetraploid *L. lanceolata* to produce tetraploid hybrids, the pollen grains were shed mixed as tetrads and single grains. This result was not expected. In this hybrid, the morphology was intermediate between *L. linifolia* and *L. lanceolata*.

HYBRIDS BETWEEN THE DIPLOID GROUP AND THE *LUDWIGIA CURTISSII* COMPLEX

A summary of the crossing results is shown in Table 12. Some of these data are supplemented by study of natural hybrid populations, as is discussed below.

Meiotic analysis and pollen stainability

Six hybrid combinations were examined to determine percentage of stainable pollen. Two of these were also studied cytologically (Table 13).

TABLE 14. *Summary of crossing results between members of the* L. curtissii *complex and the* L. pilosa *group.*

GLA b × SIM a	Plants vigorous and floriferous.
LAN a × SIM a	Plants with reddish leaves and much branched below; flowered recently.
TOR × SIM b	Seeds failed to germinate.

Of the 31 analyzable cells in *L. curtissii* ($n = 32$) × *L. linifolia* ($n = 8$), 22 formed strictly bivalents and univalents, ranging from (8–12)II + (24–16)I, with a modal configuration of 8II + 24I; nine cells formed multivalents, in which four cells had a configuration of 1III + (6–9)II + (25–19)I, and five cells showed 1IV + (6–9)II + (22–18)I. An exceptional cell with only 5II + 30I was also observed. In some cells chromosomes were so sticky that cytological analysis was impossible.

In *L. curtissii* × *L. microcarpa* ($n = 8$), only five analyzable cells were studied, the results being (14–15)II + (12–10)I. One or two sticky or precociously disjunct bivalents were noted in two cells.

Pollen stainability in all hybrids examined was very low, ranging 0–10% (Table 13). Despite this problem, a single F_2 individual of *L. curtissii* × *L. linifolia* was raised and another was raised from *L. curtissii* × *L. microcarpa*. The former remained sterile and died, whereas the latter died shortly after anthesis; it had 17% stainable pollen.

Morphology of the hybrids

Reciprocal hybrids of *L. curtissii* × *L. linearis* ($n = 8$) resemble each other. They are erect and branched on the upper stems. The tallest individual reached a height of 65 cm. The plants were extremely similar to *L. curtissii* in aspect, and before anthesis were thought to be selfed progeny of *L. curtissii*. In fact, even their flowers resembled those of *L. curtissii* except that their ovaries were slightly narrower and four-angled and their bracteoles were slightly shorter. Most flowers were apetalous; in a few cases one or two vestigial petals were present. After anthesis, the ovaries turned yellow and fell off. Pollen was shed as loose tetrads and single grains.

Hybrids between *Ludwigia simpsonii* ($n = 24$) and *L. linearis* could not be distinguished from *L. curtissii* × *L. linearis*.

Plants of *L. curtissii* × *L. linifolia* exhibited more morphological intermediacy than those of *L. curtissii* × *L. linearis*, although both resulted from hybridization between an octoploid and a diploid. Plants of *L. curtissii* × *L. linifolia* were smaller than either parent (about 25–30 cm high), much branched, and very floriferous (resembling *L. linifolia*). The flowers commonly had one to four petals (intermediate) and were congested at ends of branches (uncommon in both parents). The leaves were generally similar to those of *L. curtissii* in shape but were slightly smaller. The ovaries were about as long as those of *L. curtissii*, but were not accrescent and were narrower and four-angled. Sepals were intermediate in shape and size. Pollen was shed mostly as tetrads, and with some single grains as well. These hybrids did not usually set

TABLE 15. *Meiotic configurations and pollen stainability in hybrids resulting from crosses between members of the* L. curtissii *complex and the* L. pilosa *group.*

Hybrid Combination	Modal Meiotic Configuration Observed	Number of Cells with Modal Configuration/Total Number of Cells Examined	Pollen Stainability (%)

seed, although one or two viable seeds were occasionally obtained.

Plants of *L. curtissii* × *L. microcarpa* were very vigorous and floriferous, up to 80 cm high, and much branched. The leaves were similar to those of *L. curtissii*, but smaller. Similarly, all floral parts were reduced and somewhat resembled those of *L. microcarpa*. In the hybrid, however, the nectary discs were always distinctly raised, unlike those of *L. microcarpa*, in which they were nearly flat. The ovaries usually shriveled after anthesis, although in exceptional cases one to three seeds were produced.

Plants of *L. microcarpa* × *L. simpsonii* were also very vigorous. Their floral parts were similar to those of *L. curtissii* × *L. microcarpa*, and their flowers were sterile. These hybrids were smaller (up to 50 cm high) and had slightly broader leaves. As plant height and leaf shape are somewhat variable characters, it is difficult to distinguish between these two hybrids when they occur together in nature.

HYBRIDS BETWEEN THE *LUDWIGIA CURTISSII* COMPLEX AND THE *L. PILOSA* GROUP

As with crosses between the diploid group and the *L. pilosa* group, these crossing results were quite variable, ranging from total failure to germinate to vigorous and floriferous F_1 hybrids (Table 14). None of these F_1 plants were observed to set any seed, however, while most of the hybrids resulted from crosses between the *L. curtisssii* complex and the *L. pilosa* group set at least a few viable seeds. An F_2 family of 12 vigorous plants of *L. simpsonii* × *L. alata* was established.

Meiotic analysis and pollen stainability

In hybrids with *L. simpsonii* as one of the parents, meiosis was studied only in *L. lanceolata* × *L. simpsonii* (Table 15). Only three metaphase I cells were obtained, which had three to five bivalents, most of which were chromosomes connected by a chromatin thread and were aligned randomly. A trivalent was seen in one of the cells.

In hybrids with *L. curtissii* as the male parent, *L. polycarpa* × *L. curtissii* had sticky chromosomes, which rendered study of meiosis difficult.

Four other hybrid combinations were studied cytologically. In *L. curtissii* × *L. polycarpa*, only one first metaphase cell was analyzable; it showed a configuration of 1III + 4II + 37I with two attenuated bivalents in the equatorial plate.

The other three hybrids resulting from crossing *L. curtissii* and the tetraploid species showed significantly higher chromosome associations. A maximum of 13 bivalents were seen in at least some of the cells, and one tetravalent and a maximum of three trivalents were observed in others (Table 15). The meiotic metaphase figures of these hybrids generally consisted of bivalents or multivalents aligned in the equatorial plate with many univalents scattered throughout the cell. The following cytological aberrations were occasionally observed: attenuated bivalents, precociously separated bivalents, attached univalents, and sticky chromosomes.

The pollen stainability was, surprisingly, higher in *Ludwigia curtisii* × *L. polycarpa* (32%), which showed the least chromosome associations, and in *L. polycarpa* × *L. curtissii* (25%), which had stickier chromosomes than in other hybrids known to have higher levels of chromosome pairing. Since in *L. curtissii* × *L. polycarpa* only one meiotic cell was studied, the observed configuration possibly could represent the lower limit of chromosome association in this hybrid. Variability of chromosome pairing is a common phenomenon in species hybrids. The stickiness of meiotic chromosomes of *L. polycarpa* × *L. curtissii*, however, may have a genetic basis, as it was rarely shown by either of the parental species, or the stickiness might be attributable to environmental factors. My unpublished study of meiosis in a sterile natural hybrid between *L. spathulata* and *L. palustris* (both sect. *Dantia*) was not successful in 1979 due to pronounced chromosome stickiness. Nevertheless, very clear chromosomal configurations for the same clone were obtained the next year.

In spite of the prevalence of univalents in meiosis, these hybrids usually set at least a few seeds. They were quite unlike the hybrids between the *L. curtissii* complex and the diploid group, which were completely sterile. This difference is probably attributable to the fact that, when both parents are polyploids, the development of functional pollen and ovules is better able to withstand the random segregation or loss of some chromosomes (as lagging univalents) in meiosis because of genetic redundancy.

Morphology of the hybrids

The hybrids were generally intermediate morphologically. The leaves were characteristically oblanceolate or narrowly oblanceolate. The intermediate nature of the size, shape, and pubesence of the capsules could be diagnostic, although the winged capsules characteristic of *L. alata* and *L. lanceolata* were not taxonomically useful, as the capsules of all the hybrids shriveled to some extent and thus appeared winged. The differences between hybrids with *L. curtissii* and with *L. simpsonii* as one parent were strictly quantitative, with the latter being slightly smaller in their floral features and occasionally in height also. These differences were obvious only when the two hybrids were brought together and compared. When *L. curtissii* and *L. simpsonii*, both of which shed pollen singly, were crossed with species in the *L. pilosa* group, which shed pollen as tetrads, the resultant hybrids consistently produced a mixture of pollen in loose tetrads and single grains.

ECOLOGY AND GEOGRAPHICAL DISTRIBUTION

With the exceptions of *L. stricta*, which is endemic to Cuba, and *L. polycarpa*, which is distributed mainly in the north-central United States, sect. *Microcarpium* is confined primarily to the Coastal Plain of the United States (Fig. 20). The detailed geographical distribution of each taxon in *Ludwigia* sect. *Microcarpium* is presented in a companion taxonomic paper (Peng, in press).

The Coastal Plain is defined geologically as the flat area between the Atlantic and Gulf coasts and the Piedmont, and extending from the Gulf of Mexico to southern New England (Peattie, 1922). The soils of this area are chiefly gray sands and sandy loams, except in the swamps where the prevailing sands are covered by muck or peat (Cooke, 1925). On the Coastal Plain, especially in areas close to the coast, the water table is seldom very far below the surface, and many areas are periodically or permanently flooded (Gleason & Cronquist, 1964). At one end of the Coastal Plain, in southern Texas, the climate is semiarid and the soils are alkaline, containing a high proportion of clay (Hunt, 1974).

In addition to this general distribution of species of sect. *Microcarpium* in North America, several species extend further south. *Ludwigia alata* occurs in Jamaica, *L. simpsonii* in Cuba and Jamaica, and *L. curtissii* in the Bahamas. *L. linifolia* is disjunct to Tabasco, in the Yucatán Peninsula of Mexico, and *L. microcarpa* ranges to the Bahamas, Cuba, and Jamaica. *Ludwigia stricta*, endemic to Cuba, is the only species of the section that does not occur in the United States.

Like *Ludwigia* species occurring in other parts of the world, plants of sect. *Microcarpium* grow in at least seasonally wet habitats. They are commonly found along alluvial ground or in the shallow water of many areas, including ponds, lakes, rivers, streams, lagoons, sloughs, backwaters, swales, wet meadows or prairies, open swamp forests, drainages, and irrigation ditches. All species grow in sandy or occasionally peaty soils.

SYMPATRIC OCCURRENCE AND NATURAL HYBRIDIZATION

The results of experimental hybridizations reveal that vigorous and floriferous hybrid individuals can

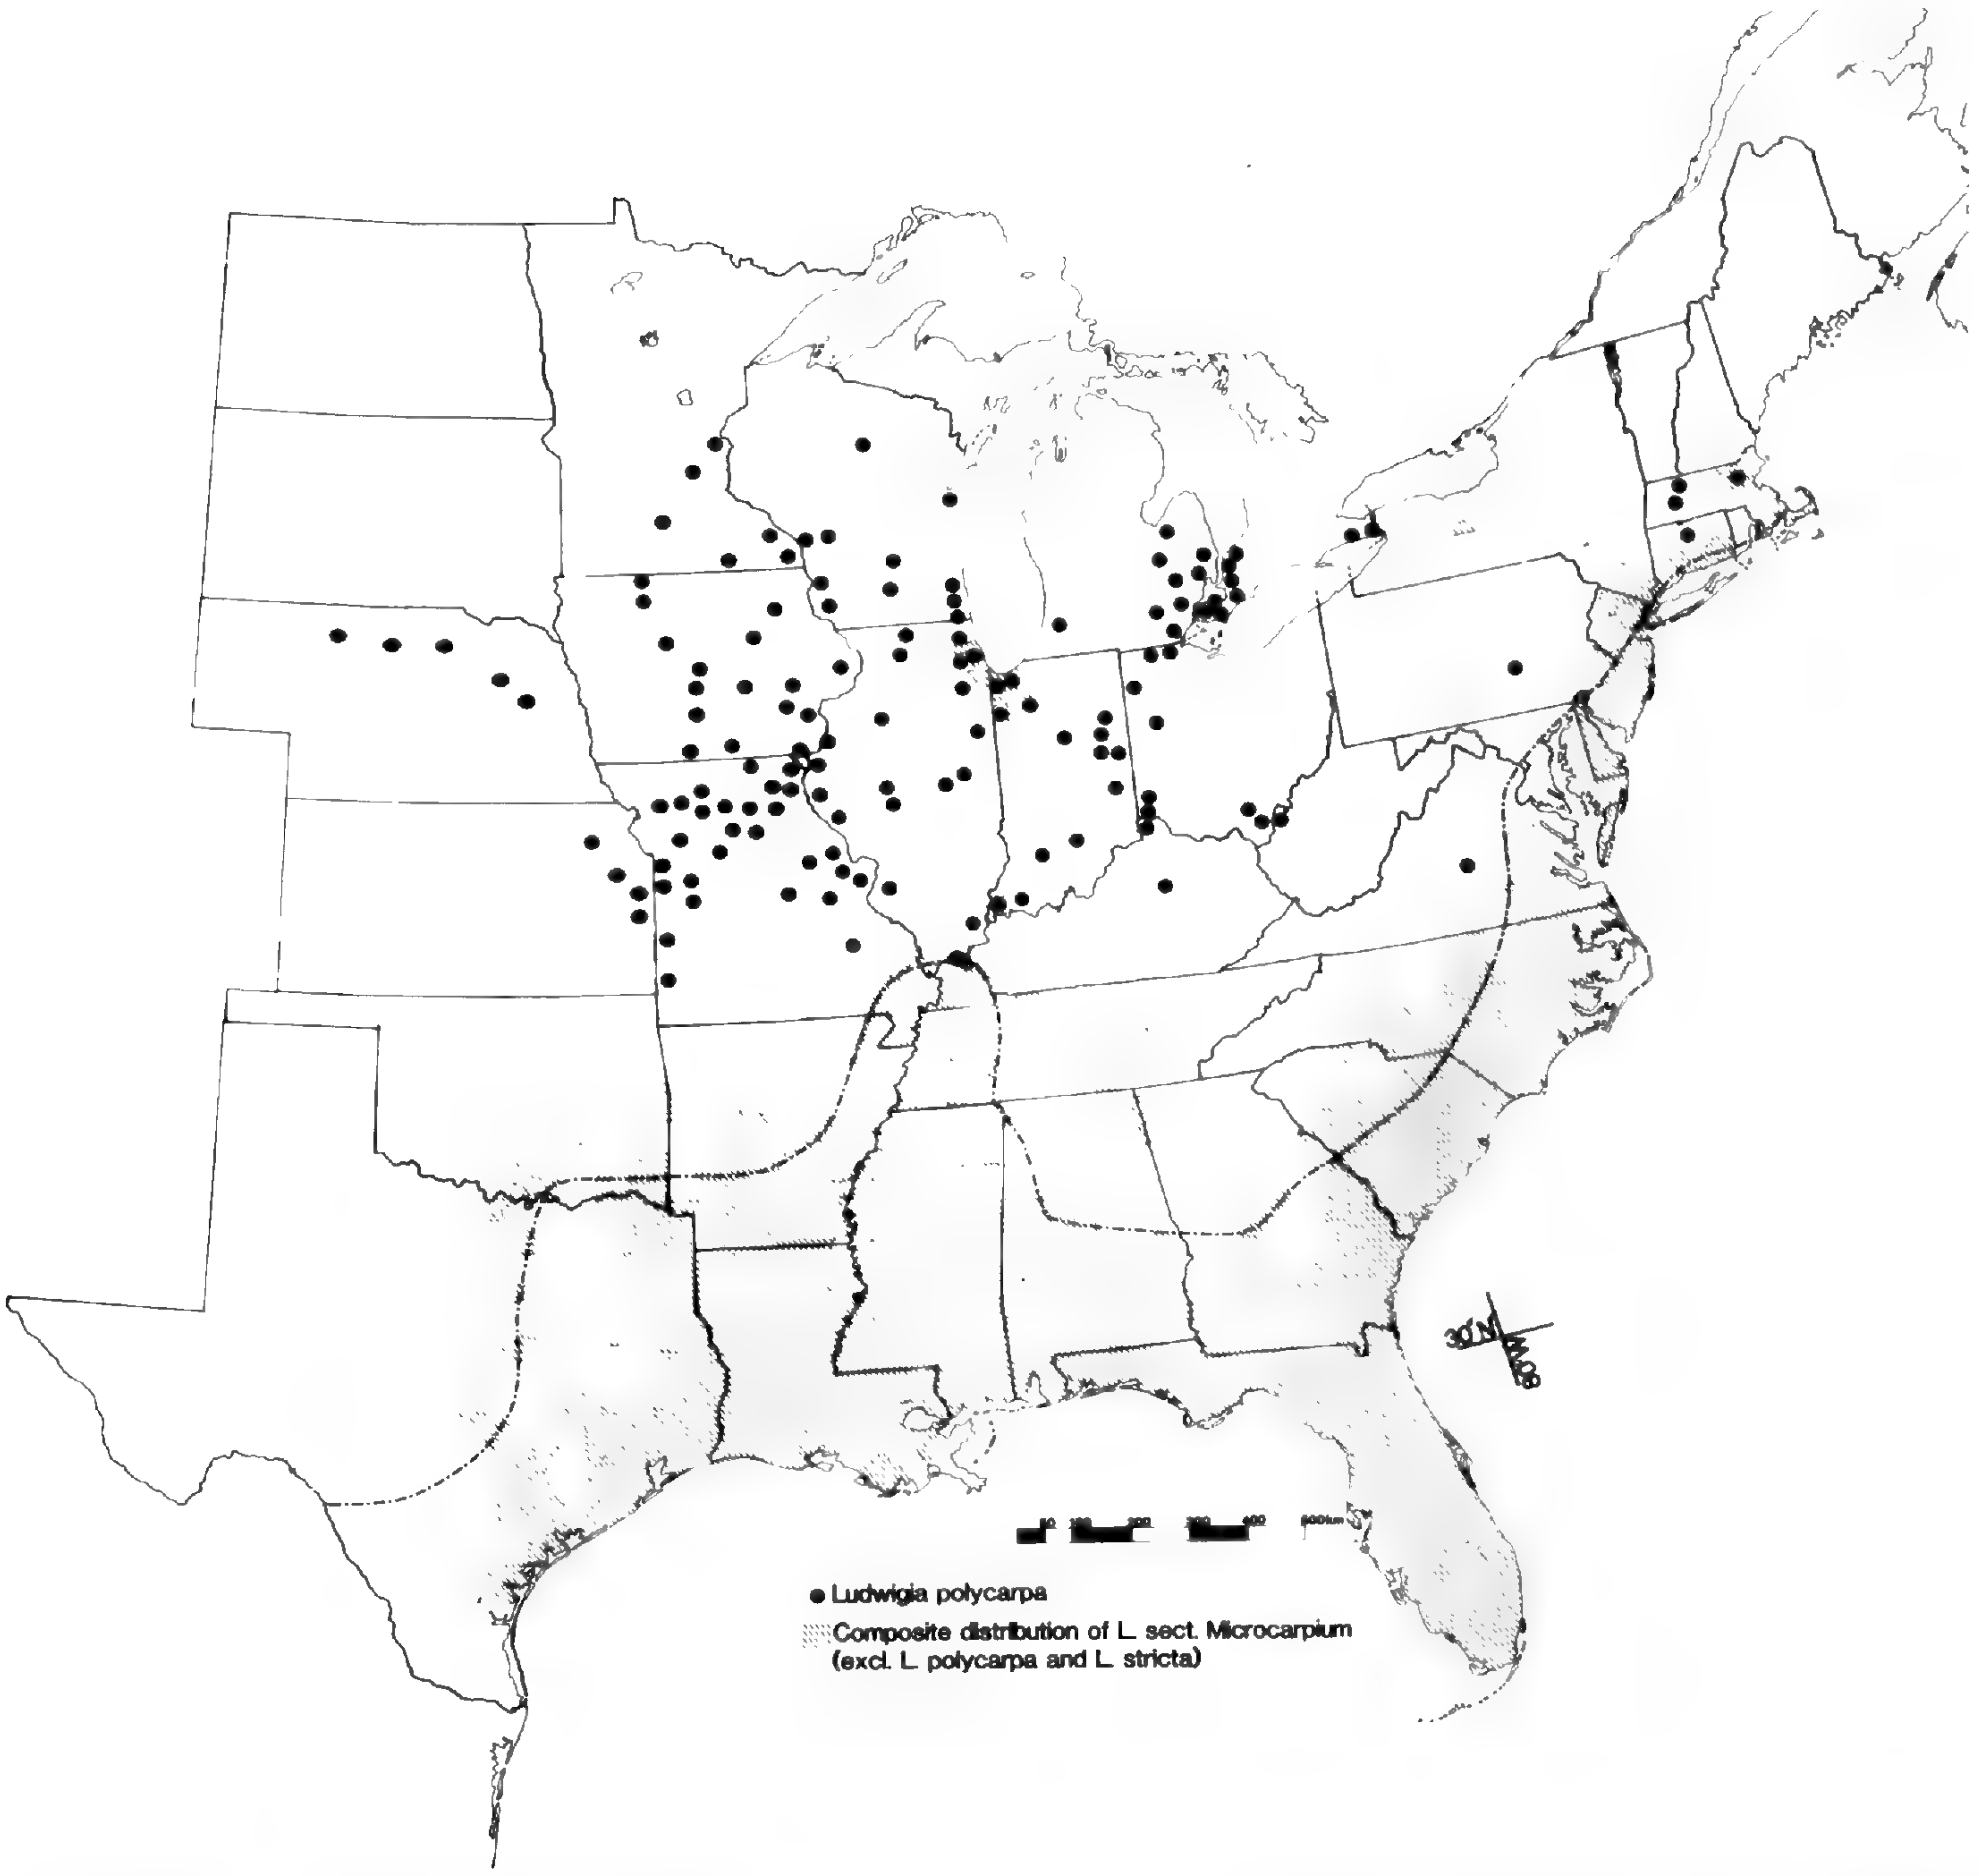

FIGURE 20. Distribution of *Ludwigia* sect. *Microcarpium* in North America, with shading to indicate the combined distribution of all species of this section except *L. polycarpa* and *L. stricta*. Distribution of *L. polycarpa* is indicated by dots; *L. stricta* is endemic to Cuba. Boundary of the Coastal Plain in the United States is marked by dashed line. Other occurrences of several species in the Bahamas, Cuba, Jamaica, and Mexico, and a disjunct population of *L. polycarpa* in Kootenai Co., Idaho, are not mapped.

readily be obtained between most members of sect. *Microcarpium*. Exceptions involved some crosses between members of the *L. pilosa* group (the tetraploid taxa plus the hexaploid *L. alata*) and either the diploid species (*L. linearis*, *L. linifolia*, and *L. microcarpa*) or members of the *L. curtissii* complex (*L. curtissii* and *L. simpsonii*) (Fig. 5). These crosses resulted in seeds that failed to germinate or in inviable hybrids. Even in these instances, if alternative parental strains were utilized to vary the genetic composition of the hybrids, vigorous F_1 individuals could sometimes be obtained. The general lack of postzygotic barriers, in conjunction with the facts that most *Ludwigia* species have overlapping geographic ranges, similar habitat requirements, and similar flowering periods (during the summer), and that they are at least facultatively outcrossing, favor natural hybridization.

Field observations and examination of herbarium specimens suggest that natural interspecific hybridization involving species of sect. *Microcarpium* occurs frequently. Intersectional hybridization is also quite common; at least seven hybrid combinations bridging sect. *Microcarpium* and sect. *Dantia* have been observed.

Observation of individuals exhibiting a combination of characters intermediate between distinct taxa initially suggests the possibility of natural hybridization. However, the members of two species

pairs, *L. alata* (*n* = 24)/*L. lanceolata* (*n* = 16) and *L. curtissii* (*n* = 32)/*L. simpsonii* (*n* = 24), are usually so similar in appearance (especially as herbarium specimens) that their hybrids cannot be recognized readily.

As indicated earlier, capsule shape and size are the most important characters for detecting hybrids in sect. *Microcarpium*. Other useful features include overall pubescence, seed-surface cell shape and orientation, presence or absence of petals, whether pollen grains are shed singly or in tetrads, and pollen stainability. Seed-surface pattern is useful only for hybrids within the tetraploid group (including *L. alata*), as these nine taxa are interfertile, yield abundant seeds, and are diverse with respect to this character. Absence of developing fruits and low levels of pollen stainability are characteristic of hybrids resulting from all other interploid crosses, with the exception of *L. curtissii* (*n* = 32) × *L. simpsonii* (*n* = 24). Chromosome number and meiotic chromosome behavior are useful indicators of natural hybrids when the parents involved have different chromosome numbers or differentiated genomes.

Field experience indicates that the occurrence of natural hybrid populations is fairly common wherever two or more species grow together. Hybrids resulting from crosses between members of the *Ludwigia pilosa* group are very common. Also, many hybrid combinations have been observed involving the following species: *L. microcarpa*, *L. curtissii*, *L. simpsonii*, *L. palustris* (*n* = 8; sect. *Dantia*), and *L. repens* (*n* = 24; sect. *Dantia*).

Anderson (1948) suggested that disturbed habitats often afford conditions suitable for establishment of natural hybrids. This does not seem to be the case for *Ludwigia* hybrids, since the parental species themselves nearly always grow with the hybrids. Figure 21 illustrates the sympatric occurrence and known cases of hybridization in nature for all taxa of sect. *Microcarpium* except the Cuban endemic *L. stricta*. Sympatry was determined primarily from personal observation (in 1979, 1980, 1982) and supplemented by field notes of Peter H. Raven and from mixed herbarium collections. Voucher information for the suspected natural hybrids is presented below with comments when appropriate. Chromosome numbers of the parents are indicated in parentheses after their names. The sequence of epithets in each formula is alphabetical.

HYBRIDS INVOLVING MEMBERS OF *LUDWIGIA* SECT. *MICROCARPIUM*

Ludwigia alata (*n* = 24) × **L. pilosa** (*n* = 16). U.S.A. FLORIDA: Franklin Co., 38.8 mi. W of jct. US 98 and US 319, *Peng 4346* (MO). Wakulla Co., 5 mi. S of Sopchoppy on US 319, *Lazor 4984* (FSU, VDB); 1 mi. S of Sopchoppy on US 319, *Morar 29* (FLAS, GH, MSU, USF). Walton Co., Freeport, *Godfrey 57653* (FSU). GEORGIA: Charlton Co., of Folkston, Okefenokee Swamp, Camp Cornelia, *Jones 22996* (GA). MISSISSIPPI: Hancock Co., along Jordan River S of Kiln, *Jones 9539* (MISS).

Notes. *Peng 4346* from Franklin Co., Florida, was found in a very wide roadside drainage ditch (ca. 10–15 m across) at the edge of a pine forest. Hybrids were very abundant and mixed with a large population of *L. alata* and a few individuals of *L. pilosa*. Large populations of *L. linifolia* and *L. microcarpa* were also present. This hybrid exhibited meiotic configurations of 15–16 bivalents and 10–8 univalents. It had 84% stainable pollen.

Ludwigia alata (*n* = 24) × **L. suffruticosa** (*n* = 16). U.S.A. FLORIDA: Hillsborough Co., on E side of FL 581, 2.8 mi. N of FL 582, *Peng 4329* (MO). Lake Co., Tavares, *Biltmore Herbarium 4170*[d] (DS); vicinity of Eustis, *Hitchcock in 1894* (F), *Nash 1154* (NY); 5 mi. SE of Lebanon Station, *Kral 7807* (GA, GH, NCU, US, USF). Taylor Co., N edge of US 27 at Fenholloway River Bridge, *Nelson 667* (USCH); ca. 20 mi. NW of Cross City, *Godfrey & Houk 60296* (FSU, MSU, NCU, SMU).

Notes. More or less congested infloresence and winged capsules are characteristic of this hybrid combination. The hybrids were often identified as *L. alata* when they had lax inflorescences. In these cases, however, reduced levels of stainable pollen and intermediate seed surface cell pattern were useful in revealing the hybrids. *Peng 4329* showed a meiotic configuration of 15 bivalents and 10 univalents.

Ludwigia curtissii (*n* = 32) × **L. linifolia** (*n* = 8). U.S.A. FLORIDA: Monroe Co., Pine Crest, *Moldenke 856*[a] (MO, NY). Pasco Co., 1 mi. E of Gowers Corner off US 41, *Ray et al. 9932* (USF).

Notes. This hybrid is very similar to *L. curtissii* in aspect, but its pollen is not stainable, and its ovaries abort. One putative parent, *L. linifolia* (*Ray et al. 9934*, USF), was collected at the same locality as the hybrid (*Ray et al. 9932*).

Ludwigia curtissii (*n* = 32) × **L. microcarpa** (*n* = 8). U.S.A. FLORIDA: Martin Co., 4.3 mi. E of Okeechobee and Martin Co. line, on FL 710, at Brady Ranch, *Peng 4202* (MO).

Notes. The hybrid population was found in a wide swampy depression between the highway and a railroad, growing with both putative parents. The hybrid had a single analyzable metaphase I cell which showed 8 bivalents and 24 univalents. Pollen stainability was 16%.

Ludwigia glandulosa subsp. **glandulosa** (*n* = 16) × **L. pilosa** (*n* = 16). U.S.A. ALABAMA: Covington Co., along Co. Rd. 42, 15 mi. E of Brooklyn, *Kral 40992* (FLAS, GH, MO, NCU, NY, US, USF, VDB). GEORGIA: Grady Co., 13 air mi. SW of Cairo, 5 air mi. NE of Concord, Florida, with *L. pilosa*, *Anderson 4044* (MO, FSU). MISSISSIPPI: Jackson Co., Ocean Springs, *Demaree 32174* (RSA, SMU); on MS 90, 2 mi. W of US 10 and MS 90, with *L. pilosa*, *Peng 4354-A* (MO). NORTH CAROLINA: Hyde Co., 1.1 mi. N of Scranton Creek on US 264, with both putative parents, *Duke 54-232B* (NCU); 1.2 mi. N of Scranton Creek on US 264, with both putative parents, *Duke 54-276*, *54-277*, and *54-278* (NCU).

Ludwigia glandulosa subsp. **glandulosa** (n = 16) × **L. linearis** (n = 8). U.S.A. GEORGIA: Long Co., 4.2 mi. SW of jct. of US 301 and 25, and GA 99, on US 301 and 25, *Peng 4118* (MO). NORTH CAROLINA: Craven Co., 0.8 mi. N of US 17 on Co. Rd. 1224 (road to Tuscarora), *Boufford et al. 21443* (MO), *Peng 3740* (MO).

Notes. Both hybrid populations were found along with the putative parents. *Peng 3740* from Craven Co., North Carolina, was found in a wet drainage ditch about 60–80 cm wide. The population consisted of ca. 15–20 floriferous individuals, some of which were even more robust than the putative parents, which grew next to and on either side of the hybrid population. The modal meiotic configuration of this hybrid was 3–5 bivalents and 18–14 univalents. Heteromorphic pairs were sometimes observed. A trivalent was seen in one of the 26 cells studied. The pollen stainability was 2%. *Peng 4118*, from Long Co., Georgia, consisted of a few scattered individuals. The putative parents were growing nearby on a grassy roadside shoulder.

Ludwigia glandulosa subsp. **glandulosa** (n = 16) × *L. sphaerocarpa* (n = 16). U.S.A. MISSOURI: Butler Co., swamps, *Eggert in 1893* (MO). SOUTH CAROLINA: Clarendon Co., near shore of Lake Marion, ca. 4.5 mi. SW of St. Paul off US 15, *Bradley & Sears 3561* (BOON, East Carolina Univ., NCU, WCUH).

Notes. Bradley & Sears 3561 is a mixed collection; all four specimens contain a mixture of hybrids and individuals of *L. glandulosa* subsp. *glandulosa*. Although evident hybrids between *L. glandulosa* subsp. *glandulosa* and *L. sphaerocarpa* were found in Butler Co., Missouri, specimens of *L. sphaerocarpa* have not yet been collected from that state.

Ludwigia lanceolata (n = 16) × **L. pilosa** (n = 16) [*Ludwigia* ×*simulata* Small]. U.S.A. FLORIDA: Franklin Co., Apalachicola, *Chapman s.n.* (F, US). Highlands Co., Bear Point, Lake Childs, *Brass 15532* (GH, US). West Florida, *Biltmore Herbarium* (NY, holotype of *Ludwigia* ×*simulata* Small).

Notes. The holotype of *L.* ×*simulata* is characterized by being densely strigillose throughout and having four-angled or slightly winged capsules, isodiametric seed-surface cells, and pollen shed in tight tetrads. Such a combination of characters clearly suggests *L. lanceolata* (which is glabrous, has winged capsules, isodiametric seed surface cells, and pollen shed in tetrads) and *L. pilosa* (which is densely hirsute, has rounded capsules, isodiametric seed-surface cells, and pollen shed in tetrads) as putative parents. Furthermore, *L.* ×*simulata* is comparable to the experimental hybrids obtained from reciprocal crosses between those species.

Ludwigia lanceolata (n = 16) × **L. suffruticosa** (n = 16). U.S.A. FLORIDA: Charlton Co., Okefenokee Swamp, *Harper 1483* (GH, MO, NCU, NY, US). Hillsborough Co., 1.5–1.7 mi. S of FL 674, on E side of Taylor Gill Dr., *Peng 4324, 4328* (MO).

Notes. Both putative parents as well as *L. linearis* were present in the same drainage ditch where *Peng 4324* and *Peng 4328* were collected. *Peng 4324* showed 16 bivalents in diakinesis and metaphase I cells. One precociously separating bivalent was occasionally observed. *Peng 4324* had 85% stainable pollen.

Ludwigia linearis (n = 8) × **L. linifolia** (n = 8). U.S.A. FLORIDA: Palm Beach Co., along the S side of Co. Rd. 74, 1.5 mi. W of the Turnpike, Palm Beach Gardens, *Popenoe 1957* (MO).

Notes. This plant is only 25–30 cm tall and has crowded leaves. It showed features somewhat intermediate between those of *L. linearis* and those of *L. linifolia* in its flowers and capsules. The pollen was shed as tetrads, many of which are unstainable. This plant probably is a hybrid between *L. linearis* and *L. linifolia*, although the experimental hybrids obtained between these taxa have been more robust.

Ludwigia linearis (n = 8) × **L. sphaerocarpa** (n = 16). U.S.A. ALABAMA: Covington Co., Conecuh National Forest, SW Andalusia, *Kral 44732* (ENCB, SMU, VDB).

Notes. The plants are very vigorous and floriferous. One to four vestigial petals are present in most flowers. Seed set is very low or possibly nonexistent.

Ludwigia microcarpa (n = 8) × **L. simpsonii** (n = 24). U.S.A. FLORIDA: Charlotte Co., Punta Gorda City, on US 41, ca. 1 mi. S of jct. of US 17 and 41, *Peng 4297* (MO). Clay Co., 5 mi. W of Penny Farms on FL 16, *Peng 4160* (MO). Collier Co., 4.8 mi. W of Monroe Station, on N side of US 41, *Peng 4263* (MO).

Sumter Co., Cedar Hammock, 1894, *Lewton s.n.* (NY).

Notes. *Peng 4297* from Charlotte Co., Florida, was found intermixed with both parents. Also occurring here were *L. microcarpa*, *L. repens* (sect. *Dantia*), and the intersectional hybrid between them. Of the nine meiotic metaphase I cells examined from *Peng 4297*, seven showed 8 bivalents and 16 univalents, and two showed 9 bivalents and 14 univalents. In the latter, one of the bivalents separated precociously. Pollen stainability was 4%. *Peng 4160*, from Clay Co., Florida, was collected from a large population located in a waterlogged roadside ditch along the margin of a pine woodland. The hybrids were intermixed with one of the putative parents, *L. microcarpa*. Across the highway in the similar habitat was another very large, pure population of *L. microcarpa*. *Peng 4160* had 9% stainable pollen. *Peng 4263*, from Collier Co., Florida, was found in an open palmetto–cypress forest, with both putative parents growing nearby. One somewhat analyzable metaphase I cell from this plant showed 8 bivalents and 16 univalents. Pollen stainability was 24%.

Ludwigia pilosa ($n = 16$) × **L. sphaerocarpa** ($n = 16$).

Before discussing this hybrid combination, a few comments on *L. sphaerocarpa* are appropriate. This species is quite variable and has a widely scattered distribution (Fig. 22). Populations of *L. sphaerocarpa* consist of individuals that are extremely varied in overall pubescence, leaf shape and size, fruit size, and density of fruits on branches. Three varieties (var. *jungens*, var. *macrocarpa*, and var. *deamii*) have been recognized previously within this species (Fernald & Griscom, 1935) based on various combinations of the above characters. Study of numerous herbarium specimens not available to Fernald & Griscom, however, revealed that correlations between these characteristics are not consistent. It is of interest to note that, although seed-surface cell pattern is generally very regular within populations of members of sect. *Microcarpium* (Figs. 1–3), this is not the case for *L. sphaerocarpa* (Fig. 4). The seed surfaces are arranged in columnar cells both transversely elongate and parallel to the seed length, with the former alignment often predominant in the central part of the seeds (Fig. 4). Seeds with variously oriented surface cells are also seen in some populations. A comparison of the irregular seed surface pattern in *L. sphaerocarpa* with that of various artificial hybrid combinations (Figs. 6–19) strongly suggests that earlier hybridizations within the interfertile tetraploid group of sect. *Microcarpium* may have resulted in production of this widespread series of populations that have more or less stabilized in some of their characteristics.

Morphological variation in *L. sphaerocarpa* is further complicated by its frequent natural hybridization with *L. pilosa* (and perhaps with *L. ravenii* as well, although it would be difficult to distinguish these hybrids from those involving *L. pilosa*), which has apparently resulted in many hybrid swarms or introgressed populations. These plants are generally neither typical of *L. pilosa* nor of *L. sphaerocarpa* and exhibit varying degrees of intermediacy between the two species. The diagnostic characters for the hybrids include overall pubescence, leaf shape, bracteole size and location, sepal shape and size, and color of abaxial leaf venation. Examples of populations of such intermediates are too numerous to cite here. Instead they have been mapped (Fig. 22). It is of interest to note that some of the hybrid populations occur in central and southern Florida where typical *L. pilosa* and *L. sphaerocarpa* are absent; this suggests that physiological characteristics, and thereby ecological tolerances, may recombine into novel adaptive combinations in the hybrids also.

Artificial hybrids between *L. pilosa* and *L. sphaerocarpa* were synthesized in an experimental greenhouse. Plants of this hybrid combination showed 15–16 bivalents and exhibited the highest level of stainable pollen (98%) among all the tetraploid hybrids.

Ludwigia pilosa ($n = 16$) × **L. suffruticosa** ($n = 16$) [*L. capitata β pubens* Torrey & A. Gray]. U.S.A. FLORIDA: Citrus Co., 5 mi. S of Homosassa, *Kral 7771* (FLAS, GH, both mixed with *L. suffruticosa*). Gadsden Co., along Old Bainbridge Rd. (Rte. 173); 0.5 mi. NW of Ochlockonee River bridge, NW of Tallahassee, *Anderson 7486* (FSU). Seminole Co., W shore of Prairie Lake, *Schallert 16009, 28652* (S). GEORGIA: McIntosh Co., on Sapelo Isl., ca. 1.4 mi. WNW of S tip of Blackbeard Isl., *Duncan 20445* (DUKE, F, GH, NCU, SMU, TEX, US, USF). Wayne Co., near Jessup, *Biltmore Herbarium 4174*^{c} (US). GEORGIA (?): *Baldwin Herbarium* (NY, holotype of *Ludwigia capitata* Michaux *β pubens* Torrey & A. Gray, mixed with *L. suffruticosa* Walter). SOUTH CAROLINA: Darlington Co., Hartsville, *Smith 44* (NCU). Georgetown Co., North Santee, *Radford 28678* (NCU, NY, VDB).

FIGURE 22. Distribution of *Ludwigia pilosa* (shading), *L. sphaerocarpa* (stippling), and their natural hybrids (dots).

Ludwigia polycarpa (n = 16) × **L. sphaerocarpa** (n = 16). U.S.A. INDIANA: Starke Co., border of Bass Lake, 5 mi. S of Knox, *Kriebel 5715* (SMU); SW corner of Bass Lake, *Friesner 16306* (CAS, NY).

Notes. *Ludwigia polycarpa*, which occurs in the central Midwest (Fig. 20), is effectively isolated geographically from all other species of sect. *Microcarpium*, with the exception of *L. sphaerocarpa*. Where the two species come into contact, hybridization occurs.

The following is a list of collections of hybrids for which the identity of the putative parents is not certain:

?Ludwigia linearis (n = 8) × **L. ravenii** (n = 16). U.S.A. NORTH CAROLINA: Duplin Co., 3 mi. E of Sarecta, *Beal 3674* (NCSC).

Notes. This is a much-branched, densely villous plant with sublinear leaves and small, elongate-pyramidal ovaries that abort after anthesis. The pubescence suggests that either *L. pilosa* or *L. ravenii* is involved in the parentage. The aborted ovaries indicate that hybridization involved one of the above species and a taxon outside of the interfertile *L. pilosa* group. The elongate ovaries and narrow leaves indicate clearly that either *L. linearis* or *L. linifolia* is the other parent. Floral characters as well as geographical distribution of these species, however, indicate that *Beal 3674* from Duplin Co., North Carolina, is probably a hybrid between *L. linearis* and *L. ravenii.*

Ludwigia microcarpa (n = 8) × **L. curtissii** (n = 32)/**L. simpsonii** (n = 24). U.S.A. FLORIDA: Flagler Co., 6 mi. E of Co. line, Hwy. 28 near Andalusia, *West in 1940* (FLAS). Lake Co., 7 mi. SW Okahumpka, *Kral 7611* (FLAS, FSU, GH).

Notes. *Kral 7611* represents a mixture of several species and hybrids. Specimens deposited in GA, GH, US, VDB are *L. microcarpa,* whereas the specimen at FSU contains both the hybrid and either *L. curtissii* or *L. simpsonii,* the separation of which is difficult, since mature capsules are not present.

?Ludwigia pilosa (n = 16) × **L. suffruticosa** (n = 16). U.S.A. FLORIDA: Jackson Co., Ocheesee Lodge Landing S of US 90, near Sneads, *Jones 23569* (GA). Co. unknown, S Florida, *Chapman Herbarium* (NY). GEORGIA: Lee Co., near US 19, ca. 4 mi. S of Smithville, *Moran 2551* (GA).

Notes. These specimens are less pubescent than typical *L. pilosa* × *L. suffruticosa* hybrids. They are for the most part densely strigillose only in the branched and somewhat lax inflorescence and may represent backcrossed populations or segregates of advanced generation of the hybrid *L. pilosa* × *L. suffruticosa.*

HYBRIDS BETWEEN MEMBERS OF *LUDWIGIA* SECTS. *MICROCARPIUM* AND *DANTIA*

Hybrids between members of sects. *Microcarpium* and *Dantia* are easy to recognize; members of sect. *Microcarpium* are erect plants with alternate leaves, whereas plants belonging to sect. *Dantia* are prostrate and have opposite leaves. Intermediacy in these two characters signals hybridization between the two sections.

Ludwigia arcuata (n = 16; sect. *Dantia*) × **L. pilosa** (n = 16). U.S.A. ALABAMA: Mobile Co., Audubon Bird Sanctuary, Dauphin Isl., *Deramus D643* (DS, UNA).

Notes. Hybrids of this combination were synthesized in the experimental greenhouse. They showed a modal meiotic configuration of 12–15 bivalents and 8–2 univalents; 1–2 trivalents were sometimes observed. The high degree of chromosome pairing observed between species of the two sections was quite unexpected. This artificial hybrid, however, had only 38% stainable pollen. Since selfing in the hybrid is physically impossible, as in *L. pilosa,* artificial pollination was attempted in order to investigate seed set. None of the pollination attempts yielded any seed set, even though some seeds were observed in mature capsules of the natural hybrids.

Ludwigia curtissii (n = 32) × **L. repens** (n = 24; sect. *Dantia*). U.S.A. FLORIDA: Glades Co., 4.4 mi. SE of jct. of FL 29 with US 27, with both parents, *Raven 18680* (MO). Lee Co., on US 41, 5 mi. N of Ft. Meyers, with both parents, *Dille & Dille 379* (MO).

Notes. *Ludwigia curtissii* (n = 32) and *L. simpsonii* (n = 24) hybridize with *L. repens* in nature. Unless chromosome numbers are counted, it is unlikely that one would be able to distinguish between these two hybrid combinations morphologically.

Ludwigia curtissii (n = 32)/**L. simpsonii** (n = 24) × **L. repens** (n = 24; sect. *Dantia*). U.S.A. FLORIDA: Charlotte Co., 12 mi. S of Punta Gorda, *Kral 18058* (VDB). Lee Co., 5 mi. S of Bonita Springs, *Crevasse in 1940* (FLAS). Manatee Co., Bradentown, *Cuthbert in 1926* (FLAS). Wakulla Co., between Hwys. 365–367, N of Spring Creek, *Lazor 4561* (NCU).

Ludwigia repens (n = 24; sect. *Dantia*) × **L. simpsonii** (n = 24). U.S.A. FLORIDA: Charlotte Co., Punta Gorda City, on US 41, ca. 1 mi. S of jct. of US 17 and 41, *Peng 4296* (MO).

Notes. This hybrid grew intermixed with both putative parents along a roadside field. It formed 0–1 bivalent(s) and 48–46 univalents in metaphase I cells. This result corroborates an earlier report by Schmidt (1967) [FLORIDA: Glades Co., 8.4 mi. SE of jct. of FL 29 on US 27, *Raven 18849* (DS)].

Ludwigia glandulosa subsp. **glandulosa** (n = 16) × **L. palustris** (n = 8; sect. *Dantia*). U.S.A. ARKANSAS: Clark Co., Okolona, *Demaree 16120* (DS, GA, GH, MO, NY, SMU, TENN). NORTH CAROLINA: Co. unknown, stagnant water just S of Upper Littel River on US 401, *Lloyd in 1962* (MO). Johnston Co., 4.9 mi. W of NC 210 and US 70, on US 70, E of Clinton, *Ahles 59736* (NCU), *61803* (DS, NCU, SMU). OKLAHOMA: Johnston Co., Devil's Den, 4.6 mi. NW of Tishomingo, *Crutchfield 2882* (LL). VIRGINIA: Fluvanna Co., just S of Rt. 696, 1 mi. S of Rt. 250, *Diggs & Diggs 353* (NCU).

Notes. Plants of *Lloyd in 1962* from North Carolina showed 24 univalents in meiosis (Raven, pers. comm.). Schmidt (1967) reported "at most three weakly joined bivalents" in the hybrid plant from North Carolina [Harnet Co., 5.1 mi. S of Lillington, *Lloyd 1022* (DS)]. Artificial hybrids recently synthesized, however, showed higher chromosome associations in meiosis, in the range five to eight bivalents modally.

Ludwigia microcarpa ($n = 8$) × **L. palustris** ($n = 8$; sect *Dantia*). U.S.A. FLORIDA: Franklin Co., 41.7 mi. W of jct. of US 98 and 319, with both putative parents, *Peng 4349* (MO). Hamilton Co., off I-75, ca. 1 mi. N of Columbia Co. line, *Bowers & Wofford 71-550-F* (TENN, a mixture of *L. repens, L. microcarpa*, and *L. microcarpa* × *L. palustris*). Lake Co., 3.7 mi. S of Mascotte city limit, on Co. Rd. 33, with *L. microcarpa* and *L. palustris, Peng 4167* (MO). GEORGIA: Camden Co., 6.6 mi. S of Woodbine on US 17, with *L. microcarpa* and *L. repens, Raven 18704* (MO). NORTH CAROLINA: Jones Co., near NC 41, 0.7 mi. E of Taylor's Corner, *Radford 37152* (NCU).

Notes. Peng 4349 from Franklin Co., Florida, was collected from a large population growing intermixed with both putative parents along a swampy ditch. *Peng 4167* from Lake Co., Florida, was found growing with both putative parents in a narrow ditch. Pollen stainability was 5% in *Peng 4349*. Artificial hybrids of this combination were synthesized and showed 2–5 bivalents and 12–6 univalents in meiotic metaphase I.

Observations from experimental hybridization indicate that hybrid combinations of *L. microcarpa* ($n = 8$) × *L. palustris* ($n = 8$; sect. *Dantia*) and *L. microcarpa* ($n = 8$) × *L. repens* ($n = 24$; sect. *Dantia*) are prostrate herbs with similar leaf shape and minute flowers that abort after anthesis. In *L. microcarpa* × *L. palustris*, the flowers are apetalous as in both parents, and the phyllotaxy is intermediate; the plants have alternate, opposite, and subopposite leaves. By contrast, in *L. microcarpa* × *L. repens* the leaves are always opposite as in *L. repens*, and some of the flowers have one to four vestigial petals. The apparent dominance of the traits of the hexaploid parent over those of the diploid parent is probably due to a multiple dosage of genetic information from the hexaploid.

In two instances, *Bowers & Wofford* (VDB) and *Raven 18704* (MO), the hybrids were collected along with *L. microcarpa* and *L. repens*; *L. palustris* was not observed locally. Although these plants, which have aborted ovaries, might have been considered as hybrids between *L. microcarpa* and *L. repens* on this basis, detailed examination of their flowers and leaves reveals that they are *L. microcarpa* × *L. palustris*.

Ludwigia polycarpa ($n = 16$) × **L. palustris** ($n = 8$; sect. *Dantia*). U.S.A. KENTUCKY: Ballard Co., at intersection of Kelley Branch Creek Rd. and KY 473, *Athey 1158* (NCU, NY, VDB). OHIO: Erie Co., in bottom of South Quarry at N edge of town on Kelley's Isl., *Stuckey 7400* (PH).

Notes. Although one of the putative parents, *L. polycarpa*, has not been recorded from Ballard Co. in extreme southwest Kentucky, it was collected from adjacent Massac Co., Illinois. *Ludwigia palustris* is common in Ballard Co., Kentucky. Plants of *Athey 1158* are comparable to artificial hybrids between these species synthesized in an experimental greenhouse.

In summary, geographical isolation and self-pollination are the primary factors limiting natural hybridization in species of sect. *Microcarpium*. For example, *L. microcarpa*, an extreme selfer, has been hybridized successfully with most species of sect. *Microcarpium* in the greenhouse, and the resulting hybrids were vigorous. It grows sympatrically with many other species (Fig. 21), but natural hybrids have been found only with *L. simpsonii, L. curtissii*, and members of sect. *Dantia*.

In general, however, natural hybrids in sect. *Microcarpium* are frequently found wherever two species occur together. This is particularly so for plants in the tetraploid group (including the hexaploid *L. alata*; Fig. 21), which were often found intermixed with their putative parents.

Especially evident in *L. pilosa* and hybrid populations involving *L. sphaerocarpa* were the effects of backcrossing and introgression, which may provide the hybrid populations with increased evolutionary flexibility, thus enabling them to grow in areas where neither of the parents are found.

As outlined above, natural hybridization is not limited to species within sect. *Microcarpium*. At least seven hybrid combinations, some of which occur commonly in nature, have been found between members of sect. *Microcarpium* and sect. *Dantia.* Most of these have also been synthesized in the experimental greenhouse. Most intersectional hybrids, however, do not set seed, although they are usually very vigorous and appear to compete well with their parents. Once established, these sterile hybrids may be able to persist in a given location due to their perennial habit. New colonies may be established vegetatively if entire parents or fragments are transported to suitable habitats, most likely by water.

SPECIES RELATIONSHIPS AND EVOLUTION

Among the four diploid species, *L. microcarpa* is quite distinct from *L. linearis, L. linifolia,* and *L. stricta.* Plants of *L. microcarpa* are small herbs with spatulate or obovate-spatulate leaves, minute apetalous flowers from which the pollen is shed singly, and short, tiny capsules; whereas the other three species have linear leaves, somewhat showy flowers with four petals from which the pollen is shed in tetrads, and elongate capsules. They appear to be relatively closely related to one another.

All eight taxa in the tetraploid ($n = 16$) group, including *L. alata* ($n = 24$), are apetalous. Their leaves range from linear-lanceolate to lanceolate, elliptic, or oblanceolate. They differ from each other in a number of characters, including capsule morphology, seed-surface pattern, pubescence, and the way in which pollen is shed.

Although *L. alata* and *L. simpsonii* are both hexaploids ($n = 24$), morphological characters suggest that they are not closely related. *Ludwigia alata,* which has winged capsules, is most similar to *L. lanceolata* of the tetraploid group, although it can be distinguished by having pollen shed singly, seed surfaces consisting of columnar cells elongate transversely to the seed length (Fig. 3), and by being modally outcrossing. *Ludwigia lanceolata* sheds its pollen in tetrads, has isodiametric seed-surface cells (Fig. 1), and is autogamous.

By contrast, hexaploid *Ludwigia simpsonii* resembles octoploid *L. curtissii* ($n = 32$). These two species can be distinguished relatively consistently only by the size of their mature capsules, although even this character is not always reliable. Both exhibit a specialized type of capsular dehiscence unique in sect. *Microcarpium.* Moreover, *L. simpsonii* and *L. curtissii,* along with the diploid *L. microcarpa,* are the only species in the section with spatulate or obovate-spatulate cauline leaves. There appears to be a close relationship between *L. microcarpa* and the *L. curtissii* complex.

Results from the crossing program and chromosome analysis of the artificial and natural hybrids confirm these general observations and provide additional evidence for some of the evolutionary relationships discussed below.

RELATIONSHIPS AMONG THE DIPLOID SPECIES (*L. LINEARIS, L. LINIFOLIA, L. STRICTA, L. MICROCARPA*)

The presence of a quadrivalent during meiosis of reciprocal hybrids of *L. linearis* × *L. linifolia* indicates that the genomes of the strains hybridized differ by a reciprocal translocation. Although reciprocal translocations are very frequent in the tribe Onagreae, they are rare in the remainder of the family; their presence here indicates that chromosomal repatterning has occurred between the strains hybridized. The artificially produced F_1 hybrids were very vigorous and set abundant seeds, although many of the F_2 plants were either weak or inviable. Presumably *L. stricta* will show a comparable degree of differentiation.

The hybrids between *L. microcarpa* and either *L. linearis* or *L. linifolia* showed very few (0–3) bivalents in meiosis. The bivalents sometimes appeared to be held together by matrix connections rather than by chiasmata; some of them were heteromorphic, and the chromosomes did not always line up in the equatorial plane. Taken together, these phenomena indicate that *L. microcarpa* has a diploid genome essentially different from that of either *L. linearis* or *L. linifolia,* and presumably *L. stricta* as well.

RELATIONSHIPS AMONG THE TETRAPLOID TAXA (*L. GLANDULOSA* SUBSP. *GLANDULOSA, L. GLANDULOSA* SUBSP. *BRACHYCARPA, L. LANCEOLATA, L. PILOSA, L. POLYCARPA, L. RAVENII, L. SPHAEROCARPA,* AND *L. SUFFRUTICOSA*)

This is a group of eight diverse and morphologically well-delimited taxa. Artificial hybridization between any two species nearly always resulted in vigorously growing individuals with nearly complete chromosome pairing, high levels of stainable pollen, and abundant seeds. Many vigorous F_2 plants were raised that exhibited various degrees of intermediacy between the parents. This group is interpreted as representing an assemblage of interfertile tetraploid species that have two genomes in common and thus represents a homogamic complex.

ORIGIN OF THE TWO GENOMES IN THE TETRAPLOID SPECIES

Most of the tetraploid species have been crossed with each of the three diploid species included in this study in order to assess whether one or more of the extant diploid species has been involved in their formation. *Ludwigia linearis* and *L. linifolia* were shown to share a similar genome that has undergone some chromosomal repatterning. Hybrids between either of these diploid species and any tetraploid species produced 3–7 bivalents in meiosis. Hybrids between *L. microcarpa* and the tetraploid species showed 1–6 bivalents in meiosis. Two lines of evidence suggest that the chromosomal pairing in these hybrids is the result of pairing of chromosomes between the diploid and the tetraploid rather than pairing between the two genomes present in the tetraploid. First, hybrids between *L. linifolia* (♀; $n = 8$) and *L. lanceolata* (♂; $n = 16$) were themselves tetraploid, modally forming 8 bivalents and 16 univalents in meiosis. This tetraploid chromosome number apparently resulted from the union of an unreduced egg from the diploid parent with a normal sperm nucleus from the tetraploid. This unexpected result strongly suggests that the 8 bivalents observed represent paired chromosomes from the duplicated *L. linifolia* genomes, while the 16 univalents are the chromosomes from the two genomes of the tetraploid parent, which are sufficiently different to remain unpaired. Pairing between chromosomes of *L. linifolia* and those of the tetraploids is evidently precluded by preferential pairing between the two sets of chromosomes derived from *L. linifolia*.

Second, when *L. glandulosa* ($n = 16$) was crossed with *L. alternifolia* ($n = 8$), a less closely related species belonging to sect. *Ludwigia*, the resulting hybrids exhibited 0–1 bivalent(s) in meiosis; the one bivalent that was occasionally observed was only loosely associated. This lack of pairing also suggests that the tetraploid species are alloploids with two unlike genomes.

As noted earlier, two distinct genomes appear to be represented among the diploid species; one shared by *L. linearis*, *L. linifolia*, and probably *L. stricta*, and another found in *L. microcarpa*.

Hybridization between any of these species and the tetraploid taxa consistently results in F_1 offspring that show only about 2–7 bivalents, some of them heteromorphic, in meiosis. This strongly suggests that neither of the two genomes present in the tetraploids was derived from an existing diploid.

ORIGIN OF GENOMES IN THE HEXAPLOID *LUDWIGIA ALATA*

Nearly all of the reciprocal hybrids between the hexaploid *L. alata* and the tetraploid species exhibited a modal meiotic configuration of 16 bivalents and 8 univalents. This suggests that they share two genomes: the 16 chromosomes of the tetraploid species pair with their homologues present in the genome of the hexaploid species, while the additional eight chromosomes in *L. alata* remain unpaired and appear to represent a third genome present in *L. alata*.

Ludwigia alata was also crossed with the diploid species in an attempt to assess whether this "third genome" is in fact homologous to one of those present in the existent diploid taxa. Hybrids between *L. alata* and either *L. linearis* or *L. linifolia* typically exhibit a configuration of 1–2 trivalents and 4–6 bivalents with the rest of the chromosomes univalents. Again, heteromorphic pairs are common here. These results are similar to those observed in hybrids between *L. linearis* and *L. linifolia* and the tetraploid taxa. Since the two genomes of the tetraploid species appear to be present in *L. alata*, it is presumed that the bivalents are formed between chromosomes derived from the parental taxa. By contrast, meiosis in hybrids between *L. microcarpa* and *L. alata* shows a high degree of chromosome pairing, with a modal configuration of one quadrivalent, 7–10 bivalents, and a corresponding number of univalents. The maximum amount of pairing seen was 11II + 10I or 1III + 10II + 8I. These chromosome associations involve bivalents of normal appearance, either rings or rods, a situation that contrasts with the sorts of loosely associated bivalents characteristic of hybrids between *L. microcarpa* and the tetraploid taxa. The higher level of chromosome pairing (more than eight bivalents) and the normal appearance of the pairs suggest that the hexaploid *L. alata* may have been derived following hybridization between *L. microcarpa* and one of the tetraploids. Indeed *L. alata* is similar to *L. microcarpa* in that (1) its seed surface consists of columnar cells transversely elongate to the seed length, and (2) its pollen grains are shed singly. These characters are rarely found among members of the tetraploid species group, with which *L. alata* shares two genomes.

ORIGIN OF GENOMES IN THE *LUDWIGIA CURTISSII* COMPLEX

The *L. curtissii* complex consists of *L. simpsonii* ($n = 24$) and *L. curtissii* ($n = 32$). Hybrids between the two species consistently reveal 24 bivalents and 8 univalents in meiosis. This indicates that chromosomes of the three genomes in *L. simpsonii* pair with homologues in *L. curtissii*, leaving the eight additional chromosomes in this species unpaired. Naturally occurring intersectional hybrids between *L. repens* ($n = 24$; sect. *Dantia*) and *L. simpsonii* produce a meiotic configuration of 48 univalents or 46 univalents and two loosely associated chromosomes. This strongly suggests that the three genomes in *L. simpsonii* are distinct from each other and not homologous with any of the genomes present in *L. repens*.

For ease of discussion, letters will be used to designate distinct, nonhomologous genomes. Since the five genomes present in *Ludwigia* sect. *Dantia* have been designated as A, B, C, D, and E (Schmidt, 1967), the genomic formula GGHHII will be used for *L. simpsonii* and FFGGHHII for *L. curtissii*.

The natural hybrid *L. microcarpa* × *L. simpsonii* has a meiotic configuration of 8 bivalents and 16 univalents. The eight chromosomes of *L. microcarpa* thus have 8 homologues in *L. simpsonii*, and its genome is designated as GG.

A configuration of 8 bivalents and 24 univalents is expected in meiotic cells of the hybrid *L. curtissii* (FFGGHHII) × *L. microcarpa* (GG). In a natural hybrid of this combination, the single analyzable cell did indeed show this configuration. In an artificial hybrid, however, more than 8 bivalents have been observed: five cells exhibited 14–15 bivalents and 12–10 univalents. Some intergenomic interaction must have led to the observed configurations.

In the meiosis of *L. curtissii* (FFGGHHII) × *L. linifolia* ($n = 8$), a modal configuration of 8 bivalents and 24 univalents was observed. The genome common to *L. linearis* and *L. linifolia* is designated FF, since it differs from that present in *L. microcarpa* (GG). As in the case of *L. curtissii* × *L. microcarpa*, however, a few meiotic cells in *L. curtissii* × *L. linifolia* exhibited more than 8 bivalents; up to 12 have been observed.

Figure 23 summarizes the chromosomal homologies in the *L. curtissii* complex. The hexaploid *L. simpsonii* appears to have been derived from three different diploid lines. Morphological as well as chromosome pairing data indicate that the diploid *L. microcarpa* has been involved in the formation of *L. simpsonii*. Based on morphology, it seems unlikely that a member of the *L. linifolia*/*L. linearis* lineage could have been a parent of *L. simpsonii*. Nevertheless, it will be necessary to examine meiosis in the artificial hybrid between *L. simpsonii* and *L. linearis* or *L. linifolia*. Although plants of *L. simpsonii* × *L. linearis* were available, my attempts to study meiosis in them were unsuccessful. The octoploid *L. curtissii* was probably derived following hybridization between a diploid similar to *L. linearis* or *L. linifolia* with the hexaploid *L. simpsonii*, based on morphological data and crossing relationships.

To study the genetic relationships among plants from the tetraploid group (including the hexaploid *L. alata*) and the *L. curtissii* complex, 11 artificial hybrids were produced, 5 of which have been studied cytologically. The number of bivalents observed ranged from 4 to 13; a few trivalents and quadrivalents were also frequently seen (Table 15). Chromosome associations between the polyploids of the tetraploid group and the three diploid species, on the one hand, and those observed between the *L. curtissii* group and the diploid species, on the other hand, are consistent with these results.

Following the differentiation of diploid species of sect. *Microcarpium*, some have evidently become extinct. Natural hybridization between the diploid lineages followed by polyploidy has played a major role in the evolution of this group. Postzygotic genetic barriers do not exist between most of the extant species in the section. Rather, the major limiting factor to natural hybridization appears to be the modally autogamous breeding system of most species. Geographical isolation is important only with respect to *L. polycarpa*, which is distributed well to the north of nearly all the other taxa.

Natural hybridization is prevalent within sect. *Microcarpium*, and hybrids often occur in more or less undisturbed habitats where the parental taxa also grow. All interploid hybrids are sterile except for crosses between *L. alata* ($n = 24$) and the tetraploid species ($n = 16$), and crosses between *L. curtissii* ($n = 32$) and *L. simpsonii* ($n = 24$). Even sterile hybrids can persist and form large colonies, at least locally, and compete effectively with their parents, because of strong vegetative reproduction by means of stolons. Natural hybrids are especially common among members of the tetraploid group (including *L. alata*) and are nearly always vigorous and fertile.

Particularly complex is the pattern of variation in the tetraploid *L. sphaerocarpa*, which is apparently comprised largely of widespread stabilized

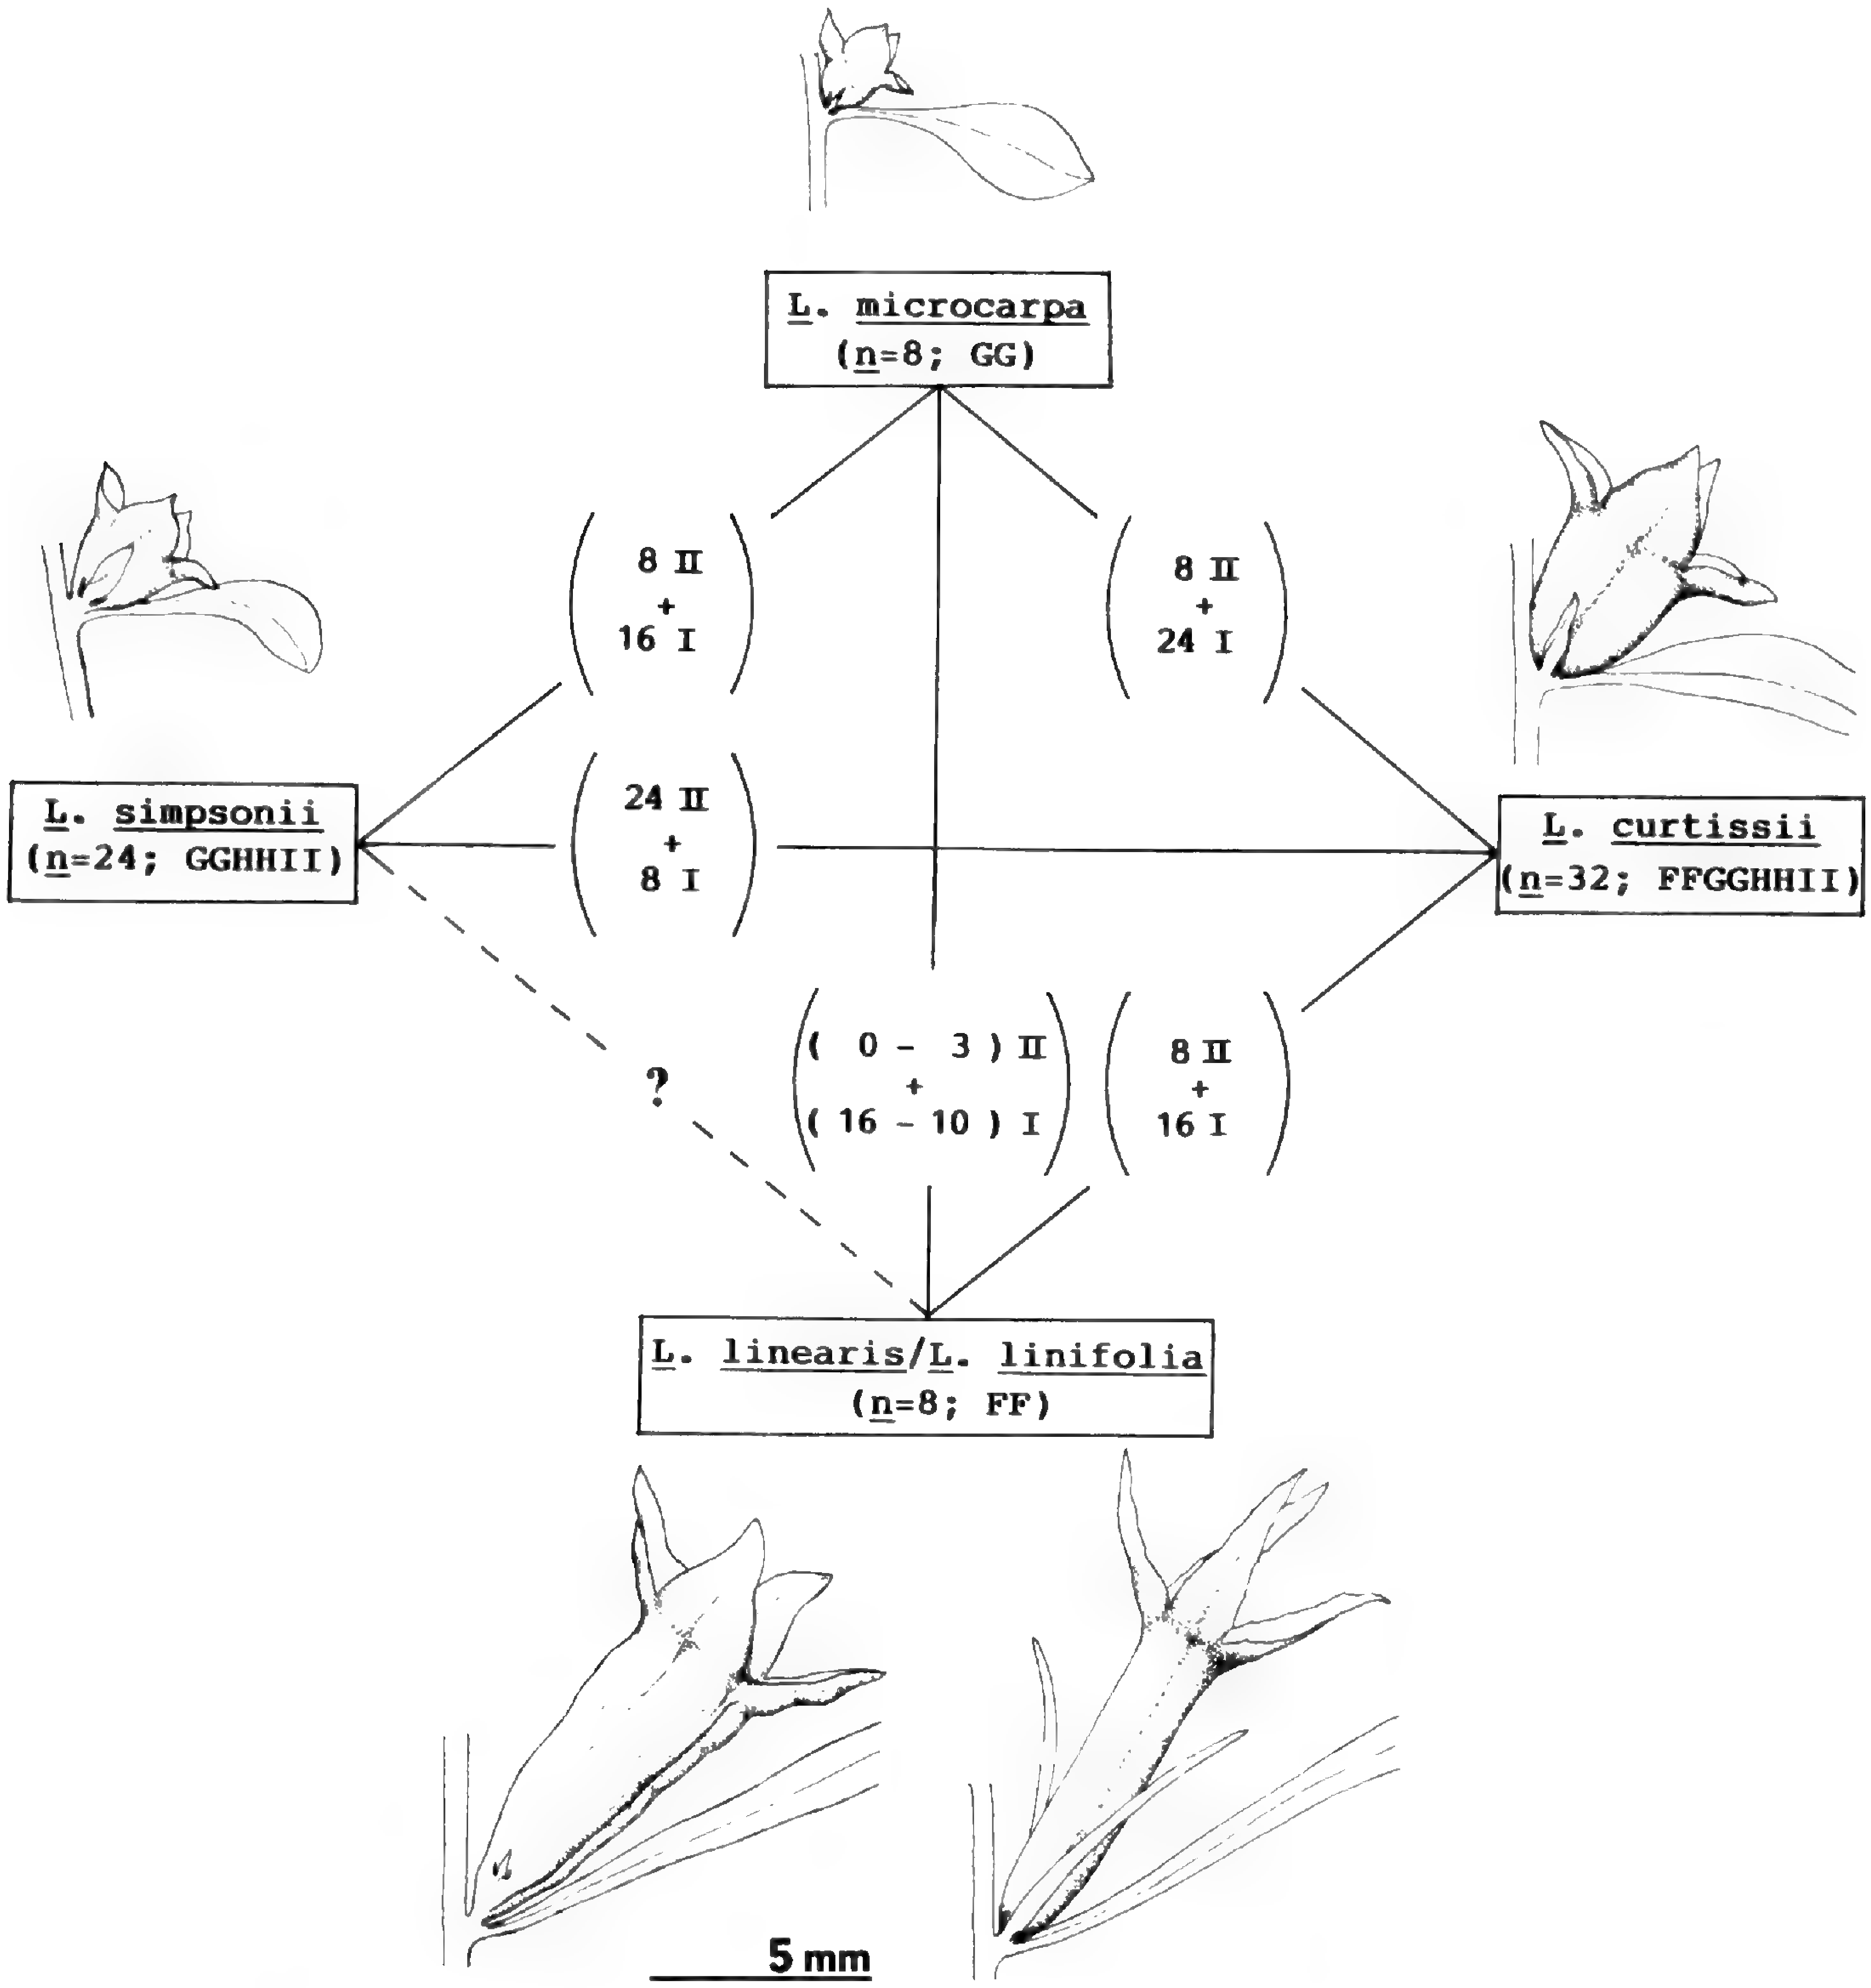

FIGURE 23. Chromosomal homologies in the *Ludwigia curtissii* complex. Dotted line indicates artificial hybrids were obtained, but meiotic analysis was not successful. Illustrations of the plants are drawn to scale.

hybrid populations that exhibit a combination of characters distinguishing them from other taxa. As in the evolution of *Epilobium* in New Zealand (Raven & Raven, 1976), recombination of genetic information from somewhat differentiated populations followed by maintenance of well-adapted genetic strains by a combination of autogamy and vegetative reproduction appears to have played a central role in the evolution of the polyploid members of *Ludwigia* sect. *Microcarpium*.

RECONSTRUCTIONS OF SELECTED SEED FERNS[1]

Greg J. Retallack[2] and David L. Dilcher[3]

This Paper is Dedicated to the Memory of
Sergei V. Meyen

ABSTRACT

Seed ferns (pteridosperms) make up a heterogeneous group of broadleaf gymnosperms. Our attempts to reconstruct these extinct plants here summarize research over many years on the best-known seed ferns. We have named each reconstructed plant after its best-preserved ovulate fructifications, because these are the most reliable parts for identification of seed plants. We envisage Early Carboniferous (about 352 million years ago) Stamnostoma huttonense *as a large tree, foresting elevated terraces and other well-drained areas of coastal plains. Swampy lagoon margins of the same coast probably were wooded with lycopods and small shrubby seed ferns such as* Lyrasperma scotica. *Of comparable age, but on well-drained ashy soils flanking inland volcanoes, was the early successional* Calathospermum fimbriatum. *Unlike these other plants, which were probably pollinated and dispersed by wind and water, arthropods may have played a role in the reproduction of* C. fimbriatum. *Earliest Late Carboniferous (about 320 million years old)* Lagenostoma lomaxii *is reconstructed as a bushy understory shrub in swamps of arborescent lycopods. Latest Late Carboniferous (about 296 million years old)* Pachytesta illinoensis *was a tree probably growing on elevated and nutrient-rich areas in and around permanently waterlogged swamps of marattiaceous tree ferns.* Pachytesta illinoensis *had large prepollen probably dispersed by insects. Its fleshy ovules may have been dispersed by large amphibians, reptiles, or fish. Another seed fern of these latest Carboniferous swamps,* Callospermarion pusillum, *is reconstructed as an early successional scrambling vine. Its pollen probably was dispersed by wind, and its numerous small seeds scattered widely by wind and water. In contrast to these Euramerican plants of tropical and subtropical climates, Late Permian (about 245 to 253 million years old)* Dictyopteridium sporiferum *was a dominant tree of cool temperate swamp woodlands of intermontane valleys in the southern hemisphere. Large air chambers in its roots enabled it to grow in waterlogged soils. Woodlands of southern hemisphere mid-continental lowlands during Late Triassic time (225 to 230 million years ago) included abundant trees of* Umkomasia granulata, *and a shrubby understory including* Peltaspermum thomasii. *Middle Jurassic (175 to 183 million years old)* Caytonia nathorstii *is reconstructed as a tree of lowland mixed conifer–broadleaf forest in a subtropical, seasonally wet paleoclimate. Its ovules were enclosed in berrylike cupules, which may have been pollinated and dispersed by small animals. From these examples, it is apparent that seed ferns were exceptionally diverse broadleaf plants which occupied a variety of niches now occupied by angiosperms.*

Reconstructions of extinct plants from dispersed fossil organs have not been attempted to the same extent as restoration of vertebrate fossils. Presumably this is because of the modular construction of plants, because of their various deciduous organs, and because of the variety of ways and places in which fossil plants are preserved. Nevertheless, many hypotheses have been published concerning which parts of fossil plants belong together. The drawings presented here are visual expressions of some of these hypotheses for especially well-known seed ferns. We intend these drawings to be working hypotheses of reconstruction in the same way as the written accounts on which they are based. Hypotheses expressed in this way are understood more readily than pages of scientific text. By the same token, however, such drawings also make mistakes of interpretation more obvious. A further

---

[1] *These reconstructions have been assembled over so many years and with such varied assistance in the field, with collections and with ideas, that it is not possible to thank adequately all those who have helped. We especially have valued and enjoyed the assistance of Drs. W. D. Dimichele (Smithsonian Institution, Washington), J. A. Doyle (University of California, Davis), R. E. Gould (Quest Ltd., Brisbane), T. M. Harris (University of Reading, England), C. R. Hill (British Museum Natural History, London), S. V. Meyen (Geological Institute, Moscow), G. W. Rothwell (Ohio University, Athens), and T. N. Taylor (Ohio State University, Columbus). Research and publication was funded by N.S.F. Grants DEB7910720 and BSR8516657 to D.L.D. and EAR8206183 to G.J.R.*

difference between written and illustrated reconstructions of fossil plants is the difficulty of expressing uncertainty and presenting detail in a drawing. With special regard to this problem, the poses of various organs have been selected carefully, and enlargements and insets have been used liberally both to reveal detail and obscure uncertainties.

The plants reconstructed here are those regarded traditionally as "seed ferns," a group of plants being increasingly recognized as an evolutionary grade rather than a clade. This is not to say that the terms "seed fern" or "pteridosperm" should be abandoned, any more than the term "dinosaur," another often loosely defined assemblage, should be discontinued. The discovery that these fernlike fossil leaves belonged to seed-bearing plants reshaped understanding of the evolutionary relationships between seed plants and pteridophytes (Potonié, 1899; Oliver & Scott, 1904), and their importance to understanding vascular plant evolution has remained undiminished. The first seed plant and the ancestors of many other gymnosperms were probably seed ferns (Rothwell, 1982). Seed ferns or allied plants remain most likely ancestors of angiosperms (Dilcher, 1979; Retallack & Dilcher, 1981; Doyle & Donoghue, 1986).

The various organs and preservational styles of each of these fossils have separate botanical names, following accepted paleobotanical nomenclature. Our gathering together of various organs and names for different parts of the same plant should not be construed to mean that each part is equally definitive of the whole plant. A fossil species of root, for example, may have belonged to several different species distinguishable among reproductive structures. It is likely that different organs of plants have evolved at different rates. In gathering together these names we merely imply that there once existed a plant for which each of these names is appropriate for its various fossilized parts.

Our choice of a single name for each reconstructed plant does not follow the *International Code of Botanical Nomenclature* (Stafleu, 1978) in its rules of priority, because there are indications in the code that these do not apply between form genera for different kinds of plant parts. In the case of the present compilation, strict adherence to priority would result in naming eight of the plants reconstructed here from leaves, one from wood, and one from a root. Instead, we use the name of the best-preserved ovular fructifications consistently as the name for these reconstructed seed plants (following Retallack, 1980a, and Anderson & Anderson, 1985). Modern seed plants are classified mostly according to their ovulate fructifications, and a new suprageneric classification of seed plants based on ovular fructifications has recently been proposed by Meyen (1984). We do not agree with all of the criteria for his classification, but it is a welcome replacement for the preexisting miscellany of suprageneric taxa based on wood for Carboniferous groups, leaves for Permian groups, and ovular fructifications for Mesozoic groups.

Meyen (1984) outlined a new botanical nomenclature for seed plants, but here we use well-established terms such as sporophyll (phyllosperm of Meyen), sporoclad (branching polysperm), head (ultimate segment of cladosperm), and cupule (also used by Meyen). The word ovule is used here in the strict sense for unfertilized integumented megasporangia. In most gymnosperms, seeds represent dispersed propagules, whereas ovules are found in place in reproductive organs. Thus the word ovule appears in this account of reproductive organs more frequently than the word seed. In much paleobotanical writing, the latter term being understood more easily in general English usage, is used loosely for ovule or seed. We have also used the term prepollen for the microspores of very early seed ferns. Prepollen look more like spores of pteridophytes than pollen of seed plants, and, like spores, prepollen germinate from the side of the grain originally oriented within the parent tetrad (Chaloner, 1976).

We have examined type material of all the seed ferns reconstructed here and a good deal of additional material. One of us (G.J.R.) also has visited the type or comparable localities of these fossil plants in order to assess and obtain new evidence for their geological occurrence. In addition to the drawings, we have written an interpretive summary as an introduction to each plant. The remainder of each account details both evidence and arguments for and against various aspects of our reconstruction. The plants are discussed in order of geological age.

STAMNOSTOMA HUTTONENSE

Hypothetical reconstruction. We envisage this plant as a tall forest tree (Fig. 1) with coniferlike wood (*Pitus primaeva* Witham, 1833). It was a prominent tree of well-drained soils of elevated river terraces surrounding lagoons of a broad coastal plain to the south of a hilly and volcanic region now forming the Southern Uplands of Scotland. During the Early Carboniferous (late Tournaisian or about 352 million years ago) the climate of this region probably was subtropical, with a

pronounced dry season. During this season, the pinnules of its large fronds (*Aneimites acadica* Dawson, 1860) may have been deciduous. In some ways these fronds resembled the plagiotropic short shoot systems of progymnosperms, but the petiole of the plant (*Lyginorachis papilio* Kidston, 1923) was dorsiventrally differentiated and its vascular structure like that of true leaves. Stalks arising from within the dichotomy of the rachis of the frond terminated in cupules (*Calathiops* sp.) bearing ovules (*Stamnostoma huttonense* Long, 1960a). The prepollen organ (*Telangium* sp. when petrified and *Telangiopsis* sp. in compression) probably was borne in a similar manner. It consisted of a copiously branched aggregate of clusters of elongate pollen sacs. The fernlike prepollen grains (*Colatisporites decorus* (Bharadwaj & Venkatachala) Williams in Neves et al., 1973) were released through an elongate dehiscence slit. These plants may have been wind pollinated at a stage when the ovules were immature. The prepollen was sealed in an apical chamber of the ovule (lagenostome) at the base of a trumpetlike opening (salpinx) by the upward and outward growth of a central plug of tissue. There it waited as the multicellular gametophyte and archegonia developed. Once fertilization was achieved, perhaps after shedding and wind dispersal of the ovule, there appears to have been little interruption in the rotting of the seed integuments and germination of the embryo.

Evidence for reconstruction. The main locality for our reconstruction is the quarries in the steep eastern banks of the Crooked Burn west of Newton Farm, near Foulden, Berwickshire, southern Scotland (Wood & Rolfe, 1985; Scott & Meyer-Berthaud, 1985). This is in the lower Cementstone Group of the Calciferous Sandstone Series, of Early Carboniferous age (late Tournaisian, or late Courceyan in the regional stratigraphic scheme; Scott et al., 1984; Clayton, 1985) or 352 million years old (following Palmer, 1983). The attribution of these various remains to a single plant is based on anatomical similarity of petrified petioles and small branches; on attachment of petrified stalks within the dichotomy of petioles as in other fertile seed ferns; on the similarity of pollen found in pollen sacs, in ovules, and dispersed; and on the association of both petrified and compressed remains at the same localities, often with few other associated plants (Long, 1960a, 1962, 1963, 1979a; Neves et al., 1973; Wood & Rolfe, 1985; Scott & Meyer-Berthaud, 1985).

Most of this evidence has been presented by Long (1979a), but we doubt that the leaf type, *Sphenopteris affinis*, or petrified stem, *Tristichia ovensii*, belonged to this plant, for the following reasons. *Aneimites acadica* is a very common leaf at the main locality for this plant (Newton Farm), where it is represented by abundant isolated pinnules, which were probably deciduous. The overall frond morphology thus remains poorly known, and Long's (1979a) objections on this basis against this being the foliage of the petrified petioles have little substance. There are several problems with Long's view that *Sphenopteris affinis* was the leaf of the plant in question. *Sphenopteris affinis* was probably a shrubby plant growing in quite different waterlogged soils (of the Oil Shales: Andrews, 1948). Only one very poorly preserved fragment (British Museum of Natural History specimen 16865) of *S. affinis* has been found at the main locality for our reconstruction (Newton Farm) of *Stamnostoma huttonense*, and this equally could be a badly lacerated specimen of *Aneimites acadica* or a ragged specimen of *Sphenopteridium pachyrrachis*, also reconstructed here as part of *Lyrasperma scotica*. In addition, the prepollen of *Telangium affine* found in association and attached to *Sphenopteris affinis* in the Oil Shales has a clear ornament and trilete mark (Kidston, 1924), quite different from the almost featureless prepollen found in the prepollen chambers of ovules and in prepollen organs attributed to *Stamnostoma huttonense* (Long, 1962, 1979a). Further, the prepollen of *Sphenopteris affinis* is somewhat smaller (52 μm according to Kidston, 1923) than that of the reconstructed plant (54–69 μm according to Long, 1979a). This would have been a more substantial difference if the prepollen grains of *Stamnostoma huttonense* are lacking their outer wall, as Long suspected.

←

Scott & Meyer-Berthaud (1985) reinterpreted *Tristichia ovensii* from the main locality for our reconstruction (Newton Farm) as a separate small seed fern with *Rhodea*-like leaves, "small uncupulate seeds," and "small, lateral, pedunculate male organs." They also questioned whether the specimens of *Tristichia ovensii* between the fork of *Lyginorachis papilio* and aligned with *Stamnostoma huttonense* (Long, 1963) are really attached. We accept their reconstruction of this other plant but see little reason to question the attachments described by Long, especially in view of the very generalized anatomy of *T. ovensii*. Very small axes of several species of seed ferns may have been comparably anatomically simple.

Habit. *Stamnostoma huttonense* was a large tree, with trunks up to 25 m long and 1.4 m in diameter (Long, 1979a). On some of the petrified trunks, branches and petioles have been found attached in a closely spaced helix, whereas other axes lack branches for considerable lengths. This is a common branching pattern in modern forest trees (Rauh's model of Hallé et al., 1978). This plant also had the long and short shoot organization found in many modern conifers, such as Scots pine (*Pinus sylvestris*).

Unlike the leaves of most conifers, its leaves were fernlike. These fossil trees were superficially similar to extinct progymnosperms such as *Archaeopteris ovata* (see Beck, 1981). These had leaves similar to the pinnules of *Aneimites acadica*, although these were arranged in large dorsoventrally planated shoot systems quite different from the true leaves of *A. acadica* (Kidston, 1924).

Ovules were attached on stalklike structures which formed the central axis of a trichotomy of the rachis of the frond. A petrified terete stalk with a triarch stele has been found in the dichotomy of a petrified petiole (Long, 1962). This was a common mode of attachment of ovular and pollen-bearing structures, seen in other Early Carboniferous compression fossils, such as *Sphenopteris affinis* (Kidston, 1924), *Sphenopteris bifida* (Long, 1979a), and *Diplopteridium teilianum* (Walton, 1926, 1931). Compared with modern gymnosperms in which axillary branching and clear differentiation of stem and leaf are the rule, this epiphyllous sporoclad is peculiar. Presumably this arrangement was inherited from progymnosperm ancestors that lacked consistently axillary branching (as shown by Scheckler, 1976, 1978).

The sporoclads of *Stamnostoma huttonense* may have been erect. Their stalks are terete and gently curved, rather than the dorsiventrally planated and flexuous as in pendent fructifications. Niklas (1981) has shown that an erect orientation would have been more effective for pollination, because the rachides of the fronds would have remained in the way of pendent ovules even if all the pinnules were abscised at the time of pollination. Long (1965) and Walton (1964) argued that cupules of other species were pendent because this would protect the pollination drop from rain. However, the open form of this particular cupule would have been a rain guide, rather than protection.

Reproduction. The life cycle of this plant was probably similar in general outline to that of a number of associated Early Carboniferous seed ferns (Rothwell, 1986). Irregularly branching cupulate structures of other species sometimes are found with poorly developed ovules or prepollen sacs (Long, 1969, 1975, 1977a, 1979b). We interpret these as fructifications at the stage of pollination or earlier, analogous to modern fructifications of cycads (*Dioon edule*) and maidenhair trees (*Ginkgo biloba*) at this stage in their development (Chamberlain, 1935). The smooth prepollen were produced in great quantity. These are features of modern wind-pollinated plants (Faegri & van der Pijl, 1966; Whitehead, 1969). The size of the prepollen (54–69 μm in diameter) approaches that of modern insect-dispersed pollen, but their aid in pollination is unlikely in view of other features of the prepollen. At pollination stage the funnellike nucellar apex (salpinx) may have retained a pollination drop for entrapment and withdrawal of prepollen (Walton, 1964) as in some modern conifers.

The best-preserved fossils of mature ovules have a central column filling much of the salpinx and a multicellular megagametophyte, occasionally with one to three apical archegonia (Long, 1960a). These may have been ovules during the long period after pollination and before or shortly after fertilization. Judging from the abundance of remains of this stage, this was a long period in the life cycle, perhaps taking several months, as in modern cycads and *Ginkgo* (Chamberlain, 1935). Even mature ovules have three small cutinized megaspore remnants at the apical end, representing aborted spores of the parent tetrad (Long, 1975). This feature, presumably a legacy of heterosporous progymnosperm ancestors, is no longer seen in modern seed plants.

Mature seeds were small (up to 3.75 mm long by 1.5 mm wide) and had a thin, dense seed coat. Compared with modern seeds (Van der Pijl, 1972), they were unspecialized and possibly scattered by

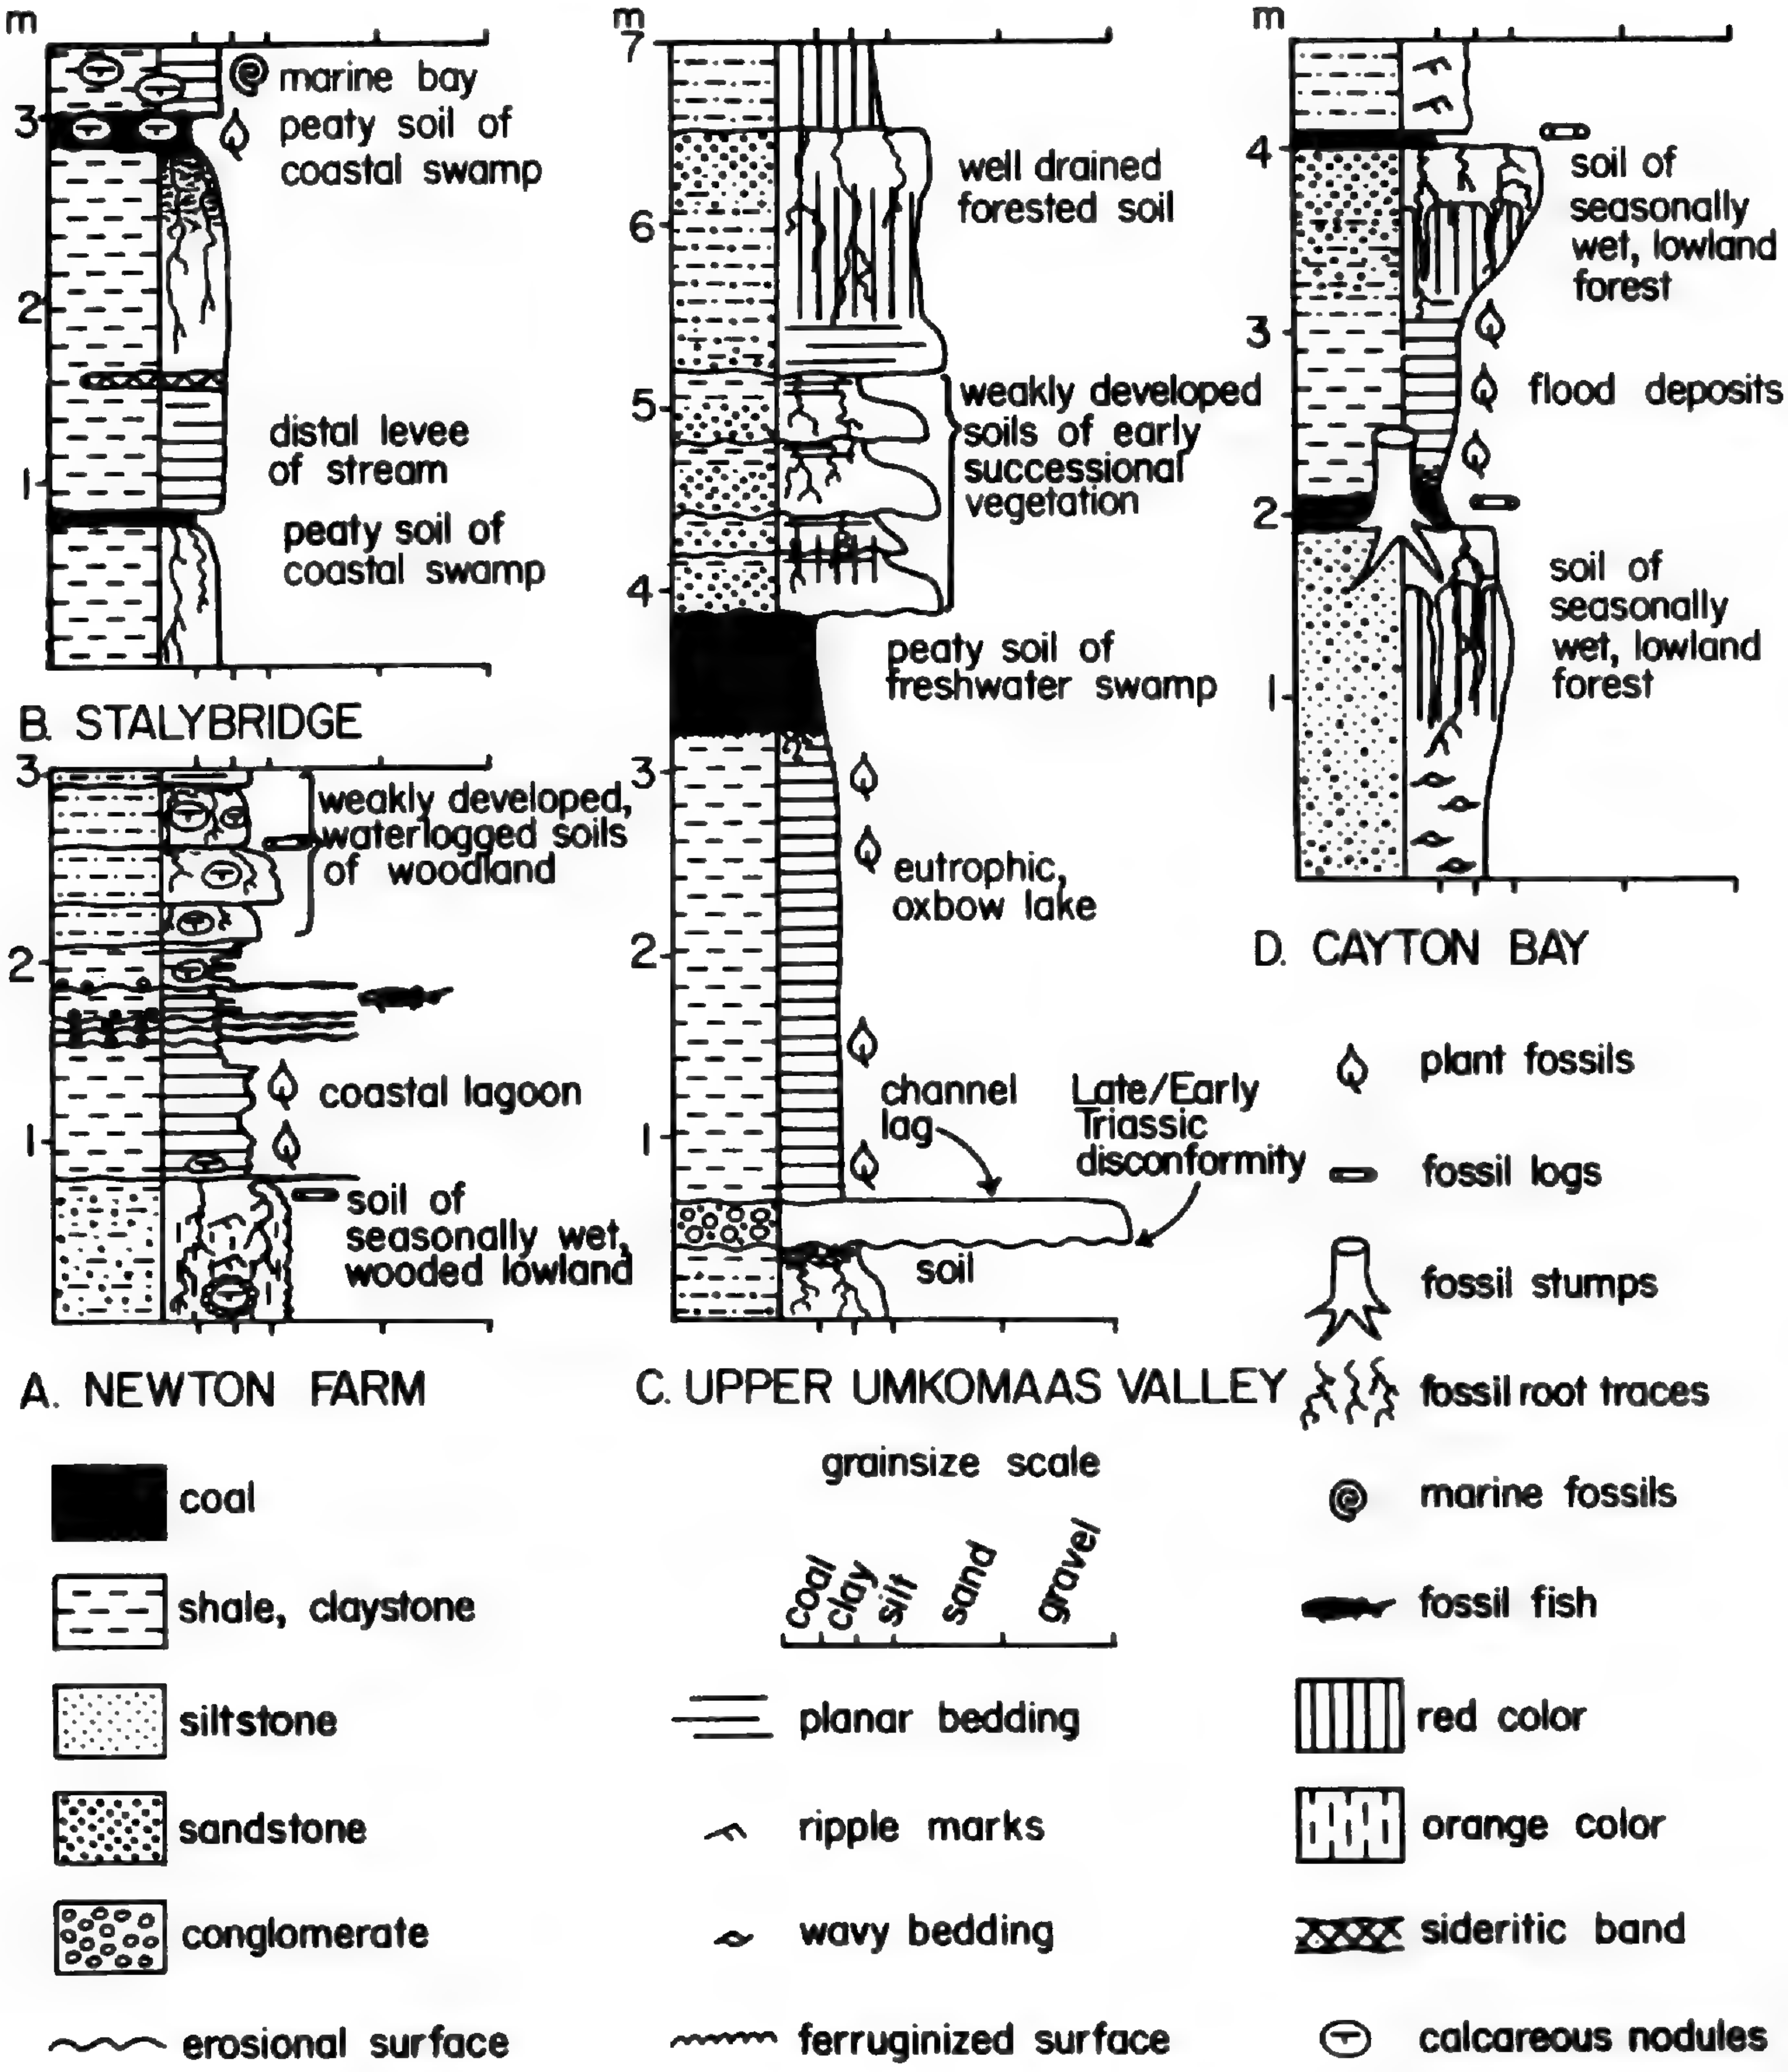

FIGURE 2. *Stratigraphic sections and interpreted paleoenvironments of fossil localities at:—A. Newton Farm, near Foulden, Scotland (for* Stamnostoma huttonense *and* Lyrasperma scotica*).—B. shaking from the cupules, followed by wind and water dispersal.

No seeds with embryos have been found among many examined in Early Carboniferous rocks. Those few possible seed fern embryos found have two seed leaves and are free of their seed integuments (Long, 1975). It is likely that germination followed rapidly after fertilization, again as in modern cycads and *Ginkgo* (Chamberlain, 1935). If most embryos grew without pause into small seedlings, this would explain their rarity.

Habitat. The gray shales at Newton Farm (Fig. 2A) have yielded a variety of fossil sharks, palaeoniscid and acanthodian fish, crustaceans, bivalves, and plants (White, 1927; Long, 1960a, 1962, 1964; Wood & Rolfe, 1985; Scott & Meyer-Berthaud, 1985). Apart from arborescent lycopods and rare sphenopsids, the best-known plants from here are the seed ferns reconstructed as *Stamnostoma huttonense* and *Lyrasperma scotica*, and a small plant with *Rhodea*-like foliage. Remains of all these plants have been found mixed together in shales of what was once a large brackish-to-freshwater coastal lagoonal system (Clarkson, 1985).

Several fossil soils (paleosols) in this sequence allow more precise understanding of where *Stamnostoma huttonense* grew. Overlying the lagoonal shales are sequential, thin, waterlogged paleosols (gleyed Inceptisols of Soil Survey Staff, 1975). The size and nonanastomosing cortical striations of fossil root traces in these are most like those of *Lyrasperma scotica*, also reconstructed here. A better-drained paleosol containing larger and more deeply penetrating root traces underlies the lagoonal shales. *Stamnostoma huttonense* probably grew in such well-drained soils, considering the deeply penetrating roots under its fossil stumps, its well-cuticularized seeds, and the growth rings in its wood, not seen in coeval arborescent lycopods of swamps (Gordon, 1935).

The well-drained paleosol thought to have supported *Stamnostoma huttonense* has a carbonaceous surface horizon: an indication that it was not always entirely dry. Its subsurface zone of iron-staining and deep (60 cm) horizon of calcareous nodules (caliche) mark the minimum usual depth of the water table. It was a young soil (probably formed in only hundreds of years before covered), because development did not proceed to the extent that the original bedding was entirely destroyed. It probably formed on an alluvial terrace, a meter or so above the level of the nearby lagoonal system.

Additional evidence of Early Carboniferous forests of *Stamnostoma huttonense* can be seen at other British localities. Along the King Water between Spadeadam and Gilsland in Cumbria, northern England, there are ten petrified stumps of *Pitus primaeva* preserved in growth position within 200 m of outcrop (Long, 1979a). Considering the likely canopy of these trees and the size of the stumps, they would have dominated a forest with closed canopy.

In addition to forests of *Stamnostoma huttonense* and swamp woodlands of *Lepidodendron* and shrubby *Lyrasperma scotica*, documented at Newton Farm, seed ferns lived in a variety of other habitats in southern Scotland during Early Carboniferous time. The oil shale north of Cove Harbour (Craig, 1975) contains abundant *Sphenopteris affinis*, as well as narrow, shallowly penetrating root traces. This was a weakly developed, waterlogged paleosol (Aquent of Soil Survey Staff, 1975), supporting scrubby vegetation similar to modern fen carr. Other seed ferns are now preserved in calcareous nodules (caliche) of paleosols (Inceptisols of Soil Survey Staff, 1975) flanking deposits of a small (about 10 m wide) creek in the Cementstone Group deposits exposed in the southern sea cliffs of Oxroad Bay, south of Tantallon Castle, East Lothian (Long, 1976, 1979b; Barnard & Long, 1973, 1975; Matten et al., 1980; Scott et al., 1984). This fossil assemblage, including *Calathospermum fimbriatum* reconstructed here, appears to have been in large part scrubby, early successional vegetation on the well-drained, ashy soils of a nearby volcano. Even at this early time in the geological history of seed ferns, they appear to have been varied in habit and habitat, and included stately forest trees such as *Stamnostoma huttonense*.

Paleogeographic setting. This plant and its various parts are widely distributed in the lower Cementstone Group of Early Carboniferous age southern Scotland. At this time, the Cementstone Group accumulated in a coastal plain south of a hilly region including basaltic and rhyolitic volcanoes, and north of a shallow marine shelf, a few large islands, and open equatorial ocean (Anderton et al., 1979). Southern Scotland enjoyed a warm tropical climate, in which corals and large fusuline foraminifera flourished. Statistical analysis of palynological data provides evidence of dry climate at this time (van der Zwan et al., 1985). Calcareous nodules in paleosols of the Cementstone Group (Fig. 2A) are evidence of a climate at least as dry as subhumid, and probably seasonally dry. A dry season is also apparent from growth rings in fossil wood of this sequence (Long, 1979a; Creber & Chaloner, 1984) and the development of marine evaporites in tropical seas to the south (Ramsbottom, 1973). Although close to the equator, this area was in the rain shadow of large mountain ranges to the west (Bambach et al., 1980).

LYRASPERMA SCOTICA

Hypothesized reconstruction. *Lyrasperma scotica* is reconstructed as a small bush, with stiff, coriaceous, fernlike leaves (Fig. 3). It probably formed a shrubby understory to swamp woodland of arborescent lycopods around coastal lagoons of the same age and areas already described for *Stamnostoma huttonense*. Its leaves (*Sphenopteridium pachyrrachis* (Goeppert) Potonié, 1899) were strengthened by a thick cuticle and, in the rachis and petiole, by a cortical mechanical tissue (dictyoxylon cortex), formed by radially arranged blades of sclerenchyma. Their petioles (*Kalymma tuediana* Calder, 1938) had a pulvinus and numerous vascular strands. They were borne stiffly and horizontally, in a well-spaced helix on slender erect stems (*Stenomyelon tuedianum* Kidston in Scott, 1909). The stems were smooth and barkless, with an outer dictyoxylon cortex and an inner parenchymatous cortex, and a soft, mixed pith within the central cylinder of secondary xylem. The prepollen organs of this plant are not known, but some ovules were found containing prepollen (*Colatisporites denticulatus* Neville in Neves et al., 1973). The ovules (*Lyrasperma scotica* (Calder) Long, 1960b, when petrified, and *Samaropsis bicaudata* (Kidston) Kidston, 1902, in compression) were lenticular and had two prominent horns on either side of the apex. Ovules only have been found isolated. They may have been enclosed within epiphyllous cupules (*Alcicornopteris convoluta* Kidston, 1887). Like other Early Carboniferous seed ferns, pollination was presumably by wind, and dispersal by wind and water. The distinctive large horns of the ovule may have aided dispersal over water.

Evidence for reconstruction. Our reconstruction of this plant is based on the same Early Carboniferous (Tournaisian) locality near Newton Farm, southeastern Scotland, already discussed for *Stamnostoma huttonense* (Wood & Rolfe, 1985; Scott & Meyer-Berthaud, 1985). The attribution of these various remains to one plant is based on the similarity of dispersed prepollen to that found in the ovule; attachment of petrified petioles to petrified stems; the similar size, shape, stelar arrangement, long internodes, evidence of sclerotic nests, and nonanastomosing woody cortex in petrified and compressed petiole-bearing stems; the similar size and shape of petrified and compressed ovules; and consistent association at the same localities (Long, 1960b, 1964). A most important specimen for our reconstruction is the large compressed trunk with attached leaves excavated by Long (1964). Although pinnae associated with this compressed trunk agree with *Sphenopteridium pachyrrachis*, the petioles of the specimen lack the pinnae below the fork and the rough transverse bars usually found in that species (Long, 1964). Comparably anomalous compression fossil leaves were referred to the same species by Walton (1931), and it is uncertain whether this is part of the natural variation of this species or represents a distinct new form.

Habit. This plant had an unbranched erect trunk (Corner's architectural model of Hallé et al., 1978). Its stems were quite succulent, as they had a wide parenchymatous cortex, a mixed pith, and inflated petiole bases (Seward, 1917: 184). Compression of soft tissues in some specimens has given the misleading appearance of "multicellular projections" (Taylor, 1981: 363). These slender stems were strengthened by an outer zone of woody mechanical tissue—bands of sclerenchyma forming a dictyoxylon cortex, which in this plant was not anastomosing. There is no indication of bark, and the stem probably was smooth.

The leaves were coriaceous and strengthened by sclerenchyma within their petioles. The base of the petiole was expanded into a broad, fleshy, pulvinuslike structure. Attached leaves were arranged stiffly and horizontally on the stem.

The arrangement of ovules in this plant is uncertain because they only are known isolated. In similar Late Carboniferous plants described by Delevoryas & Taylor (1969) and Corsin (1928), synangia and ovules were borne bipinnately on what appears to be a fertile frond, in a similar fashion to our reconstruction of *Lagenostoma lomaxii*. In contrast, Long (1977a) has argued that the ovules of *Lyrasperma scotica* were borne in complexly branched cupules, similar to our reconstruction of *Stamnostoma huttonense*. Long's argument is based mainly on the widespread association of ovules (*Samaropsis bicaudata*) and cupules (*Alcicornopteris convoluta*), the very similar anatomy (especially of the lagenostome) of other ovules (*Eurystoma angulare, E. burnense*, and *Hydrasperma longii*) known to be borne in cupules (Long, 1965, 1969, 1975, 1979b; Matten et al., 1980), and the existence of compressed fronds (of *Sphenopteridium pachyrrachis*) showing a trichotomy of the rachis (Kidston, 1923, pl. 39, fig. 5; Long, 1960b). It is most likely that the ovules, and perhaps also sporangia, of this plant were borne within infolded cupules as in *Alcicornopteris*. We regard many of Long's *Alcicornopteris*-like specimens of *Hydrasperma longii* (Matten et al., 1980) as immature and have modeled our reconstruction of the cupule after that of *Eurystoma angulare* (Long, 1969). As in the generalized reconstruction of similar plants by Camp & Hubbard (1963), the cupule is shown erect on the frond for reasons similar to those given for our reconstruction of *Stamnostoma huttonense*.

Reproduction. The early development and pollination of *Lyrasperma scotica* was probably similar to that of *Stamnostoma huttonense*. *Lyrasperma scotica* had a wide, shallow salpinx, un-

C mm

like many other Early Carboniferous seed ferns. The mechanism of sealing the pollen chamber after pollination could not have been by upward growth of a plug of tissue, as envisaged for *Stamnostoma huttonense* or *Lagenostoma lomaxii*. It may have been by lateral growth of the central column or buckling of the central column by growth of the tent pole.

The prominent horns of the ovule are somewhat reminiscent of those in the living water chestnut (*Trapa natans*), in which barbed spines may serve as floats during dispersal over water and deter consumption by fish or other aquatic vertebrates. The fossil ovule does not have an especially woody or fleshy integument of the kind found in modern fish-dispersed seeds (Gottsberger, 1978).

Habitat. A lowland habitat is indicated by the occurrence of *Lyrasperma scotica* at the same locality on Newton Farm (Fig. 2A) already discussed for *Stamnostoma huttonense* (Wood & Rolfe, 1985; Scott & Meyer-Berthaud, 1985). Here seed fern roots with nonanastomosing striations, like those of this plant, as well as poorly preserved lycopod cones, have been found in paleosols overlying the lagoonal shale. These paleosols lack coal, and fossil root traces penetrate them more deeply than usual for permanently waterlogged soils. Nor do they have the reddish oxidized minerals of well-drained soils or the prominent relict bedding of very young soils. They were weakly developed, periodically waterlogged, clayey lowland soils (gleyed Inceptisols of Soil Survey Staff, 1975), probably marginal to the lagoon. Fossil fish and shrimp in the underlying lagoonal deposits (Clarkson, 1985) are evidence that this was a brackish-to-freshwater inland part of a large coastal lagoonal system, connected to the ocean. *Lyrasperma scotica* may have formed a shrubby understory to this lagoon-margin woodland.

The suggested succulence and thick leaf cuticles of this fossil plant could be considered indications of a locally or regionally arid climate, but considering geological evidence for its habitat, these features more likely allowed its growth in salty or nutrient-poor, stagnant groundwater. This interpretation is also compatible with the elaborate, fleshy, open-mouthed seeds of this plant, which would have required moist but not necessarily nutrient-rich conditions for germination and early seedling growth.

Paleogeographic setting. This plant is found at several localities in the Cementstone Group of Early Carboniferous age in southern Scotland, in the same region and time as *Stamnostoma huttonense* (Wood & Rolfe, 1985; Scott & Meyer-Berthaud, 1985).

CALATHOSPERMUM FIMBRIATUM

Hypothesized reconstruction. Also of Early Carboniferous age (Tournaisian or 352 million years old), this small herbaceous-to-shrubby plant was possibly an early successional colonizer of the banks of gullies and ephemeral creeks in ash at the foot of volcanoes within a large rift valley, now the Midland Valley of Scotland (Fig. 4). Its leaves (*Sphenopteridium capillare* Walton, 1931) were dichotomously forked, and the pinnae copiously divided into terete and filiform segments. The stem (*Calathopteris heterophylla* Long, 1976) had a wide cortex with narrow medullated rings of secondary xylem. Ovules were borne within large cupulate structures (*Calathospermum fimbriatum* Barnard, 1960), which had a series of pinnae on the petiole like those of ordinary foliage leaves. Within the cupule were about 16 erect-growing, elongate ovules (*Salpingostoma dasu* Gordon, 1941). The prepollen organ (not yet known) may have been attached to the central stalk of a trichotomously divided leaf rachis. It may have been a copiously branched structure with numerous elongate sporangia, as in allied seed ferns. The prepollen of this plant (*Perotriletes tessellatus* (Staplin) Neville in Neves et al., 1973) were so large (104 μm in diameter) that this plant may have been pollinated by small animals. The long integumented ovules may have been shaken from the cupules by wind.

Evidence for reconstruction. The various parts of *Calathospermum fimbriatum* have been put together from similarities in anatomy and hairs between isolated ovules and cupules; from the similar anatomy of petioles of petrified cupules and petioles of petrified stems; and from close association at one especially well-studied locality (Barnard, 1960; Long, 1976; Scott et al., 1984). These are the calcareous, nodular layers of a buried creeklike feature in sea cliffs south of Tantallon Castle, in Oxroad Bay, East Lothian, Scotland (Long, 1976). This is part of the Cementstone Group, Calciferous Sandstone Series, of Early Carboniferous age (late Tournaisian or Courceyan of Scott et al., 1984), or 352 million years ago (following Palmer, 1983).

The prepollen of this plant have been found in petrified ovules (Long, 1976) and are similar to a common type of dispersed grain (Neves et al., 1973). Similar prepollen are found in a fructification of another closely allied species (*Staphylotheca kilpatrickensis* Smith, 1962) from another Scottish locality of comparable age (Loch Humphrey Burn). The prepollen organ of *Calathospermum fimbriatum* may have been similar in some respects but remains unknown. Only the petioles likely to have borne the prepollen organ of *Calathospermum fimbriatum* are known.

No compression fossils have been found in association with the petrified remains, but the petrified pinnae below the fork of the cupule agree in all respects with *Sphenopteridium capillare* (G.J.R., pers. obs.), a leaf known from other localities in Fife, Scotland (Walton's, 1931, material from Burntisland; British Museum (Natural History) specimen v31831 from Ardross). Unlike Oxroad Bay, these Fife localities are within the Oil Shale Group or its equivalents (MacGregor, 1968) and are slightly younger (Visean) within Early Carboniferous time (equivalent or older than Pettycur fossils from this area; Scott et al., 1984).

Other kinds of fronds are unlikely to have belonged to this plant, as they are thought to have had quite different fructifications (*Stamnostoma huttonense* and *Lyrasperma scotica*, as reconstructed here, and fertile *Sphenopteris bifida* of Long, 1979b), or they differ in having few (*Sphenopteris affinis*: see Kidston, 1924, pl. 100, fig. 1) or no pinnae below the fork (*Adiantites machanekii*, *Diplotmema bermudensiforme* and *Spathulopteris ettingshausenii* of Walton, 1931). The other common kind of leaves of this age (*Rhacopteris* spp.) were unforked, although their microsporangiate axes were forked (Walton, 1926). Compression fossils showing these leaves attached to stems (Walton, 1926) are very similar in size, phyllotaxy, angle of attachment of petioles, and spacing of pinnules to petrified plant remains (referred to Buteoxylaceae by Barnard & Long, 1973, 1975), different from the plant reconstructed here.

Habit. From a distance these plants probably looked like umbelliferous weeds, such as hemlock (*Conium maculatum*) and anise (*Pimpinella anisum*). The stem of *Calathospermum fimbriatum* was weak, with medullated secondary wood (Long, 1976). No growth rings were seen. The single stem found was densely clothed in leaves and showed no branches within its 17 cm length (Long, 1976). It was not a copiously branched plant and had much weaker wood than seed ferns such as *Stamnostoma huttonense*. We have reconstructed it as a small shrub, but the available specimen may have been a young plant of a species usually more complex in architecture (G. W. Rothwell, pers. comm., 1985).

Reproduction. The enlargement and differentiation of the megagametophyte between the time of pollination and fertilization was not synchronous. There are small, poorly developed ovules on short stalks near the base of the cupule, as well as large, mature ovules on long stalks near the mouth of the cupule (Barnard, 1960). Such variation in development is not nearly so marked in other Early Carboniferous seed ferns, although these do include occasional "aborted" ovules (Long, 1960a). "Continuous flowering" of this kind is commonly found in modern plants of disturbed habitats, where opportunities for seedling establishment are unpredictable (Heinrich, 1976).

Several features of this plant suggest a syndrome now associated with pollination by animals (Faegri & van der Pijl, 1966). These features are especially striking in comparison with co-existing wind-polli-

nated seed ferns such as *Stamnostoma huttonense* and *Lyrasperma scotica*. The cupules were large and almost radially symmetrical, and so might have been easily recognized by animals. They were borne erect, as can be seen from the kink where the cupule was bent farther upwards (adaxially) on the attached petiole (Barnard, 1960; Long, 1975). The prepollen of this plant were large (104 μm), much larger and heavier than is effective for wind-pollinated plants today (Whitehead, 1969). Finally, the ovules and the interior of the cupule were covered with numerous glandular hairs (Gordon, 1941; Barnard, 1960) of unknown function. They may have offered a nutritional reward to animals or protected the ovules from them.

It is difficult to be certain what kinds of creatures could have been pollinators—few likely terrestrial animal fossils are known from this geological time. There is a poor Late Devonian and Early Carboniferous fossil record of canopy-dwelling spiders and mites. Winged insects are not found as fossils in rocks older than earliest Late Carboniferous (Namurian: Rolfe, 1980).

The propagules of this plant appear to have been individual ovules, because only a few mature ovules are found in any particular cupule, and in some cases cupules contain none. Mature ovules were elongate and of moderate size (6 mm diameter and 5 cm long including nucellar extensions). There were zones of resinous hairs on the inside of the nucellar extensions and between the ribs of the body of the ovule, which was enveloped in a hard sclerotesta. The whole structure is larger, heavier, and more elaborate than propagules usually dispersed by wind or water alone, such as the pappus of modern Compositae which Walton (1964) thought comparable. They were probably shaken loose from the cupule by wind (a "wind ballist" of van der Pijl, 1972). Also possible is dispersal by ground-dwelling spiny millipedes and similar large arthropods (Rolfe, 1980).

Habitat. This fossil plant at Oxroad Bay is found encased in calcareous nodules (caliche) of weakly developed paleosols (Inceptisols of Soil Survey Staff, 1975) on the aggrading banks of a small (10 m wide) creek deposit (Gordon, 1941, pl. 1, fig. 1; Scott et al., 1984). The stabilized banks (rooted calcareous nodules) can be seen to be laterally impersistent, eroded on top, and covered alternately on each side of the creek. The area was well drained and quite near the volcano, as can be seen from the nature of these paleosols and associated bouldery volcanic mudflows. In such well-drained, frequently disturbed soil one would expect small, xeromorphic, and early successional plants.

Such a habitat agrees with several adaptive features of this plant: small size (Long, 1976), dissected pinnae (Walton, 1931; Barnard, 1960), cupular protection of ovules (Barnard, 1960), long extensions of the ovular integument, and hairy coat and woody integument of the ovule (Gordon, 1941). This also is compatible with what is known about the other fossil plants found there (listed by Scott et al., 1984). Lycopods and remains of arborescent plants such as *Stamnostoma huttonense* are rare and fragmentary. Most common are small seed ferns and enigmatic plants (family Buteoxylaceae).

Paleogeographic setting. This reconstruction is based mostly on petrified fossils of Early Carboniferous (late Tournaisian) age, from Oxroad Bay, East Lothian, Scotland (Long, 1976; Scott et al., 1984). Only the basal parts of pinnae are known from Oxroad Bay, and the remainder of the frond is modeled after compressions from Ardross and Burntisland, Fife, Scotland (Walton, 1931; British Museum specimen v31831).

All of these localities were in a large rift valley, now occupied by the Midland Valley of Scotland. This was flanked by the Grampian Highlands to the north and the Southern Uplands to the south, and opened out to the sea toward the southwest (Anderton et al., 1979). It was a volcanic landscape with extensive flows from fissure eruptions and some imposing alkali-basaltic volcanoes (Francis, 1983).

Calathospermum fimbriatum may have lived more inland and at higher elevation than the coastal lagoons colonized by *Stamnostoma huttonense* and *Lyrasperma scotica*, and probably in a similar subtropical and seasonally dry climate. As Gordon (1941) argued, it may have lived in a drier climate than these other plants. It was within the rain shadow of rift valley walls, volcanoes, and the mountain ranges of the Grampian Highlands and contiguous ranges now in North America (Bambach et al., 1980).

LAGENOSTOMA LOMAXII

Hypothesized reconstruction. We envisage *Lagenostoma lomaxii* as a shrub with an irregular crown of large leaves (Fig. 5). It grew in extensive, permanently waterlogged swamps, dominated by arborescent lycopods, on deep peaty soils. During the early part of the Late Carboniferous (early Westphalian A or about 320 million years ago) this area was in the subhumid tropics. The trunk (*Lyginopteris oldhamia* (Binney) Potonié, 1899) was slender (3–4.5 cm diameter) and strengthened by a thick outer zone of sclerenchyma forming an anastomosing system of radially arranged plates (dictyoxylon cortex). The lower part of the stem was anchored by numerous slender prop roots (*Kaloxylon hookeri* Williamson, 1875), which ran directly down from the stem and branches but did not sheath the stem as they do in many modern tree ferns and palms. Its petioles (*Rachiopteris aspera* Williamson, 1874) were flattened and had two vascular strands near the base. The leaves (*Sphenopteris hoeninghausii* Brongniart, 1828) were large and spreading, with a dichotomously forked rachis and numerous small, orbicular, third-order pinnules. The frond rachis and the stems were clothed in prominent stalked glands. Cupulate ovules (*Lagenostoma lomaxii* Williamson in Oliver & Scott, 1903, when petrified, and *Calymmatotheca hoeninghausii* (Brongniart) Stur, 1877, in compression) were borne pinnately, in modified apical parts of fronds. Prepollen organs are not certainly known, and prepollen are represented only by badly corroded specimens within the pollen chamber of the ovules. The cupulate cover to the ovules was liberally studded with stalked glands like those on the stem and leaves.

Evidence for reconstruction. Our reconstruction of *Lagenostoma lomaxii* is based principally on structurally preserved fossils in coal balls from the Hough Hill Colliery, presently abandoned on the south face of the hill 1 km south of Stalybridge, near Manchester, in Cheshire, England (Stopes & Watson, 1909). They come from the "Six Inch Mine Coal" of the uppermost Millstone Grit, of early Late Carboniferous age (early Westphalian A; Tonks et al., 1931; Phillips, 1980) or about 320 million years ago (in time scale of Palmer, 1983). The distinctive stalked glands on these fossil leaves, petioles, stems, and cupules were the main evidence used by Oliver & Scott (1903, 1904) in their reconstruction of this plant, which was the first indication that some gymnosperms included plants with fernlike leaves. There are additional anatomical similarities between the various parts, which are closely associated in coal balls and shales (Benson, 1904; Oliver & Scott, 1903, 1904; Seward, 1917; Jongmans, 1952; van Amerom, 1968).

There has been considerable debate about the likely prepollen organ of this plant. Benson (1904) argued that it was *Telangium scottii*, but *T. scottii* is nonglandular, and so more likely to have belonged with *Lagenostoma ovoides*. Kidston (1905, 1906) thought the prepollen organ was the fossil now known as *Crossotheca kidstonii* (Hemingway) Jongmans (1952) found attached to leaves in siderite nodules of slightly younger geological age (Westphalian B) in the Lancashire Coalfield. However, Jongmans (1952) pointed out that the attached foliage belongs to another species of *Sphenopteris*, lacking the characteristic stalked glands. A third possibility figured by Seward (1917) is a fragment of a petrified pinnule with an attached sporangium on the abaxial side, and a nearby emergence where it appears that another sporangium may have fallen off. A similar specimen with glands and stalks was figured by Kidston (1906, fig. 2). Until this material is studied further, the prepollen also remain poorly known, because those found in the ovules are too badly corroded to be identified with dispersed species.

Habit. Because of the small size of these stems (up to 4.5 cm diameter), this plant has been considered a vine (Phillips, 1981). This was a common habit for some Carboniferous seed ferns such as *Callospermarion pusillum* (reconstructed here). By comparison *Lagenostoma lomaxii* has a much more prominent zone of mechanical tissue in the cortex and a lesser development of secondary xylem, and lacks asymmetric wood. This plant is also very abundant locally (it may comprise up to 38% by volume of some coal balls: Phillips, 1981). It may have grown in waterlogged soils, because there are lacunae within the cortex of the stems (Blanc-Louvel, 1966). It was branched copiously, with some very slender branchlets (Blanc-Louvel, 1966). Both axillary and nonaxillary lateral branching have been observed. For all these reasons we do not think that *Lagenostoma lomaxii* was a vine. Nor do we follow the reconstruction of Scott (1900), showing the plant leaning for support on adjacent trees. Instead, it was probably a shrubby plant with a tangle of prop roots (Attim's model of Hallé et al., 1978).

Reproduction. Judging from compression fossils (Jongmans, 1952) and the anatomy of cupule stalks (Oliver & Scott, 1904), the cupulate ovules were borne pinnately on fertile fronds or parts of fronds. After pollination, the prepollen chamber was occluded by growth of the central column against the overarching sclerotesta of the ovule.

A considerable delay between pollination and fertilization is likely. This would account for the abundance of either ovules or of pollen organs of allied species, but not both, in association with compressed foliage. Jongmans (1952) has argued

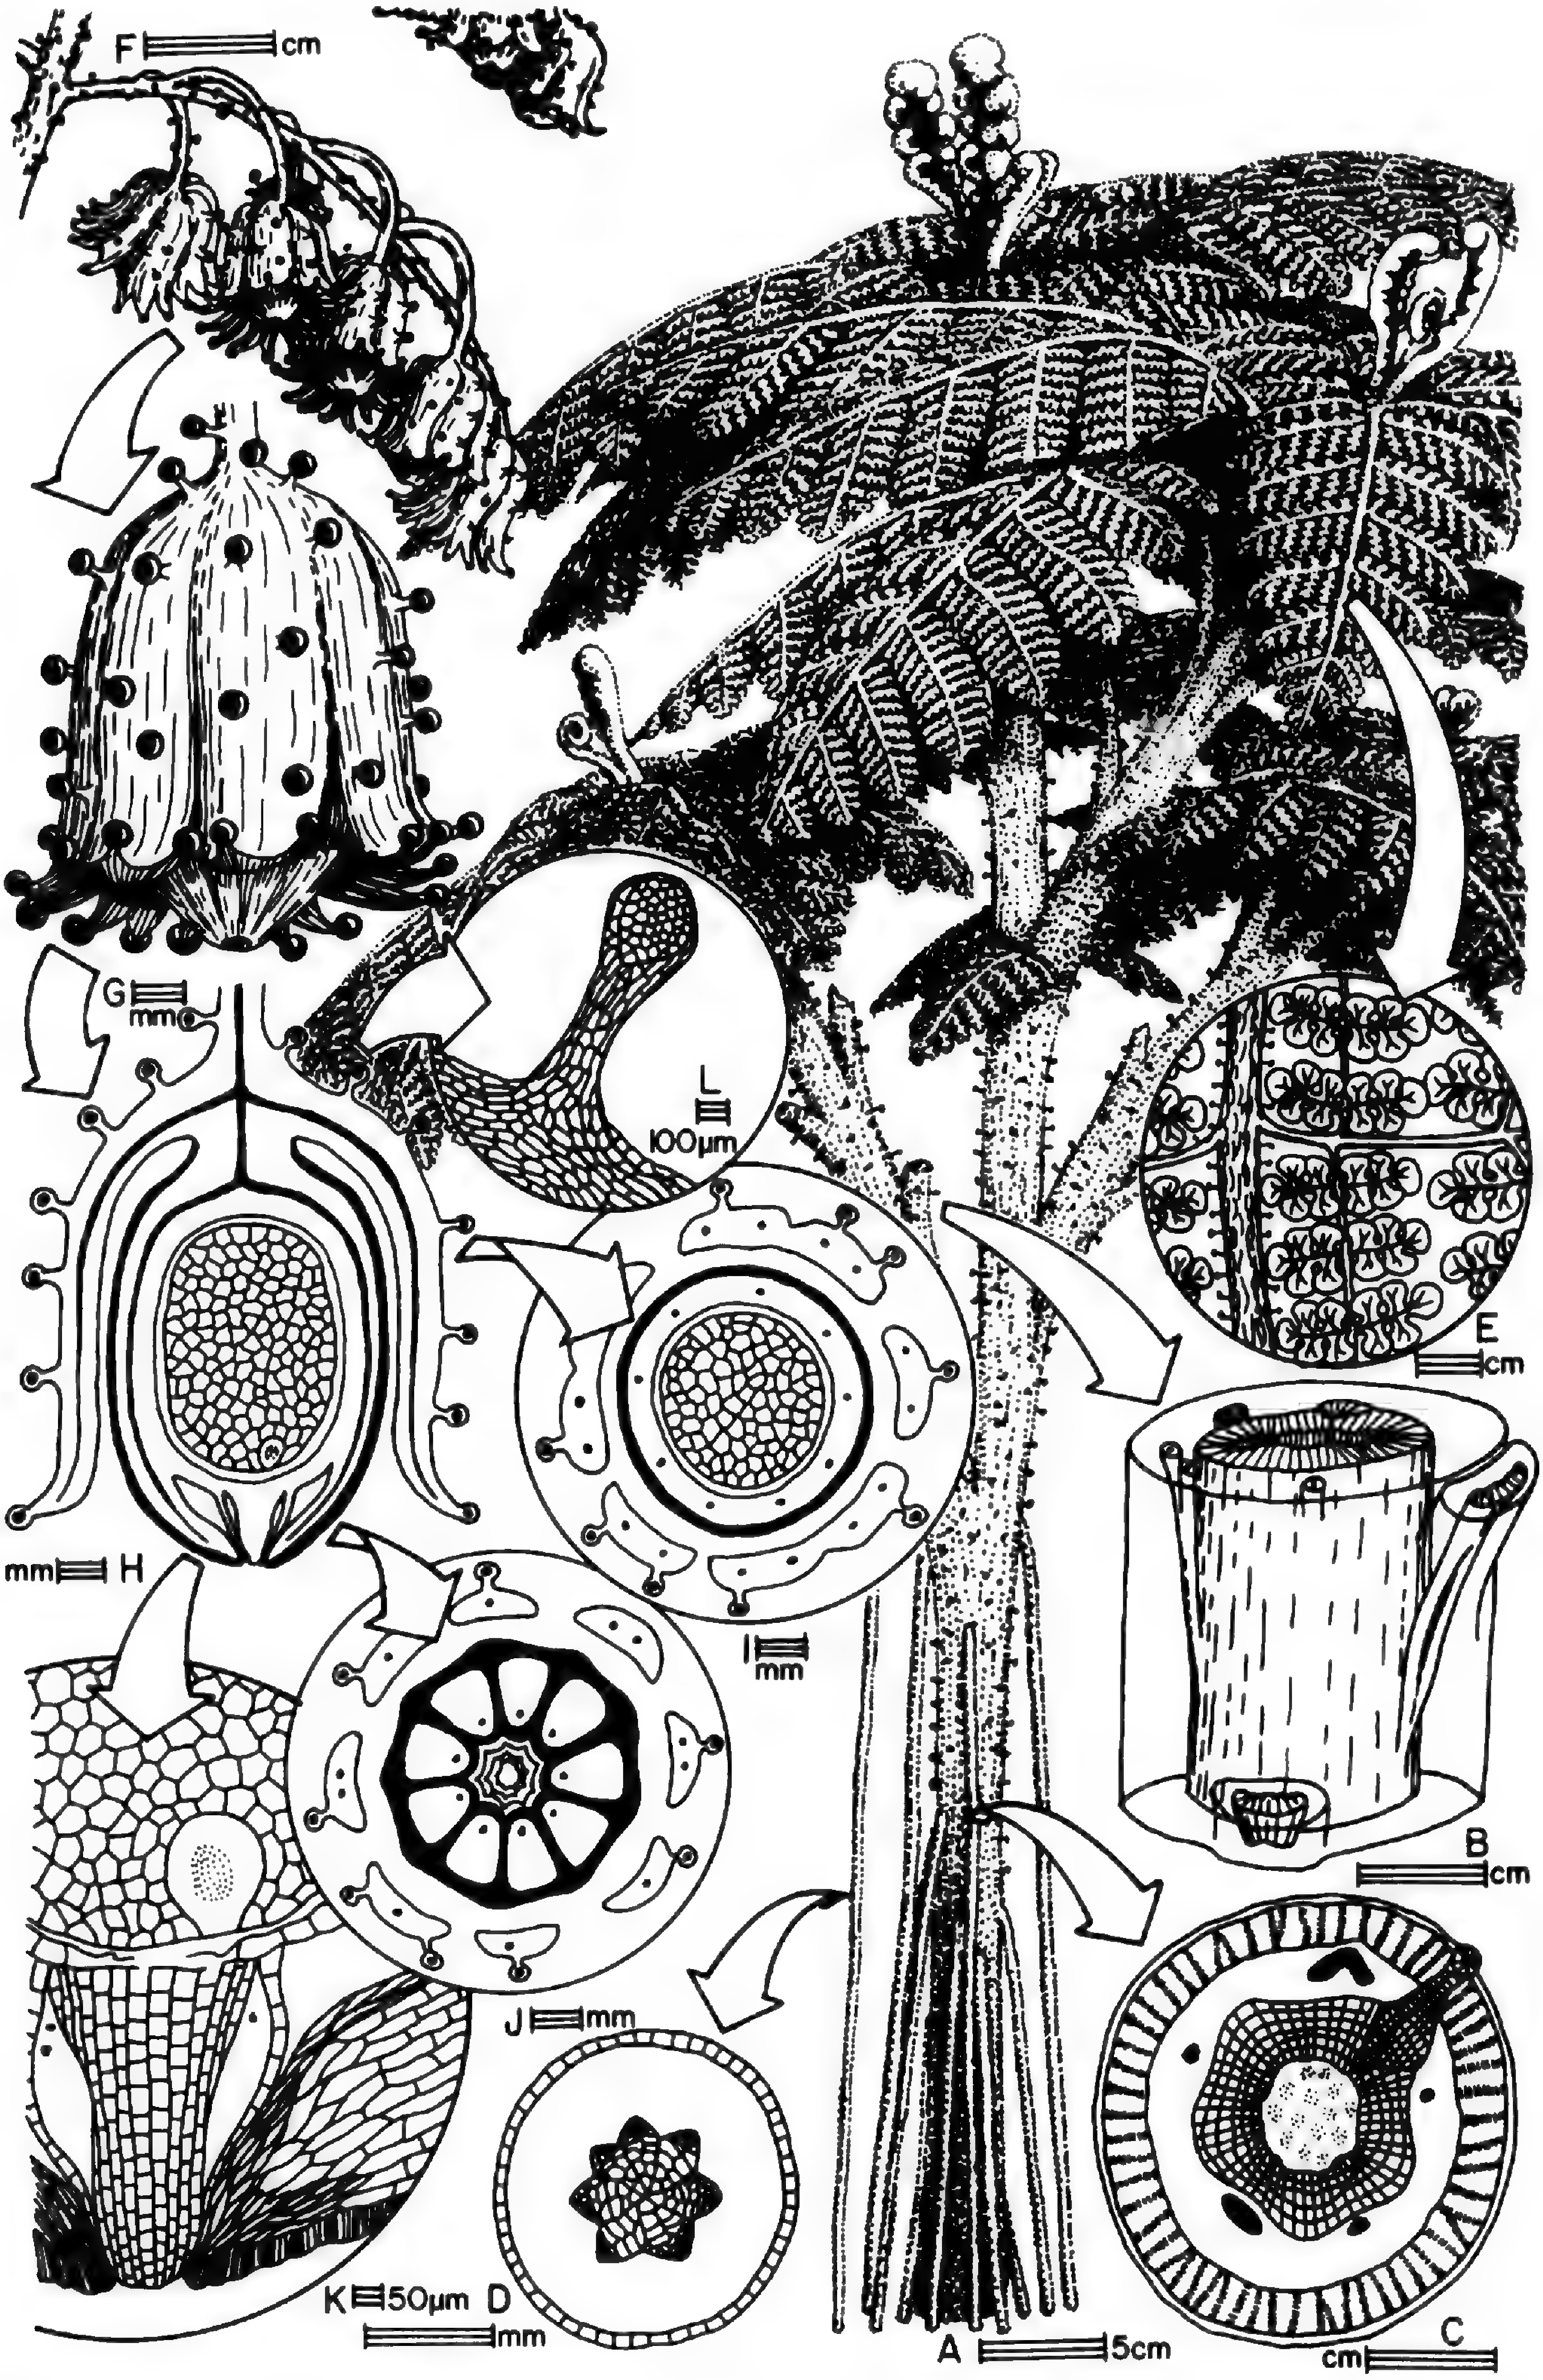

FIGURE 5. *A reconstruction of* Lagenostoma lomaxii *of earliest Late Carboniferous (Westphalian A) age, from Hough Hill Colliery, near Stalybridge, Cheshire, England.—A. Habit as a swampland shrub.—B. Xylem model of stem and petioles.—C, D. Schematic cross sections of stem and of root (respectively), showing mixed pith*

that pollen organs and mature ovules were produced, abscised, and then decayed during different parts of the year. Compressions of conical cupules lacking prominent ovules (Jongmans, 1952; van Amerom, 1968) may have been fertile fronds with immature ovules at or close to the time of pollination. Petrified ovules containing megagametophytes and archegonia are a good deal larger than these remains and set within a bell-shaped cupule with flaring lobes (Oliver & Scott, 1904).

Lagenostoma lomaxii may have been pollinated by insects, considering the large size (averaging 55 by 70 μm) and coarse ornament of the prepollen (Oliver & Scott, 1904), within the range found in modern insect-pollinated plants (Whitehead, 1969). A case also could be made that the capitate glands were insect attractants, but we find this unlikely. The distribution of glands over almost all known parts of the plant is most compatible with interpretation as organs to deter insect herbivory. Winged insects were around in some diversity and abundance by this geological period (Rolfe, 1980).

By the time the ovule was ready for dispersal, it was about 5.5 by 4.5 mm in size (Oliver & Scott, 1904). The cupule appears to have spread open and the capitate glands withered, judging from compression specimens (Benson, 1904; Seward, 1917). Since many of these lacked attached ovules, it is doubtful that the cupule played a role in dispersal.

Habitat. This fossil plant is best known in coal balls from Hough Hill Colliery near Stalybridge, England (Stopes & Watson, 1909). Coal balls are calcareous or dolomitic nodules found within coal seams (Scott & Rex, 1985). Although modified somewhat during burial (Rao, 1985), coal balls developed as the peat accumulated, as a kind of caliche nodule in peaty soils (Retallack, 1986). In most swamps the development of such nodules is limited by acidity. Coals containing coal balls form under fen or carr vegetation of neutral to alkaline wetlands, where acidity is buffered by a subhumid, seasonally dry climate and nearby limestone bedrock.

The coal containing coal balls in Hough Hill Colliery is interpreted here as the less decayed (mor) humus layer of the organic horizon of a peaty paleosol (Histosol) of permanently waterlogged ground (Fig. 2B). It is underlain by a thick zone of carbonaceous claystone (Tonks et al., 1931) representing a more decayed (mull) humus, which may have formed at a time during the development of this soil when it was periodically better drained. Below this dark clay is gray, leached clay with root traces ("fireclay"). A thin zone of siderite ("ironstone") represents a deep gley horizon of this older paleosol (comparable to cases discussed by Retallack, 1976).

This paleosol changes character along strike, and in places the organic horizon (Six Inch Mine Coal) directly overlies levee (Rough Rock Flags) and channel deposits ("massive current bedded grit" of Rough Rocks; Tonks et al., 1931) of a former stream. Clayey soils (Entisols of Soil Survey Staff, 1975) of the stream levee supported vegetation dominated by seed ferns, such as *Alethopteris lonchitica* and *Mariopteris muricata* (Stopes & Watson, 1909, discussed this "flora in shales"), quite different from vegetation of the swamp (the flora in coal balls).

The former stream may have flowed into a lagoon or bay, which ultimately inundated the swamp. The shale overlying the coal contains marine fossils such as goniatites (*Gastrioceras* sp. aff. *G. listeri*) and scallops (*Pterinopecten papyraceus*, ?*Posidonomya insignis* and *Posidoniella* sp.: Tonks et al., 1931) as well as plant fragments (*Lepidodendron lycopodioides*: Stopes & Watson, 1909).

In general, *Lagenostoma lomaxii* is found in coal balls dominated by the remains of arborescent lycopods (more than 90% by volume of the coal ball assemblage: Phillips, 1981) and a variety of understory ferns (Phillips, 1980). We envisage it as a small bush of these lycopod-dominated wetlands. Vegetation of these permanently waterlogged woodlands was distinct from that of streamsides, which were dominated by other seed ferns. There was not any detectable marine influence in these lycopod woodlands, although coastal lagoons may not have been far away.

Paleogeographic setting. *Lagenostoma lomaxii* is best known from coal balls in the uppermost Millstone Grit (Stopes & Watson, 1909; Tonks et al., 1931; Phillips, 1980). The same species is

found also in shales of about the same age elsewhere in the British Isles and western Europe (Jongmans, 1952).

In Cheshire, the coal accumulated as peat in a coastal swamp on the northern margin of the Wales–Brabant landmass (Anderton et al., 1979), which was a promontory extending west into the mountains of eastern North America (Ziegler et al., 1979). During most of the Late Carboniferous this was a subhumid part of the tropics, in the rain shadow of mountains to the west (Bambach et al., 1980). There were dry periods (perhaps seasonal) and forest fires, which left charcoal in the swamps (Scott, 1979).

PACHYTESTA ILLINOENSIS

Hypothesized reconstruction. *Pachytesta illinoensis* was similar to modern tree ferns in overall appearance (Fig. 6). It probably grew on river and deltaic levees and other open and slightly elevated or disturbed areas of midcontinental North American coastal swamps of late Pennsylvanian (Stephanian) age, about 296 million years ago. By this time the dominant swampland plants were no longer arborescent lycopods but marattiaceous tree ferns. By comparison with these and modern tree ferns, this plant had less copiously divided and more leathery leaves (*Alethopteris lesquereuxii* Wagner, 1964). Its trunk (*Medullosa noei* Steidtmann, 1944) was formed largely of closely adpressed leaf bases. It had a wide fleshy cortex and little woody tissue. Large ovules of this plant (*Pachytesta illinoensis* (Arnold & Steidtmann) Stewart, 1954) hung pendulously from beneath terminal pinnules. Synangiate prepollen organs (*Bernaultia formosa* (Schopf) Rothwell & Eggert, 1986) containing large prepollen (*Schopfipollenites ovatus* (Schopf) Potonié & Kremp, 1954) dangled in pinnate structures replacing parts of fronds. These fructifications were among the largest and most conspicuous of Carboniferous swamps, and the prepollen grains so unusually large and heavy that insect pollination is likely. Among the great variety of Late Carboniferous insects known, Paleodictyoptera such as *Homaloneura dabasinkasi* Carpenter (1964), shown in our reconstruction, were the most likely pollinators of these plants. After pollination, the megagametophyte differentiated and the pollen chamber was sealed by continued growth of the outer integument. The large (2.5 by 4.5 cm) ovules had well-developed fleshy layers of the kind attractive to animal dispersers. Their sclerotesta could have protected them from crushing and acids of the digestive tract. Animals of that time sufficiently large to swallow such ovules included reptiles, amphibians, fish, and sharks. With large food reserves, the young seedlings could grow in the shade and tolerate other adverse influences of competing vegetation. Although this plant is associated with disturbed, nutrient-rich parts of swamps, it was probably not the earliest successional colonizer, but a later species in plant succession.

Evidence for reconstruction. Our reconstruction is based on remains preserved in coal balls from the bed of Sugar Creek 3.7 km northwest of Berryville, Lawrence County, Illinois. Another well-known locality is a tributary of Bonpas Creek 4.5 km east of Calhoun, in nearby Richland County, Illinois. These are both from the Calhoun Coal of the Mattoon Formation in the McLeansboro Group, of Late Pennsylvanian (Stephanian) age (Phillips, 1980), or about 296 million years ago (in time scale of Palmer, 1983). Our reconstruction may also be valid for fossils from coal balls of the Herrin No. 6 coal of slightly older (Westphalian D) Pennsylvanian age, where many of the species gathered together here have been found in association (Phillips & DiMichele, 1981). Because of the probability of mosaic evolution, we do not mean to imply that the whole plant existed in every locality where some small part of it has been found. The attribution of these various remains to one plant is based on the

anatomical similarity of petioles attached to leaves, stems, and prepollen organs (Ramanujam et al., 1974); the similar pollen found in prepollen organs and ovules (Taylor, 1965); and close association of different organs in coal balls (Schopf, 1948; Taylor, 1965; Phillips, 1981).

Although preserved as petrifactions, splitting and degaging of coal balls has revealed the nature of the leaf, which conforms in shape and venation to *Alethopteris lesquereuxii* var. *cerverae* Wagner, 1968 (Stidd, 1981), and has a cuticle (Ramanujam et al., 1974; Oestry-Stidd & Stidd, 1976; Reihmann & Schabilion, 1976, 1978) generally similar to that of the compression species *A. davreuxii* (Barthel, 1962). There are other alethopterid leaves in coal balls at the main locality for this plant (Berryville, Illinois), and these have blunter, shorter, and straighter pinnules, more like the impression species *A. bohemica* and *A. grandinoides* var. *subzeilleri* (Mickle & Rothwell, 1982). Similar impression fossils have been found in nearby Indiana with numerous small ovules attached (Taylor, 1981, figs. 13–18A, B), and it is likely that this second type of frond is the foliage of other small fructifications, such as *Pachytesta berryvillensis* and *Dolerotheca villosa*, also found in Berryville coal balls (Schopf, 1948; Taylor, 1965; Phillips, 1980). There is only one other allied species in these coal balls (*Pachytesta hexangulata*), and this is much rarer than the other two (known from only one specimen: Taylor, 1965).

Habit. Our reconstruction of *Pachytesta illinoensis* follows that of Stewart & Delevoryas (1956), which is drawn as if it were a young plant. Fossil stems of this plant range from 10 to 50 cm in diameter. They probably were about 5 m high and occasionally attained heights of 10 m (Wnuk & Pfefferkorn, 1984). It is a common plant, yet branches have not been found on long stem compressions (Pfefferkorn et al., 1984), so it probably conformed to Corner's architectural model (of Hallé et al., 1978), as do modern tree ferns such as mamaku (*Cyathea medullaris*) of New Zealand. As in modern tree ferns, *Pachytesta illinoensis* probably had a crown of about ten large leaves, oriented so that a good deal of the trunk was visible from the side (Wnuk & Pfefferkorn, 1984). Like these modern plants also, it was perennial, growing slowly by the development of new leaves above the leaf bases of the old crown. The trunks were strengthened somewhat by several bundles of wood. These were not separate steles, but rather a single eustele with secondary xylem and phloem developed in several separate bundles (Basinger et al., 1974; Stewart, 1983; Smoot, 1984b). The base of the plant was invested in adventitious roots, although these did not cover the stem to the same extent as in associated fossil tree ferns, and it was more like New Zealand mamaku in this respect. Like this modern plant also, the fossil trees lacked lacunar spaces in their roots (Phillips, 1981).

The large, hemispherical, compound prepollen organ (microsynangium) included numerous elongated sporangia oriented perpendicularly to the flat side. The pattern of their open ends in this flat (lower) side is almost radial and has been interpreted to be homologous to an infolded stack of bladelike synangia (Rothwell & Eggert, 1982, 1986) and, alternatively, to a branch of pinnately arranged individual sporangia (Dufek & Stidd in Stidd, 1981). By either arrangement and considering the number of vascular strands in its petiole (Ramanujam et al., 1974), each large synangium is the morphological homolog of a primary pinna of a frond. We do not think that prepollen organs were scattered randomly among otherwise sterile fronds, an impression that could be gained from uncritical inspection of the reconstruction of Ramanujam et al. (1974). They were probably borne pinnately in special fertile fronds or parts of fronds. Such an arrangement has been demonstrated for other synangia of closely comparable structure (*Potoneia*), but containing different prepollen (Taylor, 1982, pl. 6, fig. 2).

Ovules of *Pachytesta illinoensis* have not been found attached, but their mode of attachment can be inferred from similar compressions of ovules found attached under the terminal pinnule of the leaves (Crookall, 1959). We do not think that they formed at the end of the pinna (as reconstructed by Darrah, 1939: 95). Close inspection of these specimens often reveals the terminal pinnule twisted into a less-conspicuous upright position beside the heavier and larger ovule (Crookall, 1959: 27, figs. 1–5). Other related species of ovule have been found attached farther back on the rachis of the pinna (Halle, 1929; Wagner, 1968; Zodrow & McCandlish, 1980).

Reproduction. The prepollen of *Pachytesta illinoensis* had an alveolate exine ultrastructure and was so large (300–350 μm long by 200–250 μm wide) and heavy that it would not have been dispersed far by wind. It was more likely dispersed by insects (Taylor, 1978). The glandular hairs of the microsynangium and the resinous internal glands of both the microsynangium and ovules may have produced a nutritional reward for pollinating insects or have deterred their herbivory. Both organs also were enclosed in fleshy tissue, which may have been nutritious.

It is uncertain which among the great variety of Carboniferous insects known could have pollinated this plant, but several circumstantial lines of evidence implicate Paleodictyoptera. These were superficially like modern dragonflies, but, unlike these modern carnivorous insects, had only narrow sucking mouthparts (Kukalova, 1970). The example we have shown in our reconstruction is *Homaloneura dabasinkasi* Carpenter, 1964, known largely from wings with camouflage color-banding in siderite nodules of slightly older Late Carboniferous age (Westphalian D) near Braidwood, Illinois. Paleodictyopterans were active, flying insects, with large compound eyes and hairy legs: all features of modern insect pollinators. Their sucking mouthparts match in size and shape the fine borings seen in petrified microsynangia and ovules (Schopf, 1948). The claim of paleodictyoptera as pollinators of these plants could be regarded as diminished by the discovery of prepollen like that of *Pachytesta illinoensis* lodged in the leg joints of a large fossil millipedelike creature (Scott & Taylor, 1983), but it is unlikely that these extinct arthropods were any more adventurous in the canopy than modern litter-feeding millipedes (Rolfe, 1980). Coprolites containing these prepollen also have been found (Scott, 1977), but these cannot be attributed to any particular animal. A variety of animals probably ate these grains, both in the canopy and on the ground.

As in all the seed ferns considered here, there was a period of time between pollination and fertilization. For ovules with such large megagametophytes this was probably at least a few weeks. Fossil prepollen grains within ovules of *Pachytesta illinoensis* have been found with two large black bodies (Stewart, 1954), which have been compared to the ciliated, motile sperm of modern cycads (Chamberlain, 1935). Such opaque "spots" in petrified cells also could be remains of decayed cytoplasm, as paleobotanists have learned from painful experience in the study of other fossils (Knoll & Barghoorn, 1975). However, there is other possible cytoplasmic material in the medullosan pollen grain in question.

The ovule of *Pachytesta illinoensis* was conspicuous in its large size (about 2.5 cm in diameter and up to 4.5 cm long). Like many modern stone fruits, the fossil ovules had well-differentiated sarcotesta and sclerotesta. The sarcotesta was especially thick near the apex, which was early to decay or be eaten, judging from some specimens (Stewart, 1954). This succulent flesh may have attracted animal dispersers. The sclerotesta can be seen to seal the micropyle in some specimens (Taylor, 1965). Similar stones in modern fruits serve to withstand crushing and acidity during passage through the guts of animals (van der Pijl, 1972). Of the array of known Late Carboniferous reptiles and amphibians (Moodie, 1916; Reisz et al., 1982), edaphosaurs, temnospondyls, and microsaurs were large enough to have been able to swallow a fruit this size. Considering the likely habitat of this plant, the ovules could have been dispersed by fish, as are some modern angiosperm fruits in the varzea swamp forests of Amazonian Brazil today (Gottsberger, 1978). Large palaeoniscid fish and pleuracanth sharks were common within parts of the Late Carboniferous swamps of Illinois (Zangerl & Richardson, 1963; Zangerl & Case, 1973).

Individuals of *Pachytesta illinoensis* and related plants appear to have borne fruit in massive bursts, judging from local accumulations of petrifactions and molds-and-casts of similar large ovules (Seward, 1917, fig. 423; Tonks et al., 1931, pl. II; Taylor, 1965; Jennings, 1974). Such a reproductive effort probably was not begun until after a few years in the life of the plant. In modern angiosperms, copious production of fruit ensures that some remains unmolested by animals and is especially common in trees with large fruits (Janzen, 1978).

Habitat. This plant was preserved in coal balls in the manner already described for *Lagenostoma lomaxii*. Although *Pachytesta illinoensis* grew in and near swamps, it lacked root lacunae usually found in plants of waterlogged ground and thrived in slightly elevated and nutrient-rich parts of the swamp (Phillips, 1981). A similar habitat is indicated by the bundle sheath cells (Krantz anatomy) found around veins within petrified leaves, thought by Baxter & Willhite (1969) to indicate the C_4 photosynthetic pathway for this extinct plant. Like modern plants using this pathway (Chazdon, 1978), *Pachytesta illinoensis* may have been able to endure hotter, sunnier, and drier sites than many associated plants.

Leaves of the plant had thick cuticles, especially on the adaxial surface. Stomates and hairs were confined to the abaxial surface, and each stomate was overhung by papillae borne on the subsidiary cells (Ramanujam et al., 1974; Oestry-Stidd & Stidd, 1976; Reihmann & Schabilion, 1976, 1978). These are all features of sun leaves of plants subject to deficiency of water or nutrients (Mickle & Rothwell, 1982).

Such large ovules would have been able to main-

tain the growth of seedlings, even under the shade and other adverse influences of other plants, as in modern plants of the "competitive strategy" (of Grime, 1979). Although *Pachytesta illinoensis* is geologically associated with disturbed and more-elevated parts of the swamps, it may have been a late species in succession, growing through and then shading out the earliest successional plants. In better-drained areas outside the swamps, similar plants may have formed stable, long-term communities, but within the swamp itself these plants were less persistent than associated tree ferns and lycopods (Phillips & DiMichele, 1981).

Judging from paleobotanical and palynological studies of Calhoun coal balls (Phillips et al., 1974; Phillips, 1980), *Pachytesta illinoensis* formed a minor part of vegetation dominated by marattiaceous tree ferns (with *Psaronius* spp. trunks and *Scolecopteris* spp. and *Asterotheca* spp. fructifications). Lycopods (*Sigillaria ichthyolepis*) and horsetails (*Calamites retangularis*) were moderately common, and the rest of this diverse flora was made up of rare cordaites, other ferns, and seed ferns.

Ecologically, *Pachytesta illinoensis* probably preferred elevated, slightly dryer, nutrient-rich parts of the swamp where there was either sandy or clayey soil or exposed dry, dusty peat. It was not the earliest successional colonizer of such habitats. In shale floras of stream and lake margins (Scott, 1979), calamites and small ferns appear to have occupied that niche. In coal balls of peat swamps, successional patterns are less clear (Phillips & DiMichele, 1981), but weedy plants of erratic occurrence include other seed ferns (such as *Callospermarion pusillum* reconstructed here), and small herbaceous lycopods and horsetails. Nor were *Pachytesta illinoensis* or allied plants part of marine-influenced swamps (mangroves) at this time. This habitat was dominated by cordaites (Raymond & Phillips, 1983).

Paleogeographic setting. The principal locality for our reconstruction of *Pachytesta illinoensis* is in Sugar Creek near Berryville, Illinois, of late Pennsylvanian (Stephanian) age (Phillips, 1980). Illinois was then part of a large central lowland within North America, bordered on the west by mountains in what is now Nevada and Montana, on the north by low hills and limestone plateaus on the Canadian Shield, and on the east by the Appalachian Mountains. These mountains were much more imposing than they are today, and more like the present European Alps (Heckel, 1977). Much of the mid continent was inundated by shallow seas opening out on deep ocean in the area of modern Texas. At the time the Calhoun Coal formed, the sea extended only as far as western Illinois and Missouri. Most of central Illinois was covered by a swamp, dissected by a large stream system draining the granitic shield and carbonate plateau country to the north. This ancient river is usually called the "Michigan River" but is in some senses a forerunner of the Mississippi (Stanley, 1985). To the west in Indiana and Ohio were more swamps and riverine lowlands. The present area of Illinois was about 5° north of the equator at this time, on the margin of the tropical humid and subtropical subhumid belts (Heckel, 1977). Evaporites formed in the dry climate of the present area of the Black Hills of South Dakota. Climate became increasingly humid southeastward toward the equatorial Appalachian Mountains (Schopf, 1975).

CALLOSPERMARION PUSILLUM

Hypothesized reconstruction. We envisage *Callospermarion pusillum* as a scrambling fernlike vine (Fig. 7). It probably formed dense tangles in moist, disturbed sites within and around Late Pennsylvanian swamp forests of tree ferns. Leaves of this plant (*Dicksonites pluckenetii* (Schlotheim)

Sterzel, 1881) had stomates on both sides and little differentiation between the upper and lower surface. The clambering stem (*Callistophyton poroxyloides* Delevoryas & Morgan, 1954) was woody and perennial. In addition to horizontal runners, there were slender erect leafy stems and, at intervals, stout adventitious roots, which arose in the axils of foliage leaves or from within bifurcations of the main axis. Pollen-bearing organs (*Idanothekion callistophytoides* (Stidd & Hall) Rothwell, 1980) and ovules (*Callospermarion pusillum* Eggert & Delevoryas, 1960) were borne in zones on the abaxial surface of foliage leaves otherwise normal in appearance. The numerous pollen organs released abundant small saccate pollen (*Vesicaspora schaubergeri* (Potonié & Klaus) Jizba, 1962). Pollination may have been by wind and possibly occurred before the megagametophyte or pollen chamber was fully differentiated. After fertilization, which may have occurred on the ground, the seeds were already worn back to their sclerotesta. The numerous small seeds were probably dispersed largely by wind and water.

Evidence for reconstruction. This plant is best known at the locality near Berryville, Illinois, already discussed for *Pachytesta illinoensis*, and also is known from nearby coal-ball localities such as the one near Calhoun, Illinois. Reconstruction of *Callospermarion pusillum* was based on the similarity of secretory cavities in stems, sterile foliage, ovules, and microsporophylls; on the occurrence of similar pollen in the pollen organs, in the ovule pollen chamber, and dispersed; and on close association of its parts (Stidd & Hall, 1970a, b; Millay & Taylor, 1974; Rothwell, 1975, 1980, 1981).

Habit. The young stems have a nearly cylindrical mass of secondary xylem, a thin zone of secondary phloem, and a subsurface zone of mechanical tissue formed from anastomosing bands of sclerotic cells (dictyoxylon cortex: Rothwell, 1975; Smoot, 1984a). These were probably erect, leaf-bearing stems. Older stems do not all have such well-developed mechanical tissue, but rather a thick bark and a large central asymmetric mass of secondary xylem. These were probably horizontal runners. Stout adventitious roots arose from these runners, usually in the axils of leaves, but also within the branches of the main axis (Kidston, 1924; Rothwell, 1975). Buds, petioles, and adventitious roots often arise from within the dichotomies of stems and leaves. These are false dichotomies (Kidston, 1924) arising by development of opposite branches with suppression of the terminal meristem. This branching system is similar to Leeuwenberg's architectural model of plants proposed by Hallé et al. (1978), although the two are not strictly comparable because the leaf-borne fructifications of seed ferns are very different from those of most modern plants. A similar architecture is seen in the modern Australian and Southeast Asian fern *Gleichenia dicarpa*.

The synangiate pollen organs were attached on the underside of the leaves in a manner similar to sporangia of marattiaceous ferns (Kidston, 1924; Stidd & Hall, 1970a). They contain, however, monosaccate pollen rather than fern spores. The saccus is laterally expanded, so that it is superficially similar to bisaccate grains (Hall & Stidd, 1971; Millay & Taylor, 1974). As in modern bisaccate grains, the saccus of the fossil pollen formed by detachment and expansion of the sexine from the lamellated nexine. These fossil pollen also were similar to those of modern gymnosperms in germinating through the side of the grain opposite the point of attachment in the original tetrad, unlike the prepollen of the other Carboniferous seed ferns already considered (Eggert & Millay, 1976).

Ovules and their attachment scars are found over large areas of compressed fronds (Grand'Eury, 1905; Kidston, 1924). Ovules were attached at the ends of veins near the abaxial margin of the pinnules, and their micropyles faced inwards toward the pinnule midribs (Loubière, 1929; Rothwell, 1980).

Reproduction. *Callospermarion pusillum* was probably wind pollinated, considering the moderate size (37–54 μm long by 30–49 μm wide: Millay & Taylor, 1974) of its pollen and the large amount of it produced. Saccae sometimes have been considered the "wings" of wind-dispersed pollen, but they are now thought to have served more for orientation and flotation in an inverted pollination drop (Doyle, 1945). Microgametophytes at the two- and four-celled stage have been found in some synangia (Millay & Eggert, 1974), indicating that these were fully formed at the time of pollination.

In some coal balls, ovules have been found which vary considerably in degree of maturity (Rothwell, 1971). Large fructifications of modern weeds of disturbed habitats show comparable "continuous flowering," thus improving chances that some propagules will mature at an appropriate time (Heinrich, 1976). The youngest ovules found are small and weakly differentiated. At what is thought to have been pollination stage, the ovule was small, with an imperfectly differentiated seed coat and no indication of a megagametophyte. A fossilized pollination drop has been reported in a closely related species (*Callospermarion undulatum*: Rothwell, 1977), but it appears rather more resinous than modern pollination drops (described by Doyle & O'Leary, 1935b) and contains spores known to belong to other plants (Rothwell, 1980). It may be an exudate from the micropyle of a partly decaying ovule rather than a pollination drop. Nevertheless, larger ovules than this do contain pollen grains and have a sealed micropyle, thus suggesting that ovules were at this stage of development at the time of pollination. With further growth after pollination, the micropyle was occluded by growth and differentiation of sclerotesta and sarcotesta as the megametophyte developed. In the most mature ovules, presumably already dispersed, there were several archegonia at the apical end of the megagametophyte, and the sarcotesta was abraded away.

A germinated pollen grain with a branched pollen tube has been found in the pollen chamber of an immature ovule of a related species (*C. undulatum*; Rothwell, 1972). It could be that this pollen tube merely served for nutrition and stabilization of the pollen grain during its long wait until fertilization was achieved by motile gametes. Alternatively, this pollen tube, or at least one branch of it, may have delivered nonmotile sperm nuclei to the archegonium (siphonogamy), as in living conifers such as black pine (*Pinus nigra* = *P. laricio* in Chamberlain, 1935). Rothwell (1980) was impressed with the coniferlike development and morphology of this plant's ovules, pollen, and pollen tubes, and thought that siphonogamy was more likely.

The small ovules were dispersed individually, as can be inferred from compressed leaves showing only the attachment scars where ovules had abscised (Kidston, 1923). The ovules were numerous, small, and somewhat flattened, with narrow wings. They were probably dispersed largely by wind and water. The ovules were made in quantity, rather than quality, thus maximizing the chance that at least a few would find places suitable for germination, as in modern weedy plants ("ruderals" of Grime, 1979).

Habitat. This reconstruction is based on specimens from coal balls found in Sugar Creek northeast of Berryville, Illinois (Rothwell, 1975, 1980), and it is known from coal balls of comparable age at several other localities in the mid-continental U.S.A. (Phillips, 1980). This species of compressed leaves (*Dicksonites pluckenetii*) has long been known from compression floras of Britain and France (Grand'Eury, 1905; Kidston, 1923), where allied species of petrified plants have also been found (Loubière, 1929; Rothwell, 1981). Like *Pachytesta illinoensis* reconstructed here, it was locally abundant in swampy lowlands.

Several features of *Callospermarion pusillum* can be construed as evidence that it was a plant of moist, somewhat shady understory habitats. The pinnules are attached along the middle of the rachis of the frond (Rothwell, 1975), and there is little differentiation between the upper and lower cuticle, both of which are stomatiferous (Barthel, 1962).

Considering this and its weedy reproductive features, we hypothesize that *Callospermarion pusillum* was an early successional plant of disturbed ground. This may have included stream margins, tracts of forest devastated by hurricanes, locally well-drained peat, forest defoliated by fire, or light gaps around fallen trees. It lived among swamp forests dominated by tree ferns during the late Pennsylvanian (Stephanian: Phillips, 1980).

Paleogeographic setting. This plant is known from the locality of *Pachytesta illinoensis* already described. *Callospermarion pusillum* lived in very similar climate and general environment.

DICTYOPTERIDIUM SPORIFERUM

Hypothesized reconstruction. In our view, *Dictyopteridium sporiferum* was a swampland tree, widely distributed in cool-temperate regions of the Gondwana supercontinent during Late Permian time, some 245 to 253 million years ago (Fig. 8). In Queensland and New South Wales, it grew in an extensive system of intermontane valleys west of a volcanic mountain range like that of the modern South American Andes, and east of the plains and hill ranges of inland Australia. Its tongue-shaped leaves (*Glossopteris communis* Feistmantel, 1876) were seasonally deciduous. They had a thick adaxial cuticle and stomates sunken into the abaxial surface. Their venation was reticulate, but not organized into veins of different thickness, as in modern angiosperms. Its wood (*Araucarioxylon bengalense* (Holden) Maheshwari, 1972) was massive and coniferlike, with clear growth rings. Large roots spread out horizontally from the trunk, and the rootlets (*Vertebraria australis* McCoy, 1847) had internal chambers, which may have allowed growth in oxygen-poor, waterlogged, peaty soils. Ovule-bearing (*Dictyopteridium sporiferum* Feistmantel, 1881) and pollen-bearing structures (*Eretmonia* sp. cf. *E. hinjridaensis* Surange & Maheshwari, 1970) were borne on the midrib of leaflike structures. These were arranged helically on fertile

short shoots, but it is not certain whether these shoots were bisexual or unisexual. Pollen sacs (*Arberiella africana* Pant & Nautiyal, 1960) were borne at the ends of slender, copiously branched stalks. They dehisced longitudinally to release numerous bisaccate, striate pollen grains (*Protohaploxypinus limpidus* (Balme & Henelly) Balme & Playford, 1967). These plants were probably wind pollinated. Numerous ovules (*Stephanostoma crystallinum* (Pant) Pant & Nautiyal, 1960) were borne on the underside of a leaflike organ and loosely enclosed by its inrolled margins. The ovules were interconnected by a meshwork of multicellular hairs and probably also a good deal of mucilage. By the time of fertilization the leaflike structure bearing ovules probably was unfurled, shrivelled, and decayed. Seeds were numerous, small, and lightweight. They probably were scattered by wind.

Evidence for reconstruction. This reconstruction is based on petrified material from near the Homevale–Elphinstone road at the southwest property boundary of Homevale Station (or "cattle ranch"), 87 km west-southwest of Mackay, Queensland, Australia (Isbell, 1955; Gould & Delevoryas, 1977). These petrified peats are part of the Fort Cooper Coal Measures, Blackwater Group, of Late Permian age (Jensen, 1975) or about 245 to 253 million years old (in time scale of Palmer, 1983). In these petrified fossils, sterile leaves are anatomically identical to leaflike structures bearing ovules; pollen is present in pollen sacs and in ovules; the same kind of tracheids are found in leaves and trunks; and identical secondary xylem is found in trunks and around large septate roots (Gould & Delevoryas, 1977).

These petrified fossils have not been named but appear identical to several compression fossils from the same region. The petrified fructifications are the same size and elongate shape and enclose numerous wingless ovules of the same size as compression fossils of *Dictyopteridium sporiferum* Feistmantel (1881) from Late Permian coal measures of India (Surange & Chandra, 1975), Queensland (as "*Cistella bowenensis*" of White, 1964, and "*Plumsteadia microsacca*" of Rigby, 1971, 1978), and New South Wales (Holmes, 1974; White, 1978). The petrified material also agrees closely in size and anatomy with compression fossils of ovules and pollen sacs comparable in age from India (Pant & Nautiyal, 1960). The petrified pollen organs have up to 17 pollen sacs in a cluster (Gould & Delevoryas, 1977), more like the compression genus *Eretmonia* than *Glossotheca* (as defined by Surange & Chandra, 1975). Impressions of *Eretmonia* from New South Wales (White, 1978) and a variety of "scale fronds" from Queensland (White, 1964) have a thickened tip, most like *Eretmonia hinjridaensis* Surange & Maheshwari (1970). Most of the pollen from petrified remains (Gould & Delevoryas, 1977) is identical to the broadly defined dispersed species *Protohaploxypinus limpidus* (Balme & Henelly) Balme & Playford, 1967 (Foster, 1975; Rigby & Hekel, 1977).

Impressions of *Dictyopteridium sporiferum* from Queensland have been found attached to leaves of *Glossopteris communis* Feistmantel, 1876 (White, 1964; Rigby, 1971). *Glossopteris communis* is a common fine-meshed leaf, like *G. indica*, *G. linearis*, and *G. angustifolia*. This last-mentioned species also has been considered the leaf of *Dictyopteridium sporiferum*, although on less secure evidence of association and venation density (White, 1964; Maheshwari, 1965). The petrified ovular heads and associated leaves (Gould & Delevoryas, 1977; G.J.R., pers. obs.) were also fine-meshed (veins about 0.2 mm apart), but they have a clearly defined midrib of a size most like that in *Glossopteris communis*. Associated coarse-meshed *Glossopteris* leaves in the Late Permian coal measures of Australia belonged to quite different plants, as shown by their attachment to nearly circular ovulate fructifications bearing winged seeds (Holmes, 1974; White, 1978). The petrified leaves of the

plant reconstructed here are hypostomatic, with low papillae on the abaxial side, similar to the cuticles of the compression species *Glossopteris waltonii* Pant & Gupta (1968), after which our cuticular restoration was modeled.

Petrified wood of this plant, both within trunks and its distinctive chambered roots, includes late wood like *Araucarioxylon arberi* (Seward, 1919) Maheshwari (1972) and early wood like *A. bengalense* (Holden, 1917) Maheshwari, 1972 (Gould, 1975). We have chosen the latter name for our reconstruction on the grounds of priority.

There have been some nomenclatural problems also with the name for the root of this plant, which Schopf (1982) decided should be *Vertebraria australis* McCoy (1847). Only one species of *Vertebraria* is recognized. This fossil species probably includes remains of what were roots of numerous species of glossopterid plants recognized from their reproductive structures.

Habit. The overall habit of the plant has been reconstructed from specimens of trunks showing alternate and whorled branching (Gould & Delevoryas, 1977). The whorled specimen conforms to Rauh's architectural model of modern trees (Hallé et al., 1978). The other trunks may represent other growth forms but also could be old or damaged trunks. Regularly whorled young trees and extensively repaired and irregular old trees are characteristic of many living conifers, of *Ginkgo biloba*, and some angiosperms (Hallé et al., 1978; Retallack & Dilcher, 1981). The wood of this plant was like that of modern softwoods, with very narrow unicellular rays and abundant pitting in the cross field. It was a kind of wood apparently conservative in gymnosperms and still found in many conifers and in *Ginkgo biloba* (Beck, 1971).

Leaves were arranged in close helices on short shoots, which in turn were arranged on long shoots (Pant & Singh, 1974). The venation of the leaves was a fine mesh, with a zone of much narrower meshes and a sclerenchyma sheath forming a midrib. There is a good deal of evidence that these plants were seasonally deciduous: the noncoriaceous nature of the leaves compared with those of associated and presumably evergreen conifers, well-developed abscission scars at the bases of the petioles, and well-marked growth rings in its fossil wood (Gould & Delevoryas, 1977; G.J.R., pers. obs.). A variety of triangular scalelike leaves have been found in association with these fossils (Walkom, 1922; White, 1964, 1978). Some of these were fertile scales, but others may have been young leaves or protective scales of dormant winter buds.

Fertile structures were attached to leaflike organs arranged in a closely spaced helix (Pant & Singh, 1974). Fertile scales arranged on the same short shoot as sterile leaves would have formed distinct clusters (White, 1978). On some short shoots there were up to three kinds of scales or leaves (White, 1978), but there is no evidence that any of these shoots were bisexual.

Pollen sacs were borne at the end of copiously dichotomizing stalks arising from the midrib of a scale leaf. Although much reduced, this epiphyllous structure is similar to that found in seed ferns such as *Telangium affine* (Kidston, 1923) and *Diplopteridium teilianum* (Walton, 1926, 1931). In many of these Early Carboniferous plants, the sporangia were fused into bell-like synangia, but in *Dictyopteridium sporiferum* the sporangia were free, as in other enigmatic Early Carboniferous plants (Skog & Gensel, 1980) and Late Devonian progymnosperms (Beck, 1981). The walls of each pollen sac were only one cell thick (Gould & Delevoryas, 1977). They opened by way of a long, sinuous slit (Pant & Nautiyal, 1960), which presumably developed because of diagonal stresses arising during drying.

Ovules were borne on the underside of an infolded leaflike structure which was attached by a long stalk to the midrib of the adaxial side of what looks like an ordinary foliage leaf. This epiphyllous structure also can be compared with fructifications of Early Carboniferous seed ferns, such as *Sphenopteris bifida* (Long, 1979b). The structure of these fossils was anticipated in some studies of impression fossils (Schopf, 1976) but did not become clear until well-preserved petrified fossils were studied (Gould & Delevoryas, 1977). In earlier studies of impressions, they were thought to have been bivalved cupules (Plumstead, 1958a) or bracteate cones (Surange & Chandra, 1975). The first view is now thought incorrect, but the second interpretation has gained some support from experimental compaction of model structures (Rex, 1986) and from cuticular studies of compressed specimens (Chandra & Surange, 1976). In our view, however, the three separate cuticles can be explained as (1) a central abaxial hair-bearing cuticle with holes marking positions of ovule attachment; as (2) a peripheral abaxial stomatiferous cuticle with hair bases; and as (3) an adaxial thick nonstomatiferous cuticle. A comparison of experimentally deformed structures with compression fossils indicates that some real biological diversity may be reflected in the large number of generic names for glossopterid fructifications (reviewed by Rigby, 1978), but some of them may be merely different developmental and preservational states of the same kinds of fructifications (Gould & Delevoryas, 1977).

Reproduction. Each pollen sac contained numerous pollen grains. The combined release of pollen from a stand of trees could have produced clouds of yellow dustlike grains. Considering the amount of pollen produced and its moderate size (32–46 μm in breadth and 14–26 μm in corpus diameter: Gould & Delevoryas, 1977), this plant was probably wind pollinated. As in *Callospermarion pusillum,* the saccae may have served to orient and float the grains in a pollination drop. Stout striae on the body of the pollen grain also may have functional significance, because similar striate bisaccate grains were also produced by apparently unrelated seed ferns in Permian coal swamps of Siberia (Meyen, 1984). Mormon tea (*Ephedra* spp.) has pollen with bands that strengthen the grain against stresses arising from desiccation in a dry climate (Hughes, 1976). Striae on the pollen of *Dictyopteridium sporiferum* may have served to withstand stresses associated with moisture losses during wind pollination.

At the time of pollination the ovule-bearing head was infolded to enclose the ovules and an interovular mesh of unicellular hairs. Rigby (1978) has suggested that these filaments were fungal hyphae, from decay of the fossil. This seems unlikely considering their radiation from the micropyles of the ovules without plugging them, the apparent lack of damage tissue in petrified specimens (Gould & Delevoryas, 1977), and the cuticularized hair bases seen in macerated preparations (Pant & Nautiyal, 1960; Chandra & Surange, 1976). The filamentous meshwork may have produced or trapped fluid which bulged from the gaping lips of the underside of the ovule-bearing structure, like pollination droplets. Pollen of *Dictyopteridium sporiferum* entrapped in this material and floated and oriented by their inflated saccae would have been pulled into the micropyles of the ovules inside as the fluid dried back along the guiding filaments.

Ovule-bearing heads have been found withered and open, partly or wholly naked of ovules (Gould & Delevoryas, 1977). The seeds of this plant lacked wings or fleshy layers found in associated fossil plants (Walkom, 1922; Holmes, 1974; Plumstead, 1963). They were numerous, small (0.8–1.5 mm long: Gould & Delevoryas, 1977), and possibly were shaken from the fructifications by swaying in the wind (a "wind ballist" of van der Pijl, 1972), then dispersed widely by wind and water. The hair bases appear to have been quite persistent on dispersed seeds (Pant & Nautiyal, 1960) and may have aided dispersal.

Habitat. Leaves of this plant are abundant in roof shales and clastic partings within coal seams, and its roots riddle the drab underclays to coal seams (Jensen, 1975; Retallack, 1980b). These plants lived in waterlogged muds, silts, and sands (gleyed Entisols of Soil Survey Staff, 1975), as well as in peaty organic substrates (Histosols of Soil Survey Staff, 1975).

Trunks of this plant (Jensen, 1975, fig. 45; Gould, 1975) and of glossopterids in general (David, 1907; Plumstead, 1958b) had shallow root systems. This kind of tabular root system is commonly found in modern plants of waterlogged habitats (Jenik, 1978). Such a habitat also may explain the peculiar construction of the roots of these plants, in which xylem is restricted to narrow radial arms and transverse platforms that enclose empty spaces within the root. There has been some concern whether these spaces were filled with parenchyma, but calluslike groups of parenchyma cells on the walls of mature examples is evidence that they were originally empty (Gould, 1975). They may have served for aeration of the root in oxygen-poor ground, as in living crack willow (*Salix fragilis*: Kawase & Whitmoyer, 1980).

The texture of the leaves, with an adaxial thick cuticle and an abaxial stomatiferous and papillate cuticle (Gould & Delevoryas, 1977) is similar to sun leaves of modern angiospermous trees (Salisbury, 1927). This, together with the abundance of these leaves, is an indication that these probably were dominant canopy trees.

Modern riverside weed trees such as sycamore (*Platanus occidentalis*) and sheoak (*Casuarina cunninghamiana*) produce seeds in comparable numbers and sizes to those of *Dictyopteridium sporiferum.* Associated fossil seeds of other glossopterid plants (Walkom, 1922) are generally larger and more elaborate, thus supporting the view that *D. sporiferum* was weedy in comparison. Judging from their sedimentary context, the earliest successional plants were horsetails (*Phyllotheca* spp.) and lycopods (*Selaginella harrisii*). Other species of glossopterids were probably the dominant plants of stable swamp woodlands. Associated osmundalean tree ferns (Gould, 1970) may have formed understory shrubs and small trees. In contrast to those of *Glossopteris,* the leaves of these tree ferns were delicate, like those of shade plants. Higher land to the west, and perhaps also the volcanic highlands to the east, were forested by conifers (*Walkomiella australis*: Retallack, 1980b).

Paleogeographic setting. Dictyopteridium sporiferum is exquisitely preserved in Late Permian silicified peat near Homevale Station and is found as compression fossils in shales elsewhere in the northeastern Bowen Basin (Jensen, 1975). This

FIGURE 9. *A reconstruction of* Peltaspermum thomasii *of Late Triassic (Carnian) age, from the upper Umkomaas Valley, Natal, South Africa.—A. Habit as a shrub of seasonally wet bottomlands.—B. basin is continuous to the south with the Sydney Basin of New South Wales. Coal measures in the Sydney–Bowen Basin accumulated in a broad intermontane depression between the plains and hill ranges of inland Australia to the west and a volcanic, Andean-style mountain range to the east (Jensen, 1975).

The eastern Australian part of the Gondwana supercontinent was at very high paleolatitudes during the Late Permian (Herbert, 1980). There is no clear evidence of glaciation in the Bowen Basin at this time, but there were probably alpine glaciers on high mountains to the east. There are several lines of evidence for a seasonal, cool temperate climate throughout these lowlands. Growth rings are seen not only on fossil wood (Rigby, 1971) but also in the shells of marine shellfish, which were much less diverse in this region of the world during Late Permian time than in other formerly tropical regions (Runnegar & McClung, 1975). Varved lacustrine shales have been found with rafts of leaves at the very top of the silty layer, overlain by the thin shaley layer of the varve. This may be explained as coarse material washed out by brisk spring runoff and summer storms, followed by autumn leaf fall and slow winter accumulation of clay (Retallack, 1980b). Winters were not harsh by this time, because osmundalean tree ferns were widespread. They are represented by silicified trunks and foliage in the Bowen Basin (Gould, 1970).

PELTASPERMUM THOMASII

Hypothesized reconstruction. This plant is thought to have been a low-growing perennial shrub, vegetating stream, pond, and lake margins within temperate mesophytic woodlands and forests of South Africa and other southern continents during Late Triassic (Carnian) time, about 225 to 230 million years ago (Fig. 9). Its leaves (*Lepidopteris stormbergensis* (Seward) Townrow, 1956) were coriaceous, stiff, and fernlike. They varied from pinnatifid to bipinnatifid and in the proportion of stomates on either side of the leaf. This and the blisterlike hydathodes covering the frond rachis and the stem are features found in some modern waterside plants. Leaves had clear abscission scars, so it probably was a long-lived, perennial plant and may have been seasonally deciduous. The pollen-bearing (*Antevsia extans* (Frenguelli) Townrow, 1960) and ovulate organs (*Peltaspermum thomasii* Harris, 1937) were pinnately arranged, and each frondlike structure formed a large paniclelike fructification. Pollen (*Monosulcites minimus* Cookson, 1947) was moderately sized (23–40 μm) and produced in great quantity: both features of modern wind-pollinated plants. The reconstructed plants may have had a pseudostigmatic kind of pollination, in which pollen adhered to the ovule or head and only pollen tubes entered the micropyle, as in modern conifers with relatively inaccessible ovules and nonsaccate pollen. Seeds of the fossil plant probably were dispersed mainly by water.

Evidence for reconstruction. This reconstruction is based largely on fossil compressions from the black shales of "Burnera Waterfall," where a tributary creek of the Umkomaas River drops over a scarp of the basal Molteno Formation, 4 km southeast of Vergelegen Nature Reserve, Natal, South Africa (our Fig. 2C; locality Umk 111 of Anderson & Anderson, 1983). These shales form the base of the Molteno Formation and are Late Triassic in age (*Yabeiella* oppel-zone of Retallack, 1977; or Carnian in the marine time scale), which is about 225 to 230 million years old (in time scale of Palmer, 1983). The various fossil organs attributed to this species have also been found in association at other localities in South Africa, South America, and New South Wales (Retallack, 1977; Anderson & Anderson, 1983). The remains discussed were attributed to one plant by Townrow (1960) for several reasons: the close similarity of the cuticles of leaves, microsporophylls, and megasporophylls; pollen found dispersed and in microsporophylls; and close association at several localities.

Habit. This plant is mainly known from coriaceous, bipinnatifid to pinnatifid leaves. Unipinnate leaves also have been included in the genus (Townrow, 1960). These have identical cuticle and may be closely allied plants but are now placed in the genus *Pachydermophyllum* (Retallack, 1981). Also variable is the distribution of stomates on both sides of the leaf in *Lepidopteris stormbergensis.* They are usually more numerous on the abaxial side but occasionally are more common on the adaxial side, which can be distinguished because

of its thicker cuticle and less-bulging venation. Such a stomatal distribution is found in leaves of understory shrubs (Salisbury, 1927) and of waterside herbs (Townrow, 1960). The peculiar blisterlike swellings under hair bases on the stem and rachis of this plant are similar to hydathodes in waterside herbs such as water dock (*Rumex hydrolapathum*: Townrow, 1960). A waterside understory habitat seems likely, but we reconstruct this plant as a small, much-branched, perennial woody shrub for the following reasons. The leaves have thick cuticles and were probably stiff and coriaceous. Leaf bases with clear abscission scars and two leaf traces have been found (Townrow, 1960). These were abscised, perhaps seasonally. Slender stems of this plant have also been found which have stomates and blisters like those of the leaves (Townrow, 1960). Such stems are unlikely to have been the main stem of a plant with a single palmlike stem. It is more likely that these were short shoots of a branched plant.

Pollen sacs and ovules were arranged radially on more or less laminar organs, which were arranged pinnately. These pinnate structures formed large, lax, paniclelike structures (Anderson & Anderson, 1983, pl. 23, and possibly also their "female cone gen. C. sp. A." of pl. 26).

Reproduction. Wind pollination of this plant may be indicated by its copious production of smooth, moderately sized (23–40 μm) pollen. However, its large (5 mm long by 2 mm wide) pollen sacs, with glandular bumps and borne in groups of four, are distinct from the more numerous, nonglandular, smaller pollen sacs of other Mesozoic seed ferns usually regarded as wind pollinated, such as *Umkomasia granulata* (also reconstructed here).

Ovulate fructifications have been found in several different stages of maturation. The least-developed examples have only bumps rather than obvious ovules underneath the ovular head (Retallack et al., 1977). These may be remains at or close to the time of pollination, when the ovules and their elongate micropyles were not as obvious as in other remains with ovules attached (Townrow, 1960).

Pollination by means of a pollination drop is unlikely, considering the nature of the pollen grains. Unlike the bisaccate pollen of related peltasperm seed ferns such as *Pteroma* (Harris, 1964) and *Townrovia* (Retallack, 1981), *Peltaspermum thomasii* had nonsaccate pollen grains. This is also true of some modern conifers such as western hemlock (*Tsuga heterophylla*) and Prince Albert's yew (*Saxegothaea conspicua*), compared with closely allied conifers with bisaccate pollen (Doyle, 1945). These modern conifers with nonsaccate pollen have pseudostigmatic pollination, in which pollen grains adhere to parts of the plant near ovules, and long pollen tubes enter the ovules. The time between pollination and fertilization in these conifers is no less brief, compared with other conifers such as pines (Doyle & O'Leary, 1935b), because the tip of the pollen tube overwinters in the nucellus of the ovule (Doyle & O'Leary, 1935a, c).

The largest ovules seen are attached singly or in pairs to fructifications with abscission scars indicating a former complement of about six ovules (Townrow, 1960). The most complete remains lack ovules, and the most common remains are of isolated ovular heads only rarely with attached ovules (Anderson & Anderson, 1983). Even at these stages, associated ovules lack differentiation of woody and fleshy integuments to the degree seen in associated seeds, such as those of *Umkomasia granulata.* Neither the ovular heads, which may have been dispersal units, nor the ovules were adapted to specialized modes of dispersal, and they probably were scattered by wind and water.

Habitat. The black shale in the Umkomaas Valley (Umk 111 of Anderson & Anderson, 1983) is the deposit of a poorly oxygenated lake. The lacustrine shale overlies a thin conglomerate, which disconformably overlies floodplain deposits of the Katberg Formation, of Early Triassic age (*Lystrosaurus* zone). Such conglomerates at the base of a shale are found often in abandoned channels (oxbow lakes) of meandering streams (McDonnell, 1974).

At the Umkomaas Valley locality the shales are overlain by a variety of paleosols in which the plants may have lived (Fig. 2C). The so-called "oil shale" overlying the black shales is a coal (du Toit, 1954) and was probably a peaty soil (Histosol of Soil Survey Staff, 1975) fringing the Oxbow Lake. Overlying this are some very weakly developed fossil soils (Entisols of Soil Survey Staff, 1975), consisting of little-modified alluvium riddled with fossil root traces. These are interpreted as early successional soils of river levees. Above these are red, clayey, noncalcareous paleosols with slightly sandier surface horizons (probably Alfisols or Ultisols). Their root traces, profile differentiation, and degree of oxidation are typical for well-drained forested soils.

Of these various possible habitats, we think that *Peltaspermum thomasii* preferred the peaty lakeside soils. Unlike other associated fossil plants, this species lived very close to the lake, because it is equally abundant through the entire thickness of the lacustrine shales (Townrow, 1960). There also are reasons for regarding it as a waterside plant (as already discussed). *Peltaspermum thomasii* has been found in place in the organic layer and immediately overlying carbonaceous shales of waterlogged, peaty paleosols at other localities, such as Konings Kroon, South Africa (Kon 111 of Anderson & Anderson, 1983; G.J.R., pers. obs.) and in Nymboida Open Cut Mine, New South Wales, Australia (Retallack, 1977). In all of these localities *Peltaspermum thomasii* is associated with *Umkomasia granulata.*

Although a waterside and lowland plant, there are indications that it could tolerate deficiencies of water or nutrients. The stomates, for example, are overarched by papillae on the subsidiary cells. The blisters on the stems and leaves are comparable to water control structures (Townrow, 1960), such as salt glands or hydathodes (discussed by Esau, 1977). Judging from its geological occurrence, it is more likely that these peculiar features of the plant reflect growth in nutrient-deficient habitats rather than lack of water. It may have been suited to siliceous, nutrient-poor, streamside sands of point bars, or acidic swampy lowlands.

The other local habitats revealed by paleosols at the Umkomaas Valley locality seem less likely for this plant, because there is evidence from other localities that they were vegetated by other plants. Entisols of streamsides may have been colonized by broad-leaved conifers (*Heidiphyllum*) in drier, sandy, and elevated areas, and by ferns (*Cladophlebis* sterile, or *Asterotheca* when fertile) and horsetails (*Neocalamites*) in wetter places. Alfisols and Ultisols of well-drained floodplain forests and woodlands in contrast were dominated by other seed ferns (*Dicroidium elongatum* and *D. coriaceum*) and a variety of plants with ginkgolike leaves (Retallack, 1977). Within this mosaic of vegetation, *Peltaspermum thomasii* is envisaged as an understory plant of woodlands dominated by *Umkomasia granulata* in periodically waterlogged lowlands.

Paleogeographic setting. During Late Triassic time the Molteno Formation formed an extensive lowland piedmont north of the mountainous Cape Fold Belt (Turner, 1978). The lower part of the formation in the Umkomaas Valley lies disconformably on older alluvial rocks, which may have formed low hills flanking low ranges of much older (Precambrian), resistant rocks to the north, west, and east. This far north of the mountains, streams laid down sequences of sediment of a type formed in loosely sinuous modern streams transporting a mixed load of clay and sand (Turner, 1978; compare general models of Schumm, 1981).

Climate in this region was humid and cool temperate, perhaps seasonally snowy. This can be inferred from the high paleolatitude of this part of Gondwana (Anderson & Schwyzer, 1977). Late Triassic fossil wood from South Africa (Walton, 1923) has well-marked growth rings, an indication of strong seasonality. A humid climate is indicated by the quartz-rich composition of Molteno sandstones (Dingle et al., 1983) from which most of the easily weathered minerals have been lost. High rainfall probably also accounts for noncalcareous fossil soils and the dearth of vertebrate fossils in the Molteno Formation (G.J.R., pers. obs., following general models of Retallack, 1984).

UMKOMASIA GRANULATA

Hypothesized reconstruction. This was probably a woodland tree which dominated seasonally waterlogged floodplains of extensive lowlands north of mountains in the Cape region of South Africa, and of other humid regions of Gondwana during Late Triassic time, some 225–230 million years ago (Fig. 10). The leaves of this plant (*Dicroidium odontopteroides* (Morris) Gothan, 1912) had callused abscission scars, so probably were deciduous. Its wood (*Rhexoxylon tetrapteridoides* Walton, 1923) was coniferlike, but with exceptionally wide rays. Ovulate (*Umkomasia granulata* Thomas, 1933) and pollen-bearing structures (*Pteruchus johnstonii* (Feistmantel) Townrow, 1962b) of this plant were pinnately organized, and the pinnate structures were arranged helically in large paniculate fructifications. The copious production of moderately sized (corpus averaging 46 by 32 μm), bisaccate pollen (*Alisporites australis* de Jersey, 1962) is compatible with pollination by wind and possibly with a pollination drop. At ovulation, the ovules were weakly developed, and their bifid, elongate micropyles extended out below the margin of the cupulate head that enclosed their inverted bases. During subsequent development the ovule elongated well below the cupule margin and gained a sclerotesta with three broad ribs as the formerly elongate micropyle withered away. Seeds were released as their stalk abscised and the bivalved cupule spread open. The moderately-sized (3.7–7 mm × 2.2–5 mm) seeds were produced in great numbers and protected by a sclerotesta from desiccation or damage during possible ingestion. They probably were dispersed in a variety of ways, mainly by wind and water.

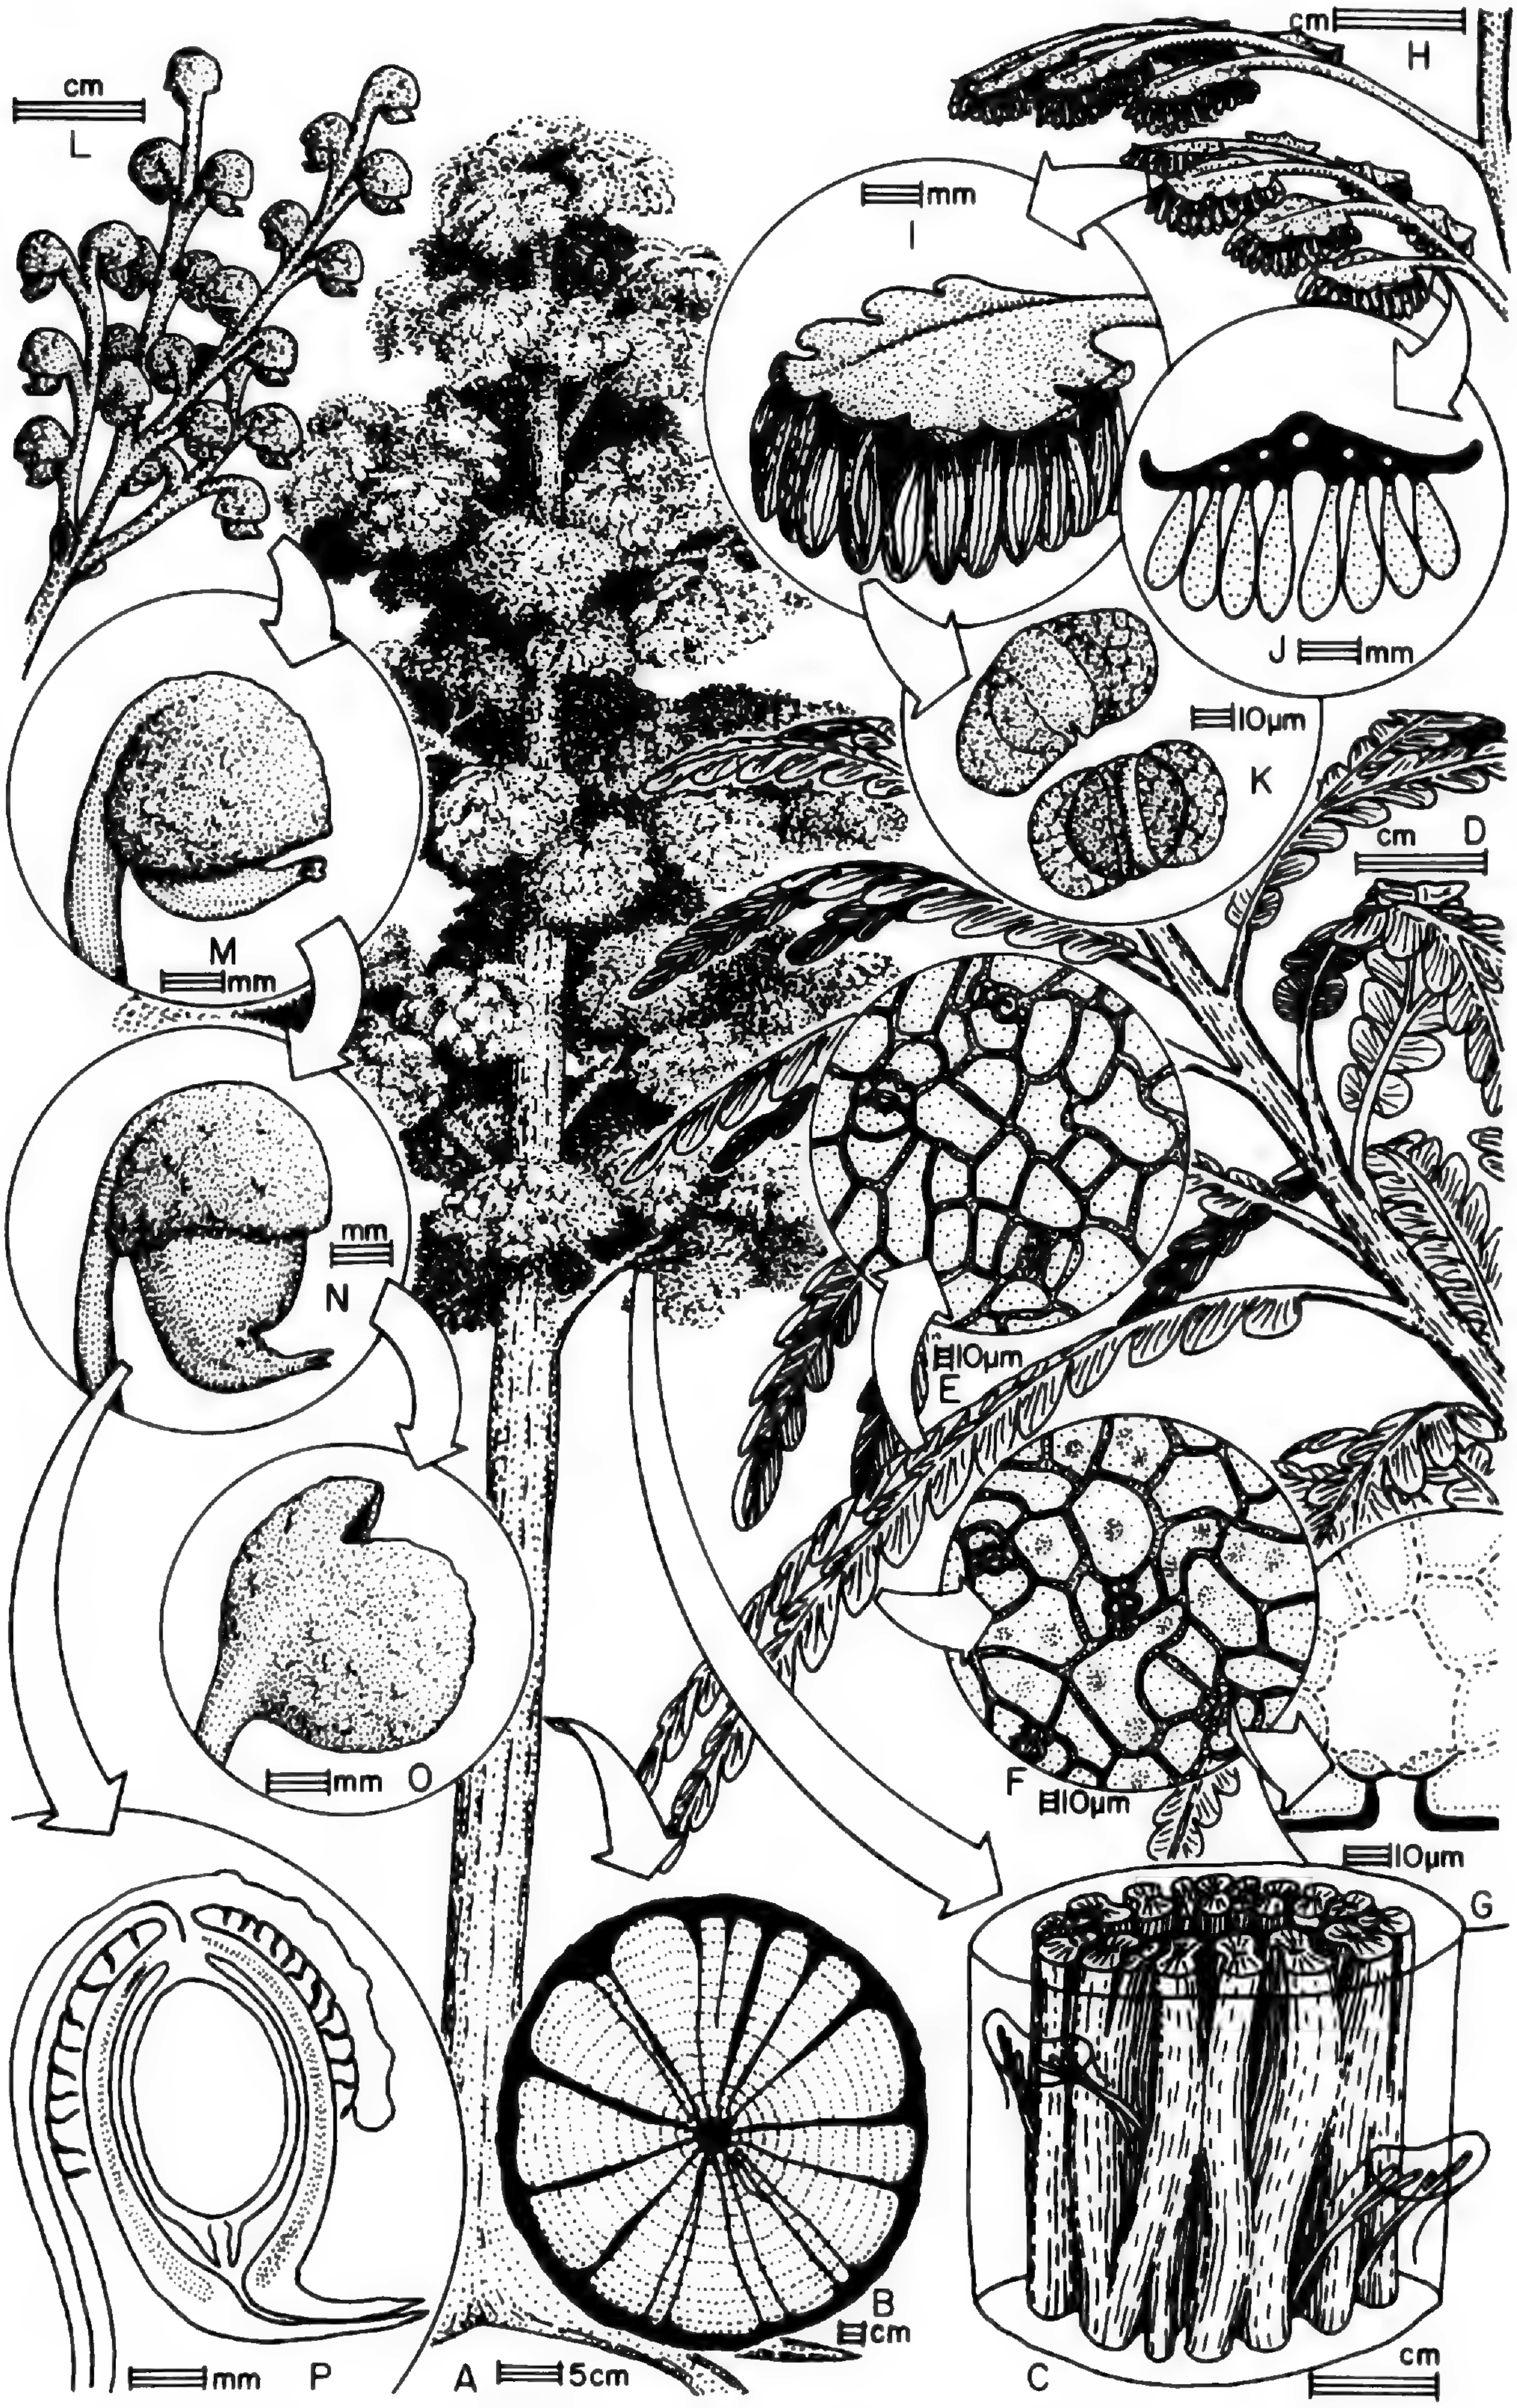

FIGURE 10. *A reconstruction of* Umkomasia granulata *of Late Triassic (Carnian) age from the upper Umkomaas Valley, Natal, South Africa.—A. Habit as a tree of seasonally wet bottomlands.—B. Diagrammatic cross section*

Evidence for reconstruction. This plant has been put together on the basis of compressed remains of leaves, ovulate and pollen-bearing organs with similar cuticle, and similar pollen grains in pollen sacs and ovules (Thomas, 1933; Townrow, 1962a–c). These remains were first demonstrated to be closely associated in the same locality (in the Umkomaas Valley, South Africa) that also serves as a basis for our reconstruction of *Peltaspermum thomasii*. The association of these fructifications and leaves is now known at most localities where it is found in South Africa, South America, Australia, and New Zealand (Retallack, 1977, 1980c).

Evidence that this plant was a tree of deciduous woodlands and forests includes associated fossil trunks, root traces, and the callused abscission scar at the base of its leaves. Other lines of evidence have been used in support of the idea that its wood, at least in South Africa, was *Rhexoxylon tetrapteridoides* Walton (1923). There is a close association of *Dicroidium* with petrified wood of *Rhexoxylon pianitskyi* at two localities in Argentina (Archangelsky, 1968). Of the two species of *Rhexoxylon* found in South Africa, *R. tetrapteridoides* is the only one found in the Molteno Formation near, but not at, the same localities (such as the Umkomaas Valley; Walton, 1923; Anderson & Anderson, 1983) from which our reconstructions of *Umkomasia granulata* and *Peltaspermum thomasii* came. A petrified leafy shoot of *Rhexoxylon pianitskyi* from Argentina (Archangelsky & Brett, 1961) formed the basis for our reconstruction of *R. tetrapteridoides* here, which we have assumed also to have six vascular traces leading into the petioles of the leaves. Because of this, *Rhexoxylon* could not be the wood of associated conifer (such as *Rissikia* or *Heidiphyllum*) or ginkgolike foliage (such as *Sphenobaiera*), which had only one or two vascular strands in their petioles. Nor does *Rhexoxylon* show the girdling leaf traces or intimately admixed parenchyma and xylem seen in the wood of cycads and cycadeoids, which presumably produced associated foliage of *Pseudoctenis* and *Taeniopteris*. Among associated seed ferns in South Africa, *Peltaspermum thomasii* (as reconstructed here) had only two leaf traces in the petiole (Townrow, 1960) and is here reconstructed as an understory shrub. *Glossopteris verticillata* is a rare element with multistranded petioles of this Triassic fossil flora, but it has been found attached to stems in a much closer helix than apparent for petrified *Rhexoxylon pianitskyi* or natural groups of impressions of *Dicroidium odontopteroides* leaves (du Toit, 1927; Thomas, 1952; Anderson & Anderson, 1983).

Thomas's (1933) numerous species of pollen organs have been revised and reduced in number by Townrow (1962a, b). This task has not yet been completed for ovulate organs, although most of these remains have been transferred to the genus *Umkomasia* (Holmes, 1987). From our examination of Thomas's specimens and preparations (in the British Museum of Natural History), we think that there are probably only three species. The type species of Thomas's three genera can be taken as representative of these species, which can be recognized by deeply incised cupular lobes (*Umkomasia macleanii*), weakly lobed cupule margins (*Umkomasia sewardii*), and smooth, bivalved cupule margins (*Umkomasia granulata*). These three taxa also show cuticular differences comparable to those found in the three associated species of *Pteruchus* by Townrow (1962a). Thus, the species name *Umkomasia granulata* is used broadly here to include several other named species ("*Pilophorosperma*" *costulatum*, "*P.*" *geminatum*, "*P.*" *paucipartitum*, "*P.*" *burnerense*, "*P.*" *natalense*, "*P.*" sp. type A, "*P.*" sp. type B, and "*P.*" sp. type C), which we regard as different stages of development and different parts of a large fructification. In the case of one of these species ("*P.*" *geminatum*), Thomas (1933, 1934, fig. 12F) thought that it had paired cupules, back to back. From comparison of the branching pattern of this specimen with the others, as well as our examination of its cuticular preparations, we interpret this as a dehisced, bivalved cupule. The branching pattern and small bractlike organs were regarded by Thomas (1933) as evidence that these fructifications were stalked, like the flowers of angiosperms. We prefer Townrow's (1962a) interpretation, developed for the pollen organ, that each

---

cupule is a homolog of a pinna, each "bracteole" a sterile pinna, and the whole pinnate structure homologous with a frond. This structure is in some ways similar to the ovule-bearing cupule arising from the dichotomy of a frond in early Carboniferous seed ferns such as *Sphenopteris bifida* (Long, 1979b).

Habit. Judging from the trunks of *Rhexoxylon tetrapteridoides* found (up to about 16 cm in diameter), this plant was a woodland tree (Archangelsky & Brett, 1961; Petriella, 1985). A trunk showing branch scars (Walton, 1923) provides evidence that the large branches were arranged in tiers that were not quite whorled. Like *Dictyopteridium sporiferum* reconstructed here, *Umkomasia granulata* probably had tiered branching which became more irregular with old age. This, and a long shoot and short shoot organization apparent from small petrified leafy stems and leaf groups, is very similar to our envisaged habit of *Dictyopteridium sporiferum.*

The leaves of this plant were variable in morphology, as documented in detail by Anderson & Anderson (1983). They may have belonged to a complex of hybridizing species. The Andersons have identified aberrant fossil leaves with narrow segments (*Dicroidium coriaceum* and *D. elongatum*) in some parts of the frond, and wide ones (*D. odontopteroides*) elsewhere on the same frond. These may represent hybrid leaves. Disregarding these as sports and considering variation in natural populations of these leaves (Anderson & Anderson, 1983, figs. 3, 4), *Umkomasia granulata* probably included leaves referred to *Dicroidium odontopteroides*, as well as those which have been referred to "*D. lancifolium*" and "*D. obtusifolium.*"

Stomates were distributed on both sides of the leaf but were much more abundant on the abaxial side, which had a thinner cuticle covered in papillae (Anderson & Anderson, 1983; Petriella, 1985). Fossil leaves have been found in radial groups and with asymmetric basal petioles (Anderson & Anderson, 1983).

The ovulate and pollen-bearing structures were pinnately organized and helically arranged on a larger stem (shown well in "*Umkomasia* sp. A" and "*Pteruchus* sp. B" illustrated by Anderson & Anderson, 1983, 1985). Only the ovule-bearing structure has been found in an apical position on slender shoots (Thomas, 1933; Holmes, 1987).

Reproduction. Individual laminar heads of the pollen organ bore hundreds of pendent, elongate pollen sacs (Townrow, 1962a). Pollen grains were bisaccate, nonstriate, and of moderate size (corpus averaging 46 by 32 μm in size: Townrow, 1962a). It is likely that the saccae were areas of porous exine (as indicated by Taylor et al., 1984, for a closely allied fossil species, really from the Ipswich Coal Measures near Dinmore, Queensland, according to these authors' erratum) rather than completely detached from the corpus. These are all indications that *Umkomasia granulata* probably was wind pollinated.

Only in specimens with small ovules does the elongate micropyle protruding from under the cupule appear to have been turgid and open. This was probably the stage of pollination, because in specimens with larger, more elongate ovules, the micropyle is withered and torn. The pollen chamber was narrow and tubular. It has been compared (by Thomas, 1933) to the salpinx of Paleozoic seed ferns such as *Lagenostoma lomaxii* reconstructed here. However, there is no sign of a central column, and it was not exposed like the salpinx. In these respects it was more like the pollen chamber of *Callospermarion pusillum.* Both were passive receptacles, not sealed from within by a plug of tissue, but sealed by the overarching sclerotesta of the integument. As the ovule enlarged and elongated, three broad ribs developed in the sclerotesta. This period of growth may have been when the megagametophyte and archegonia developed during the time between pollination and fertilization, as already described for *Callospermarion pusillum.*

Mature ovules and seeds were shed from the cupules by abscission from their stalk and by the cupule splitting into two lobes. Cupules at this open stage, revealing fully the degree of lobation of their margins, are the easiest of these remains to identify (Retallack, 1977). The branching fructifications found as fossils were presumably aborted or torn from the trees during storms. Much more common are isolated seeds, which were presumably the propagules. The seeds were neither exceptionally large nor small (3.5 to 7 mm long by 2.2 to 5 mm wide: Thomas, 1933), nor especially woody or fleshy, winged or spiny, even compared with the variety of associated fossilized propagules (Anderson & Anderson, 1983). They were probably dispersed by generalized methods, mainly by wind and water.

Habitat. This plant is best known from the Late Triassic locality in the Umkomaas Valley of South Africa (Fig. 2C), already described for *Peltaspermum thomasii.* Remains of these species drifted into a lake and were mixed with a variety of other plants. Fossil leaf litters preserved in paleosols at Konings Kroon, South Africa (locality Kon 111 of Anderson & Anderson, 1983) and at

Nymboida Open Cut, New South Wales, Australia (Retallack, 1977) are better evidence of its habitat and associated plants. As already discussed for *Peltaspermum thomasii*, the soils were periodically (probably seasonally) waterlogged in lowland floodplains. High soil acidity and deeply weathered parent material of this humid region depleted nutrients in these fossil soils. Stumps and root traces penetrate deeply into these carbonaceous paleosols (Hatch & Corstorphine, 1909). This is unlike roots of modern plants in permanently waterlogged soils (Jenik, 1978). Although waterlogged for some part of the year, thus retarding decay of carbonaceous material in the soil (Retallack, 1984), these soils were moderately well drained at other times.

Also relevant to the former habitat of this plant are the distinctive wide parenchymatous rays of the wood here included in our reconstruction. This wood structure has been compared to that of modern vines, in which wide parenchymatous rays bestow flexibility (Walton, 1923). These plants are unlikely to have been vines, considering their size, but some flexibility may have been advantageous during seasonal fluctuations in water availability (Carlquist, 1975).

Judging from its abundance and likely stature, *Umkomasia granulata* was probably a dominant canopy tree of lowland mesophytic woodlands in humid, cool temperate regions of Gondwana (Retallack, 1977). Other trees included rare conifers (*Rissikia media*) and plants with ginkgolike leaves (*Sphenobaiera stormbergensis*). Among the understory plants were other seed ferns (*Peltaspermum thomasii*), cycadophytes (*Pseudoctenis* and *Taeniopteris*), ferns (*Cladophlebis*), and horsetails (*Neocalamites*). These last-mentioned pteridophytes also may have colonized disturbed parts of the forest, because they are found in other nearby localities (such as Konings Kroon localities Kon 211 and 221 of Anderson & Anderson, 1983) where they form distinctive early successional assemblages in very weakly developed paleosols (Entisols of Soil Survey Staff, 1975: G.J.R., pers. obs.).

Paleogeographic setting. *Umkomasia granulata* is best known from the same locality and region as *Peltaspermum thomasii*.

CAYTONIA NATHORSTII

Hypothesized reconstruction. We reconstruct this plant as a forest tree of an extensive Middle Jurassic (Bajocian or 175 to 183 million years old) coastal plain, in what is now northeastern England (Fig. 11). Climate in England at this time was subtropical, monsoonal, and seasonally dry, with an annual rainfall within the humid range. The compound leaves (*Sagenopteris phillipsii* (Brongniart) Presl in Sternberg, 1838) of this plant had four leaflets paripinnately arranged but so close together that they appear palmately compound. Leaves developed by elaboration of the apical region of an initial scale into the four leaflets and by modification of the body of the scale into a petiole. The adaxial cuticle of the leaflets was thick and lacked stomates. The abaxial side had a thin cuticle, stomates, and papillae. Both ovulate (*Caytonia nathorstii* (Thomas) Harris, 1940) and pollen-bearing structures (*Caytonanthus arberi* (Thomas) Harris, 1941) were organized imparipinnately and arranged in a helix on slender axes. The pollen (*Vitreisporites pallidus* (Reissinger) Nilsson, 1958) were moderately sized (22–28 μm wide), bisaccate, and produced in large quantities. These are typical features of wind-pollinated plants. Pollen grains in coprolites provide evidence that these were also eaten by small animals that may have been effective as pollinators. The ovules (*Amphorispermum pullum* Harris, 1943) were borne on the inside of fleshy, berrylike cupules. At the time of pollination, ovules were small and poorly developed, and the ovulate structure consisted of cuplike inrolled flaps. Pollen were probably entrapped by a pollination drop at the opening of the ovulate structures and drawn back into the micropyles of the ovules along a series of guiding filaments as the droplet dried out. In mature cupules the ovules were completely enclosed by the overarching pressure of the turgid fleshy "fruit" and by sealing the entrance with bands of cutin and perhaps also of other substances. The fleshy, berrylike cupules have been found burst and split. They may have spilled ovules as they fell on the ground. More effective in their dispersal may have been reptiles and small mammals attracted by these fleshy fructifications. The seeds were fortified against crushing and acidity during ingestion by their sclerotesta.

Evidence for reconstruction. *Caytonia nathorstii* is best known from a thin (1 m) shale bed (Fig. 2D) in the rock platform south of Cayton Bay, Yorkshire, England (Harris, 1964). This is the Gristhorpe Bed of the Cloughton Formation, Ravenscar Group (Kent, 1980), and is Middle Jurassic (Bajocian) in age, or some 175 to 183 million years old (in the time scale of Palmer, 1983). This plant has been reconstructed from compression remains of leaves, buds, pollen organs, and ovule-bearing organs with similar cuticles; from the similarity of pollen in pollen sacs and ovules; and from close association at several localities (Harris, 1964).

At the best-known locality, Cayton Bay, the fructifications of most of the other associated fossil plants are known to be different (Harris, 1961, 1964, 1969, 1979; Harris et al., 1974).

Habit. There is evidence from association with poorly preserved fossil stumps (Thomas, 1925; Black, 1929; Harris, 1971) in a forested paleosol (Spodosol or Inceptisol, Fig. 2D) that this plant was part of a mixed fern–cycadophyte–conifer forest. Its exact habit within this vegetation is less certain. Harris (1971) has argued that *Caytonia nathorstii* was a tree, as shown by finds such as leaves attached to stout woody shoots and of budlike short shoots of young leaves. As he argued, few shrubby plants have such stout leafy limbs, and those that do are often more succulent or more completely invested with leaf bases. Buds are typical of a perennial deciduous plant.

The four leaflets of the compound leaves appear palmately compound but are paripinnately arranged with very close points of contact (Harris, 1951). The diffuse, anastomosing venation of leaflets of *Caytonia nathorstii* is superficially like that in leaves of *Dictyopteridium sporiferum*, also reconstructed here. *Sagenopteris* differs from *Glossopteris* in having compound leaves, a true midrib to the leaflets, and secondary venation in which radiating and dichotomizing veins are undeviated by confluent strut veins. These differences from *Glossopteris* have been indicated also by Delevoryas & Person (1975) for *Mexiglossa* leaves, which we regard as closely related to, if not congeneric with, *Sagenopteris*.

Fossil buds (Harris, 1964) indicate that short shoots of leaves developed synchronously, presumably after a period of leaf fall, then dormancy during a harsh season. Leaves developed from the scalelike organs by the differentiation of two orbicular apical leaflets, followed by a second pair on either side behind them (Harris, 1940). Most of the scales became differentiated into the petiole of the compound leaf. The developing leaves were pilose, as are many young organs (Esau, 1977), but mature leaves were glabrous.

The ovules and pollen sacs were arranged paripinnately on leaflike structures on either side of an axis, which had a different adaxial and abaxial cuticular structure, more like a petiole than a stem. The ovulate structure was unipinnate (Harris, 1964), and the pollen-bearing structure was bipinnately arranged (Harris, 1951). These fructifications probably formed paniculate structures, like those of other Mesozoic seed ferns reconstructed here.

Pollen sacs of this plant are thought to have been attached to the abaxial side of the leaflike microsporophyll (Thomas, 1925; Harris, 1964), but the orientation of the ovules is more controversial. For the following reasons we believe that they were also morphologically abaxial, as were the openings to the cupules. The most important evidence is a single specimen of *Caytonia nathorstii* attached to another axis (Thomas, 1925, pl. 12, fig. 16). This specimen was thought lost (Harris, 1971) but was discovered during 1980 by us in the paleobotany teaching collection of Cambridge University. We confirm that the megasporophyll at right angles to the axis is attached, as are two berrylike cupules displayed with their occluded opening crushed on top of their stalks. From our interpretation of the creasing at the attachment points, clearly visible in Thomas's excellent photograph, the attachment does not appear twisted into an unusual orientation. The occluded opening of the fruit appears to be abaxial, and the ovules enclosed by the fruit wall are also morphologically abaxial. This is because, as Harris (1964) and Reymanowna (1974) argued, the cupule is homologous with an infolded leaf. By our interpretation, papillae and hair bases consistently characterize the abaxial surface of leaves, microsporophylls, and megasporophylls (Thomas, 1925; Harris, 1940, 1964). In addition, the outer cuticles of the cupules lack stomates and have a structure in thinner areas (probably lenticels) very similar to

the adaxial cuticles of the leaves (Harris, 1940). Interpretation of the ovules as abaxial brings these plants into line with closely allied plants and with seed ferns as a whole.

We have taken pains to justify our reconstruction on this point, because it runs contrary to the opinion of the leading authority on *Caytonia nathorstii* (Harris, 1940, 1964). Since the thickest cuticle on the rachis of this fructification is on the narrow side, Harris argued that the ovules of *Caytonia* were morphologically adaxial. He interpreted this as similar to the thicker adaxial cuticle of leaves and pollen organ of this plant. We, on the other hand, have pointed out other ways of viewing cuticular homologs between different organs of this plant and regard the thick narrow cuticle of the abaxial side of the rachis as a structural thickening that prevented drooping of the heavy cupules.

Reproduction. It is difficult to determine whether fertile shoots of this plant were bisexual or unisexual. Thomas (1925) argued that individual plants were unisexual, because the best-preserved fructifications of either sex were found in different parts of the same bed. We confirmed this during our own collecting. This is compatible with the view that this plant, like modern plants that have unisexual fructifications, was wind pollinated. The fossil plant produced copious amounts of weakly sculptured, moderately sized (22–28 μm wide: van Konijnenburg-van Cittert, 1971), bisaccate pollen. Shriveling of the saccae on release, as observed in modern pine pollen by Wodehouse (1935: 254), would have greatly reduced the size of the pollen grains. The central body of the grains is only 12–18 μm long by 6–12 μm wide (van Konijnenburg-van Cittert, 1971). They could not have shrunk this much because the sacci contained an internal mesh of sporopollenin, in some ways like that found in pollen from the corystosperm microsporophyll *Pteruchus* (Pedersen & Friis, 1986). Some possible evidence for animal pollination of this fossil comes from small (4 mm diameter) coprolites full of these pollen grains. These were produced by small animals that lacked the ability to digest sporopollenin (Harris, 1964), perhaps a small arboreal mammal or lizard. Australian honey possums (*Tarsipes spencerae*), and a variety of other small animals are known to be effective pollinators, even though they are unable to fly, as is usual among the most important modern pollinators (Rourke & Wiens, 1977). Apart from dinosaur footprints (Kent, 1980), no fossil vertebrates or insects have been found in association with these plants, but from what is known of Middle Jurassic life on land elsewhere in Britain (Clemens et al., 1979; Savage, 1984), there were varied small mammals and arboreal gliding and flying reptiles. Birds had not yet appeared, and despite the diversity of insects at this time, the fossil coprolites are too large for them.

As is common in modern conifers with bisaccate pollen (Doyle, 1945), pollination may have been aided by pollination droplets. In this case it probably emerged from the mouth of the cupules at an early stage of development, when they were little more than infolded flaps (Harris, 1943, 1964). As in *Dictyopteridium sporiferum* reconstructed here, there may have been a reticulum of filaments, which guided pollen toward the micropyles of ovules inside. Filaments were observed in preparations of ovules by Thomas (1925) and Krassilov (1977) but were not noticed by Harris (1933). Pollination must have occurred when ovules were young and the cupule was open, because later in development the opening was sealed by inflation of the fleshy fruit wall and the development of cutinous bands, and perhaps also waxy or other substances (Harris, 1933, 1943). This subsequent development may have disrupted internal filaments so that they were difficult to see in mature fruits. This closure also prevented penetration of clay in the fallen mature fruits. Early ideas (Thomas, 1925) about stigmatic, angiospermlike pollination of these plants were long ago disproved by the discovery of pollen grains within the ovules inside the cupules (Harris, 1933, 1940).

At maturity the berrylike cupules were swollen and completely enclosed the ovules. Each ovule had a well-developed sclerotesta. An enigmatic layer within the ovular coat, the "spotted layer," is quite unlike a true cuticle, but nevertheless somewhat maceration-resistant (Harris, 1958a). It could be the basal layer of a zone of osteosclereids or lagenosclereids, as found in the seed coat of modern soybean (*Glycine max*: Esau, 1977). Inside the nucellus of the ovule was a layer of poorly preserved brown cell contents. Harris (1958a) called it an "aleurone layer," which is a distinctive outer enzyme-producing layer of the endosperm well known in modern angiospermous cereals, such as barley (*Hordeum vulgare*: Esau, 1977).

Dispersal of seeds may have been by bursting on impact or by rotting of the cupule. Many comparably fleshy modern fruits with stony seeds are animal dispersed. The same kinds of small reptiles and mammals already discussed as possible pollinators of this plant may also have aided in its dispersal.

Habitat. The fossiliferous shale (Gristhorpe Bed) at Cayton Bay (Fig. 2D) is a sequence of flood deposits overlying a thick (1.3 m), moderately developed sandy paleosol with a white surface (E) and orange-red subsurface (Bs) horizon (Thomas, 1925; G.J.R., pers. obs.). It was probably a base-poor, forested soil (Gley Podzol of Stace et al., 1968, or Spodosol or spodosolic Inceptisol of Soil Survey Staff, 1975) of periodically waterlogged lowlands. Stumps and large roots have been found within this paleosol (Black, 1929). These are surrounded by a layer of carbonaceous shale, which when macerated yields many fruits and seeds of *Caytonia nathorstii* and other plant debris. We interpret this as an imperfectly decayed (mor) humus layer of leaf litter in a periodically (perhaps seasonally) wet soil. Plants preserved in the overlying shales represent other leaf litter entrapped as clay and floodwaters were slowed around the trees, as in cumulic horizons of modern floodplain soils (modern examples are discussed by Birkeland, 1984). The shale layer becomes more silty and sandy higher towards the next overlying paleosol. This reflects an increase in the power and frequency of flood disturbance, which would have introduced early successional species of plants not usually found in undisturbed lowland forest.

A great variety of plants have been found in the Gristhorpe Bed (Harris, 1961, 1964, 1969, 1979; Harris et al., 1974). The commonest tree species from near the base of the bed are the seed fern *Caytonia nathorstii* and the taxodiaceous conifer *Elatides williamsonii*. Other common remains likely to have been understory plants include the osmundalean fern *Todites williamsonii*, the cycad *Nilssonia compta*, and the cycadeoid *Nissoniopteris vittata*.

Caytonia nathorstii was not common in other habitats in the coastal plains of Yorkshire. Fluvial levees were colonized largely by ginkgoes (*Ginkgo huttonii*: van Konijnenburg-van Cittert, 1971; Nami, 1976) and other nearstream, early successional environments by horsetails (*Equisetum columnare*: Harris, 1961). Near-coastal peat swamps were vegetated by cycads (*Nilssonia kendallae*), cycadeoids (*Ptilophyllum pectinoides*), and czekanowskialeans (*Sphenobaiera gyron*); and the most marine-influenced vegetation of tidal creeks was dominated by another seed fern (*Pachydermophyllum papillosum*: Thomas & Bose, 1955; Spicer & Hill, 1979). Compared with these other plants, *Caytonia nathorstii*, although a lowland plant, lived in more inland and stable sites.

Paleogeographic setting. During Middle Jurassic time Yorkshire was a flat deltaic coastal plain between moderately elevated plateaus of older rocks to the north, south, and east. To the west was a shallow sea, which connected to the south past several low islands and a broad shelf of tropical reefs to the open Tethys Ocean (Sellwood, 1978).

Yorkshire at this time was at a paleolatitude of about 35° north (Briden et al., 1974). Climatic zonation was less marked than at present, and this region enjoyed a subtropical climate (Hallam, 1975). Overall rainfall was probably in the humid range, considering the lush vegetation of pteridophytes (Harris, 1961), noncalcareous and podzolic nature of paleosols (Fig. 2D), and corrosion of the umbos of fossil unionid bivalves (Wilson, 1948). Growth zones in fossil shoots (Harris, 1971, 1979) are evidence of seasonality. The harsh season was probably dry and a time of forest fires (Harris, 1958b). As in modern continents at about this latitude and orientation, climate was probably monsoonal and winter dry (Hallam, 1975).

DISCUSSION

The reconstructions given here range from vines to stately forest trees, from plants of intertidal swamps to those of well-drained soils in locations ranging from the tropics to the high latitudes. These extinct broadleaf plants appear to have occupied many niches. In the face of such diversity it is difficult to characterize seed ferns. Certainly, they were not merely small swampland shrubs. They were a prominent component of much late Paleozoic and Mesozoic vegetation.

The seed ferns reconstructed here, representing well-understood examples of these plants, have a few features in common. They are all characterized by fernlike leaves, ovule-bearing structures which are leaflike or adnate to leaves, and gymnospermous anatomy, more or less as originally envisaged by Potonié (1899) and Oliver & Scott (1904) in proposing the terms "cycadofilicales" and "pteridosperms." However, we think it unlikely that they form a natural group or clade, because the same features distinguish other groups of plants, such as cycads. The earliest gymnosperms were probably seed ferns (Rothwell, 1982, 1986). Cycads, cycadeoids, pentoxylans, ginkgoes, czekanowskians, cordaites, conifers, and other gymnosperms all probably were derived from seed ferns (Meyen, 1984). Seed ferns were thus central to the evolutionary radiation of seed plants, and in this sense represent a grade of evolution embracing the evolutionary roots of these various other gymnosperms.

The phylogenetic relationships of gymnosperms can be expected to become clearer as lineages of seed ferns are better understood. Phylogenetic inference is beyond the scope of this article, but we point out two quite different groups of seed ferns to underscore the artificiality of seed ferns as a taxon. The plants with fernlike prepollen (*Stamnostoma huttonense, Lyrasperma scotica, Calathospermum fimbriatum, Lagenostoma lomaxii,* and *Pachytesta illinoensis*) were different in many ways from those with true pollen (*Callospermarion pusillum, Dictyopteridium sporiferum, Peltaspermum thomasii, Umkomasia granulata,* and *Caytonia nathorstii*). The group with fernlike prepollen was similar in many ways to modern cycads, whereas the others were more like conifers. The second group includes both Paleozoic and Mesozoic plants, some of which show a number of important biological similarities (Reymanowna, 1974). The supposed morphological gap between Mesozoic and Paleozoic seed ferns, apparent in many general discussions of these plants, may be seen as a study bias. It arose from the varied experience of different investigators of these plants and from quite distinctive styles of preservation and geological settings for Paleozoic and Mesozoic plants, rather than from the plants themselves.

A variety of seed ferns have been considered as possible ancestors of angiosperms: especially forms allied to the plants here reconstructed as *Stamnostoma huttonense* (Long, 1966, 1977b), *Dictyopteridium sporiferum* (Retallack & Dilcher, 1981), and *Caytonia nathorstii* (Doyle, 1978). Another gymnospermous group thought to be ancestral to angiosperms, the cycadeoids (Arber & Parkin, 1907) were probably also derived from seed ferns. The origin of angiosperms is still a puzzle, for which more detailed understanding of seed ferns is needed.

In our role as arbitrators of conflicting views on the nature of the plants reconstructed here, we have become aware of the ease with which mistakes can be made. We do not imagine that our reconstructions will be the last word (or image) for these plants, and hope that they will serve as hypotheses that stimulate as well as instruct.

FLORA OF THE VENEZUELAN GUAYANA—V[1]

Julian A. Steyermark[2]

ABSTRACT

In the preparation of various families for the Flora of the Venezuelan Guayana, *many new taxa have been detected. These include specimens collected from recently completed expeditions and earlier herbarium material. The following new taxa are described:* Portulaca insignis, P. pygmaea *(Portulacaceae);* Maytenus huberi, M. insculpta, M. longistipitata, M. neblinae, M. pustulata, Zinowiewia aymardii *(Celastraceae);* Matayba affinis, M. longipes *subsp.* yutajensis, M. oligandra *var.* occidentalis, M. yutajensis, Talisia amaruayana, T. caudata, T. glandulifera, T. heterodoxa, T. pentantha, T. sancarlosiana, Toulicia anomala *(Sapindaceae);* Gouania wurdackii, Rhamnus longipes, R. sipapoensis *(Rhamnaceae);* Pochota ewelii, P. fuscolepidota, P. gracilis *subsp.* bolivarensis, P. liesneri, P. mawarinumae, P. redmondii, P. tepuiensis *(Bombacaceae);* Schefflera simplex, S. yutajensis *(Araliaceae);* Symbolanthus huachamacariensis, S. yaviensis *(Gentianaceae);* Remijia sessilis, Simira ignicola *(Rubiaceae). In addition, comments are supplied, where pertinent, on the affinities of various taxa in the several families treated.*

PORTULACACEAE

PORTULACA

Portulaca insignis Steyermark, sp. nov. TYPE: Venezuela. Bolívar: laja granítica con bosque y matorral seco, cerca del afluente del Río Aro, carretera Ciudad Bolívar–Maripa, 100 km W of Ciudad Bolívar, 100–200 m, 26 Feb. 1980, *G. Morillo & G. Carnevali 8260* (holotype, VEN). Figure 1.

Planta herbacea annua diminutiva 4.5–10 cm alta, radice palari elongata; caulibus aliquot procumbentibus vel erecto-adscendentibus vel curvatis e basi exorientibus a pilis lanosis albis 8–15 mm longis omnino densissime obtectis absconditisque; foliis per longitudinem vel apicem versus dense confertis, alternis carnosis applanatis, laminis lanceolato-linearibus apice obtusis basi in petiolum angustatis 4.5–6 mm longis 0.5–1 mm latis; petiolis 0.8 mm longis 0.6 mm latis; foliis involucralibus 10–12 foliorum caulinorum similaribus; sepalis 4 mm longis; petalis 4–5 mm longis; staminibus 13–15; lobis stigmatosis quattuor; capsulis 2.5 mm longis 1.5 mm diam. prope medium circumscissilibus; seminibus numerosis lenticularibus 0.5–0.6 mm diam., a latere compressis conspicue tuberculatis, tuberculis apice subacutis anguste elevatis basi 4–5 radiatis angustis ornatis.

Herbaceous diminutive annual, 4.5–10 cm tall with an elongated slender tap root. Stems several, procumbent to erect-ascending or curving, simple or sparingly branched, densely foliose up to the apex, densely covered and nearly concealed by a dense, white, woolly mass of elongate hairs 8–15 mm long; internodes conspicuously abbreviated. Leaves alternate, densely imbricate to the apex of the stem, fleshy, flattened, lance-linear, obtuse at apex, 4.5–6 mm long, 0.5–1 mm wide, base attenuate. Petioles 0.8 mm long, 0.6 mm wide. Involucral leaves 10–12, similar to the cauline, 4–7 mm long, 1 mm wide. Sepals 4 mm long, subacute. Petals 4–5 mm long, slightly connate at base. Stamens 13–15; filaments ca. 2 mm long, attached 0.5–0.8 mm above base of petals. Stigmatic lobes 4; style filiform, 0.8 mm long. Capsules 2.5 mm long, 1.5 mm diam., circumscissile near the middle. Seeds numerous, lenticular, 0.5–0.6 mm diam., laterally compressed, conspicuously tuberculate, the tubercules with a subacute apical projection, at the base with 4–5 spreading narrow rays.

Paratype. VENEZUELA. BOLÍVAR: Dist. Paez, Laguna Larga, 8 km SE of Upata, sabanas con chaparrales, 350 m, July 1978, *Delascio & Liesner 6882* (MO, VEN).

In this species the entire plant is more or less concealed by a dense cover of white, woolly or cottony hairs up to 15 mm long. It differs from *Portulaca elatior* Mart. in its much smaller size, shorter stems, shorter cauline and involucral bracts, fewer stamens, 4-fid style, and much denser woolly covering over the entire plant.

Portulaca pygmaea Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: 1 km E of Hotel Amazonas, Puerto Ayacucho, gravel pockets

---

[1] *Flora of the Venezuelan Guayana was carried out under National Science Foundation Grant (BSR) 85152085. I am greatly indebted to the curators of F, NY, US, MER, MY, PORT, and VEN for the loan of critical material.*

on laja, along contact between laja and Orinoco gallery forest, 100 m, 12 Nov. 1953, *Bassett Maguire, John J. Wurdack & George S. Bunting 36188* (holotype, NY). Figure 2.

Planta herbacea diminuta 2–3 cm alta glabra vel fere; foliis sub capsulis oppositis aliter alternis, laminis suborbicularibus suborbiculari-obovatis ovalisque apice rotundatis basi acutis vel subacutis 1.5–4(–6) mm longis 1.5–3 mm latis glabris vel interdum pilis in axillis plerumque desunt vel interdum axillaribus inconspicuis 0.2–0.6 mm longis; petiolis 0.7–1 mm longis; sepalis suborbicularibus obtusis, 3 × 3 mm; petalis luteis 4.5–5 mm longis; capsulis depresso-hemisphaericis prope basem circumscissilibus 1.5–2.3 mm longis 1.7–2.3 mm latis; seminibus griseis 0.5 mm diam., superficie tuberculato, tuberculis tessellatis haud projectantibus marginibus arcte contiguis.

Diminutive herbaceous plant 2–3 cm tall, glabrous or nearly so; roots napiform, the short tuberous root 1–1.5 cm long, 4–8 mm thick. Leaves subtending the capsules opposite, otherwise alternate; leaf blades suborbicular, oval, or obovate, rounded at the apex, acute at base, 1.5–6 mm long, 1.5–3 mm wide, glabrous or sometimes with minute hairs present in the axils; petioles 0.7–1

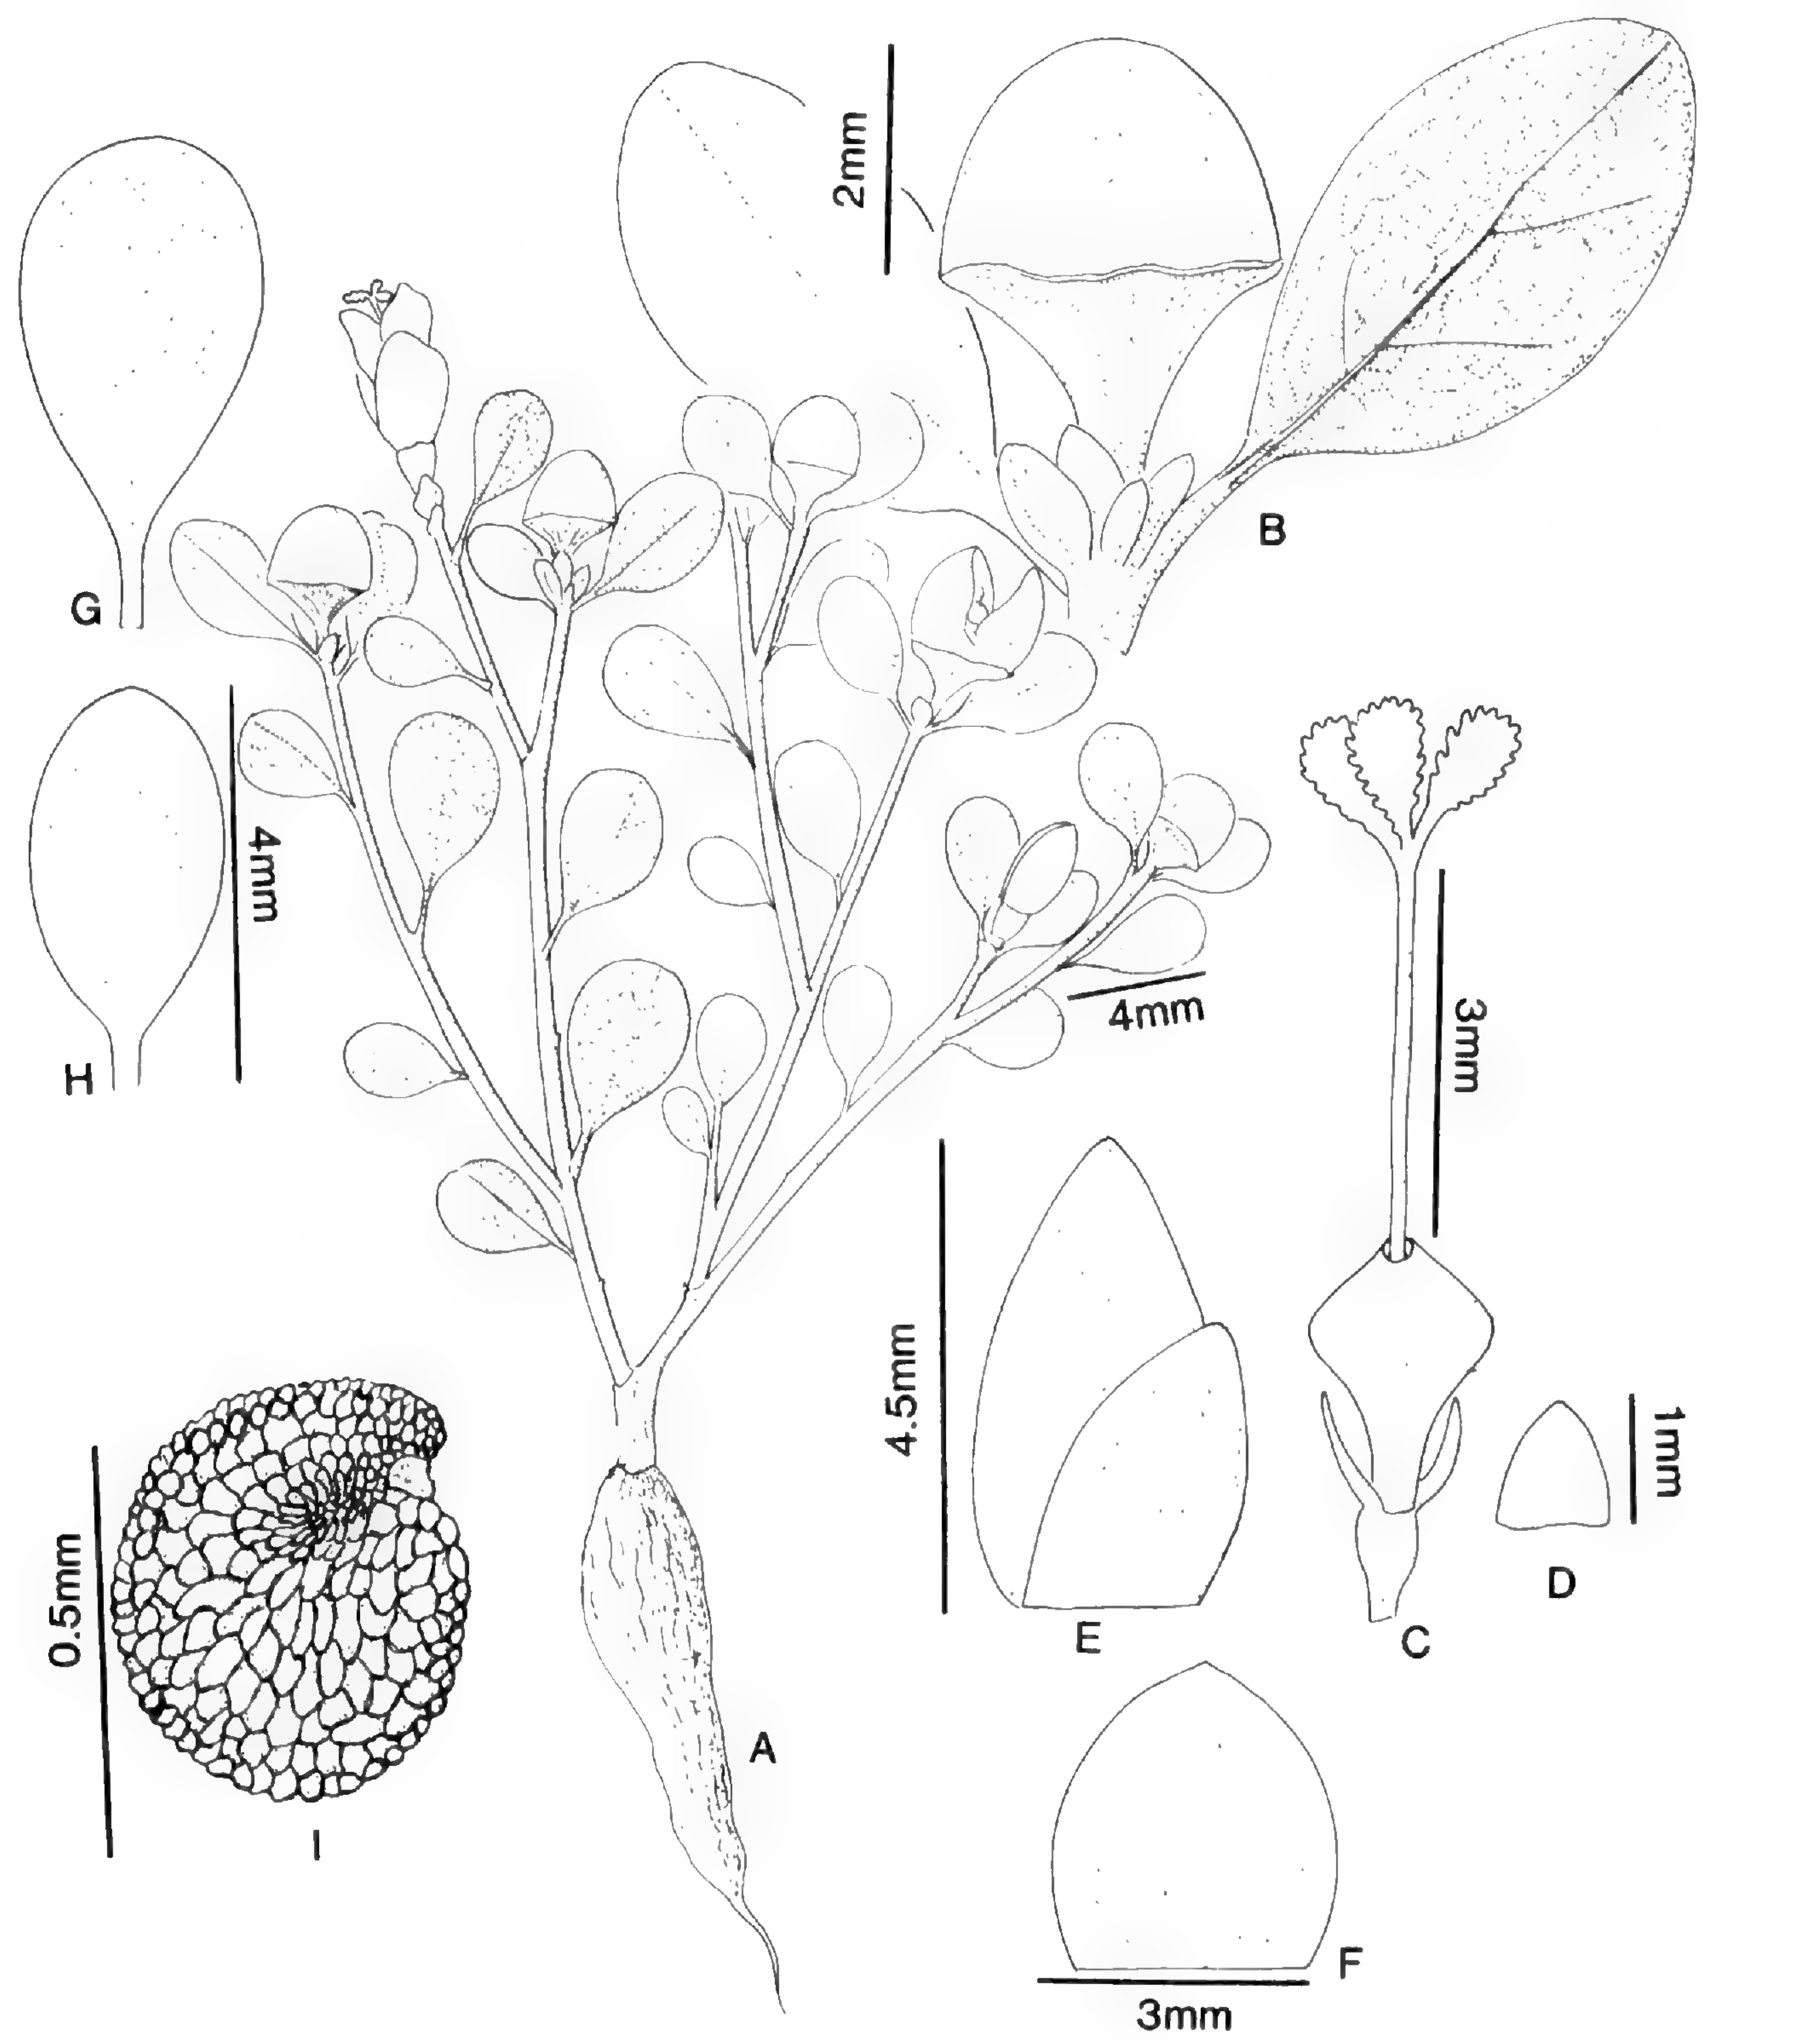

FIGURE 2. Portulaca pygmaea.—*A. Habit, showing tuberoid root.—B. Capsule subtended by uppermost opposite leaves.—C. Pistils subtended by bracts.—D. Ovate-triangular bracteole.—E. Petal subtended by sepal, lateral view.—F. Sepal, dorsal view.—G, H. Leaves, showing different shapes.—I. Seed, showing platelike, subflattened tubercules.*

mm long. Flowers bibracteate, slightly substipitate, the bracts 1 mm long. Sepals suborbicular, broadly obtuse, 3 × 3 mm. Petals yellow, ligulate-oblong, rounded at the apex, 4.5–5 mm long, 2 mm wide in the upper half, 0.7–1 mm wide at the base. Stamens 5; filaments 2.7 mm long; anthers suborbicular, 0.5 × 0.5 mm. Style 3 mm long; stigmas 3, spathulate, 1.2 mm long. Capsules hemispherical, subdepressed at the apex, 1.5–2.3 mm long, 1.7–2.3 mm wide, circumscissile near the base. Seeds gray, 0.5 mm diam., tessellate-tuberculate, the tubercules scarcely projecting, their margins strongly contiguous.

This is a rarely collected species, occurring on the lajas in the vicinity of Puerto Ayacucho with *Portulaca pusilla* H.B.K. and *P. sedifolia* N. E. Brown. It differs from the very similar dwarf *P. pusilla* in the yellow petals; napiform, short, thickened tuberous root; 5 stamens; longer and broader

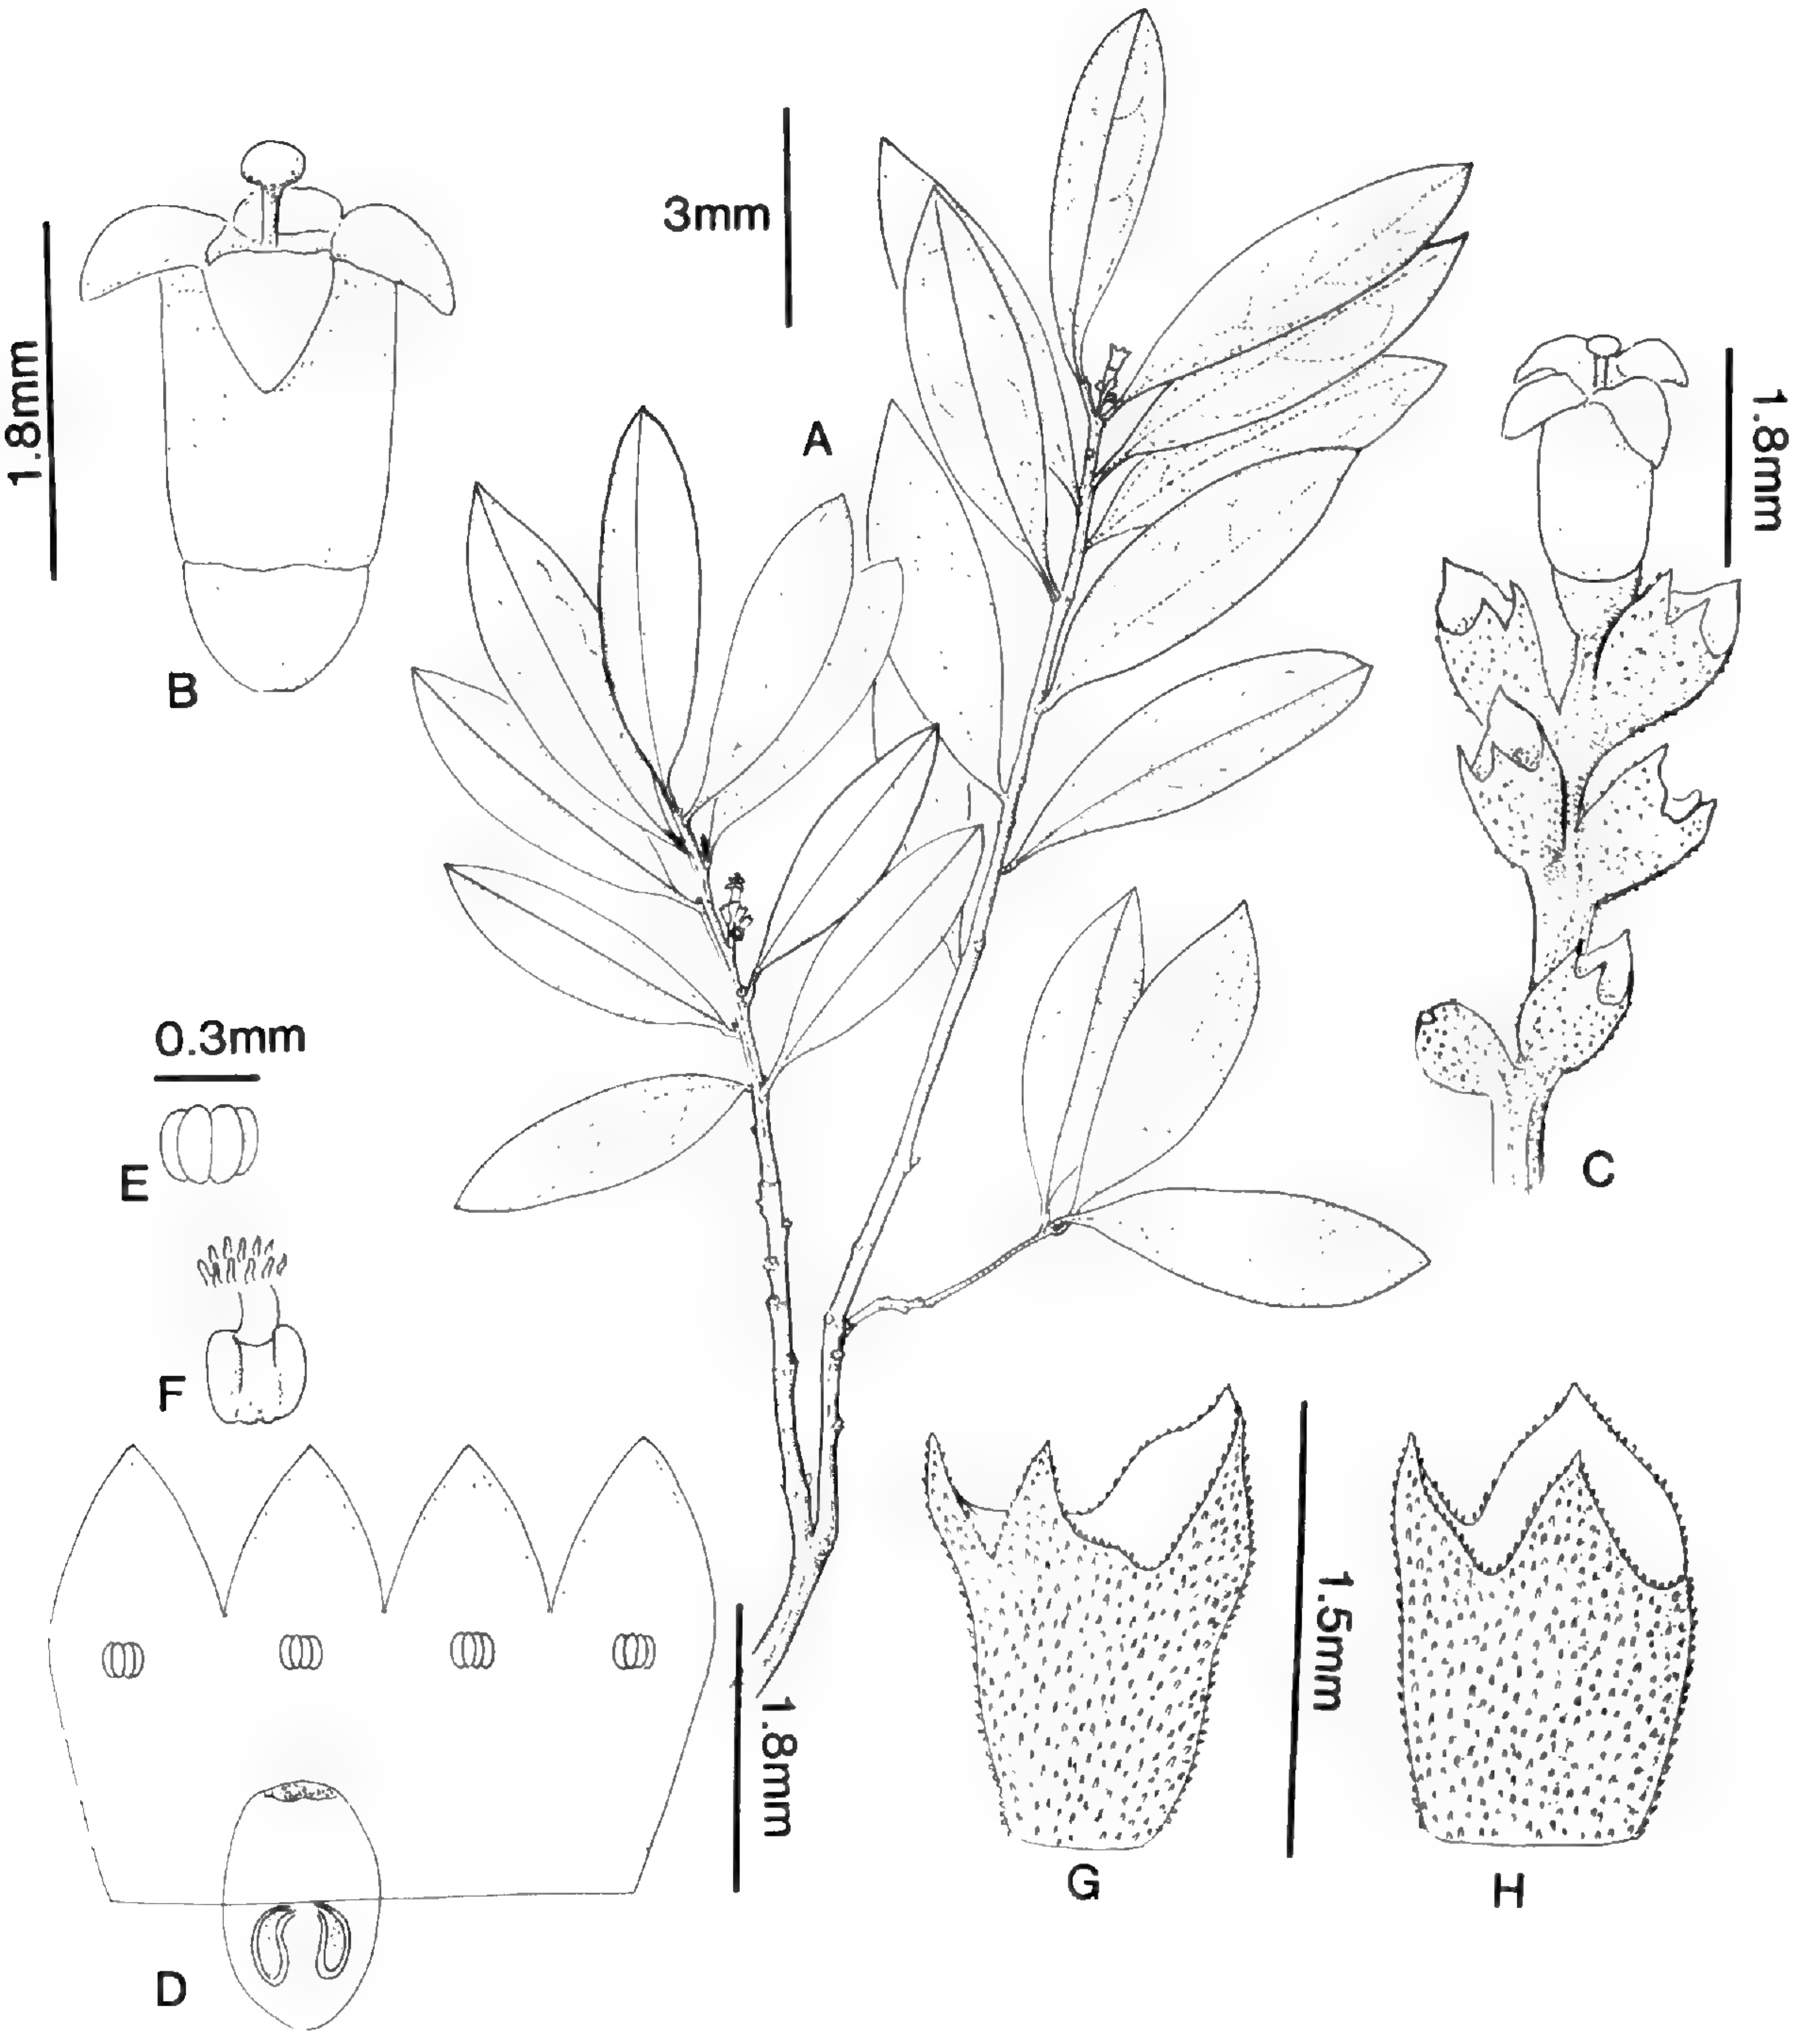

FIGURE 3. Schoepfia clarkii.—*A. Habit of flowering branch.—B. Flower.—C. Inflorescence.—D. Interior of corolla with disk and longitudinal section through ovary in position.—E. Anther, ventral view.—F. Stamen turned back to show minute puberulence on corolla tube.—G, H.—United bracteoles and bract (epicalyx), two views.*

leaf blades; depressed-hemispherical capsule opening very close to the base; and seeds with gray, flattened, contiguous tubercules that do not protrude above the general surface contour. It differs from *P. sedifolia* and *P. teretifolia* H.B.K. in its general glabrity and leaf shape.

OLACACEAE

SCHOEPFIA

Schoepfia clarkii Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Mari's bana (low Amazon caatinga), 10.8 km NE of San Carlos on Solano road, 1°56′N, 67°3′W, 119 m, 16 Aug. 1987, *H. L. Clark 8111* (holotype, MO). Figure 3.

Frutex 2 m; foliorum laminis anguste lanceolato-ellipticis apice acutis vel subacutis base cuneatim acutis, 4.5–5 cm longis 1.2–1.5 cm latis glabris integerrimis; nervis lateralibus obsoletis utroque latere 3–4; petiolis 4–5 mm longis; inflorescentia axillari spiciformi simplici usque ad 7-flora 6–7 mm longa; pedunculis ut videtur solitariis; floribus sessilibus; bracteolis bracteisque (epicalyce) supra medium connatis 1.5–1.8 mm longis apicem versus 1.5 mm latis extus dense papillato-puberulentibus; corolla late cylindrico, tubo 1.8–2 mm longo 1.6 mm lato glabro, lobis 1.2 × 1.2 mm; ovario infero 0.8 mm longo.

Shrub 2 m tall. Leaf blades narrowly lance-elliptic, acute or subacute at apex, cuneately acute at base, 4.5–5.5 cm long, 1.2–1.5 cm wide, glabrous, entire; lateral nerves obsolete, 3–4 each side; petioles 4–5 mm long. Inflorescence axillary, spiciform, simple, up to 7-flowered, 6–7 mm long; peduncle solitary, 2 mm long. Flowers sessile. Bracts and bracteoles (epicalyx) connate more than halfway, forming a 3-lobed involucre 1.5–1.8 mm long, 1.5 mm wide, narrowing to 0.9 mm wide at base, densely papillate-puberulent without; 1 larger lobe broadly triangular-ovate, abruptly acute at apex, 0.8 mm long, 0.9 mm wide at base; 2 smaller lobes narrower, broadly triangular, slenderly acuminate-attenuate, 0.5 mm long, 0.4 mm wide; tube of epicalyx shallowly campanulate, 1 mm long, 1 mm broad at summit, 0.6 mm broad at base. Corolla greenish yellow, thick-cylindric, the tube 1.8–2 mm long, 1.6 mm wide, glabrous without, glabrous within except for a minute tuft of papillate hairs behind the anthers; lobes 4, spreading-squarrose, broadly triangular-ovate, obtusely acute or subacute at apex, 1.2 × 1.2 mm. Stamens 4, subsessile, suborbicular, 0.2 mm long, 0.3 mm wide; filaments 0.2 mm long. Disk depressed-subglobose, fleshy, annular, 0.7 mm long, 1 mm wide. Ovary inferior, 0.8 mm long, 1.3 mm broad at the truncate summit, narrowed at base to 0.3 mm wide. Style 1.8 mm long; stigma capitate, 0.4 mm long, 0.7 mm wide.

This taxon is characterized by small corollas with a short tube 1.8–2 mm long, bracts and bracteoles of the epicalyx upwardly connate more than halfway, narrowly lance-elliptic leaf blades up to 1.5 cm wide, and spiciform solitary inflorescence with sessile flowers on a short rachis.

CELASTRACEAE

MAYTENUS

In preparing an account of the genus *Maytenus* for the *Flora of the Venezuelan Guayana*, the near uniformity of the floral structures and general inflorescence types has necessitated greater reliance on vegetative characters, especially those of leaf venation. In the majority of the taxa studied, the calyx lobes are uniformly suborbicular and rounded with erose-fimbrillate or ciliolate margins. Rarely, as in *M. apiculata* Steyerm. and *M. kanukensis* A. C. Smith, they are acute or apiculate. Likewise, the fruit does not vary sufficiently to separate taxa. In a few cases, such as in *M. apiculata*, the apex is noticeably prolonged to form a more prominent beak, while in *M. longistipitata* Steyerm. the base is greatly extended into a longer stipitate portion. In both *M. longistipitata* and *M. oblongata* Reiss., the fruit is larger than in the other species studied. In *M. neblinae* Steyerm. the leaves are smaller, while the leaf margins are more prominently dentate with more numerous teeth than in the other taxa examined. An insculpted type of venation characterizes the leaves of *M. insculpta* Steyerm., whereas a pustulate lower leaf surface is characteristic of *M. laevis* Reiss., *M. huberi* Steyerm., and *M. pustulata* Steyerm. In *M. sieberiana* Krug & Urban, the upper leaf surface has a finely lineolate-striolate character.

A partial treatment of the genus was published by Reissek (1861) for the Brazilian species. An account of the West Indian taxa by Urban (1904), together with descriptions of additional South American species by Briquet (1919) and A. C. Smith (1939a, b) contain the remainder of the known species from South America and the West Indies. The numerous collections from the Venezuelan Guayana have yielded the new taxa described here.

URBAN, I. 1904. Symbolae Antillanae 5: 53–72.

Maytenus huberi Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Dept. Atures, cuenca del Río Manapiare, sabanas situadas en los cerros ubicados entre el Cerro Morrocoy al sur y Serranía Colmena al Norte, 5°21′N, 66°10′W, 200–300 m, 29 Jan. 1977, *Otto Huber 441* (holotype, VEN).

Frutex 2–6 metralis; foliorum laminis crasso-coriaceis saepe pruinosis vel subglaucis oblongis elliptico-lanceolatisque vel ovato-oblongis apice late obtusis vel obtuse acutis basi rotundatis subcordatis subobtusiusculis vel rariter acutis (4.5–)6–15.5 cm longis (2.5–)3–9 cm latis integerrimis, nervis lateralibus obsoletis vel inconspicuis utroque latere 8–10, venulis tertiariis obsoletis, in superficiebus amabus folii pustulatis; inflorescentia 1–8-flora fasciculata, pedicellis sub anthesi 1–5 mm longis sub fructu 3.5–5 mm longis; calycis lobis suborbicularibus rotundatis ciliolatis; capsulis majoribus obovoideis apice rotundatis 10–11 mm longis 7–8 mm latis.

Shrub 2–6 m tall. Leaf blades thick-coriaceous, often pruinose or subglaucous on one or both surfaces, oblong, elliptic-lanceolate, or ovate-oblong, broadly obtuse or obtusely acute at the apex, rounded, subcordate, subobtuse, or rarely acute at the base, (4.5–)6–15.5 cm long (2.5–)3–9 cm wide, entire; lateral nerves obsolete or inconspicuous, 8–10 each side; tertiary venation obsolete; both surfaces pustulate. Petioles 4–11 mm long, 1.5–2 mm wide. Inflorescence 1–8-flowered, fasciculate; pedicels 1.5 mm long in anthesis, 3.5–5 mm long in fruit. Calyx lobes suborbicular, rounded, ciliolate. Petals broadly ligulate-oblong, rounded apically, 1.1–1.5 mm long, 0.8–1 mm wide. Capsules obovoid, rounded at summit, mature ones 10–11 mm long, 7–8 mm wide.

Paratypes. VENEZUELA. ATURES: cuenca del Río Manapiare, sabanas al pie de los cerros al N de Cerro Morrocoy, alrededores del sitio Pozo de la Carolina, 12 km W de San Juan de Manapiare, 5°19′N, 66°6′W, 225 m, *Huber 1223* (MO, VEN); 4.5 km N de Puerto Venado, E de Sanariapo, 5°15′N, 67°47′W, 85 m, *Huber & Tillett 16764* (MO, VEN); vegetación de laja sobre afloramiento granítico en raudal Pereza en el Río Autana, 4°48′N, 67°18′W, 100–115 m, *Guánchez & Melqueiro 3403* (MO, TFAV).

This species is distinguished by the thick-coriaceous, pustulose or verruculose leaf blades; these are usually pruinose on one or both surfaces, often drying discolored, and have scarcely evident or obsolete venation adaxially. It differs from the newly described *M. pustulata* Steyerm. in the pruinose leaf blades, inconspicuous or obsolete nervation of the upper leaf surface, and the mainly rounded or subcordate leaf base.

Maytenus insculpta Steyermark, sp. nov. TYPE: Venezuela, T. F. Amazonas: Dept. Atures, cuenca del Río Manapiare, sabanas al pie de los cerros al N del Cerro Morrocoy, alrededores del sitio "Pozo de la Carolina," 12 km W of San Juan de Manapiare, 05°19′N, 66°6′W, 225 m, 16 Oct. 1977, *Otto Huber 1229* (holotype, VEN; isotype, MO).

Frutex 3-metralis, ramulis juvenilibus teretibus tenuiter corrugatis; foliorum laminis elliptico-oblongis apice obtuse acuminatis basi subobtusis vel subacutis 11–18 cm longis 5–7 latis, marginibus haud revolutis integerrimis, nervatione ubique omnino insculpta, nervis lateralibus utroque latere 7–10 obsoletis, nervatione tertiaria ubique tenuiter insculpta-reticulata, in superficiebus amabus folii pustulatis, inconspicue decurrentibus; petiolis 6–9 mm longis; inflorescentia pauciflora breviter pedunculata, pedunculis 1.5–2.5 mm longis; pedicellis 1 mm longis; calycis lobis suborbicularibus rotundatis 0.8 × 0.8 mm valde ciliato-erosis; petalis ligulato-oblongis 1.5 mm longis 0.8 mm latis.

Shrub 3 m tall, the young stems terete, finely corrugated. Leaf blades subcoriaceous, drying concolorous, elliptic-oblong, obtusely acuminate at apex, the acumen 3–7 mm long, 3–4 mm wide, subobtuse or subacute at base, 11–18 cm long, 5–7 cm wide, the margins not revolute, entire; both lateral and tertiary nervation completely finely insculpted on both sides; lateral nerves very faint, 7–10 each side; lower and upper surfaces pustulate. Petioles 6–9 mm long, the base of leaf blade inconspicuously decurrent. Inflorescence few-flowered, shortly pedunculate; peduncles 1.5–2.5 mm long; pedicels 1 mm long. Calyx lobes suborbicular, rounded, 0.8 × 0.8 mm, strongly erose-ciliolate. Petals ligulate-oblong, 1.5 mm long, 0.8 mm wide.

This species is distinct in having the venation of both sides of the leaf blade delicately insculpted with a prominent pustulate surface between the veins. It is related to *Maytenus nitida* of Brazil, from which it differs by having rounded, suborbicular, strongly ciliolate calyx lobes, and by having larger leaf blades that are more conspicuously pustulose on the lower surface.

Maytenus laevis Reissek, in Mart., Fl. Bras. 11(1): 27. 1861.

This taxon, as Reissek noted, has the upper portion of the young stems distinctively carinate-angled and leaves "sub lente marginatis repandisque" and "subtus opacis scrupulosis." The leaves, petioles, and the young branches often take on a grayish color upon drying. While many of the specimens can be satisfactorily delimited by the application of such vegetative differences, one encounters atypical specimens on the higher slopes and summits of the table mountains in the Territorio Federal Amazonas and Estado Bolívar that indicate possible introgression from another source, such as *Maytenus guianensis* Kl. Specimens from the summit of Cerro Guaiquinima, Estado Bolívar (*Steyermark et al. 113333, 113424, 113428, 117216*), from Cerro Sarisariñama, Estado Bolívar (*Steyermark et al. 109252*—type of *M. jauaensis* Steyerm.), and from Cerro Yutaje, Territorio Federal Amazonas (*Maguire & Maguire 35441, 35455; Holst & Liesner 3272, 3357; Liesner & Holst 21807*) generally preserve the grayish dried leaf blades, petioles, and young stems as well as the thickened repand leaf margins, but the carinate-angled young stem is either lacking or scarcely apparent. These specimens may represent a variation of this taxon at higher altitudes, or may indicate introgression from *M. guianensis*, which possesses terete young stems and occurs in the Paragua and the Caura river basins, where Cerro Guaiquinima and Cerro Jaua are located, respectively.

Maytenus longistipitata Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Cerro Uroi, summit, north portion, Río Uroi, Río Chicanán, 700 m, 12 Sep. 1962, *B. Maguire, J. Steyermark & C. K. Maguire 53731* (holotype, VEN; isotype, MO).

Arbor 10 metralis, foliorum laminis lanceolato-ellipticis apice basique acutis 15–18 cm longis 5.5–6 cm latis integerrimis; nervis lateralibus principalibus utroque latere 8–10 tenuibus supra impressis subtus paullo elevatis, venatione tertiaria tenui laxe irregulariter reticulatis; petiolis 8–9 mm longis; pedicellis fructiferis fasciculatis 9–10 mm longis; capsulis late obovoideis apice rotundatis 21–26 mm longis 12–14 mm latis conspicue longistipitatis, stipite 5–7 mm longo.

Tree 10 m tall. Leaf blades lance-elliptic, acute at apex and base, 15–18 cm long, 5.5–6 cm wide, entire; main lateral nerves 8–10 each side, with finer intermediate nerves, impressed above, slightly elevated below, arcuate-ascending at an angle of 35–45°, scarcely anastomosing; tertiary venation fine, laxly irregularly reticulate and subelevated below, inconspicuous above. Petiole 8–9 mm long. Fruiting pedicels fasciculate, 9–10 mm long. Capsules broadly obovoid, rounded at summit, 21–26 mm long, 12–14 mm wide at and above the middle, conspicuously long-stipitate, the stipitate portion 5–7 mm long.

The conspicuously stipitate fruit readily distinguishes this species from *Maytenus oblongata* Reiss.

Maytenus neblinae Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Cerro de la Neblina, ridge at divide between Brazil and Venezuela, 26 km ENE of Base Camp, wet cloud forest on steep SW-facing slopes, 0°53′N, 65°56′W, 2,000 m, 15 Apr. 1984, *Timothy Plowman & Wayt Thomas 13610* (holotype, MO; isotypes, F, MO, VEN).

Arbor 8-metralis; foliorum laminis ovatis vel elliptico-ovatis vel oblongo-ellipticis apice obtusis vel obtusiusculis basi acutis vel subacutis 4.5–9.5 cm longis 2.5–3.5 cm latis, utroque margine uniformiter 30–40 crenulato-dentatis praedito, dentibus 7–8 per cm conspicuis 1–1.5 mm latis; nervis lateralibus utroque latere 8–13 supra impressis vel subelevatis subtus vix manifestis; venatione tertiaria supra manifesta subtus paullo manifesta; pagina inferiore subpustulata; petiolis 6–9 mm longis.

Tree 8 m tall. Leaf blades coriaceous, ovate or elliptic-ovate or oblong-elliptic, obtuse at apex, acute or subacute at base, 4.5–9.5 cm long, 2.5–3.5 cm wide; margins uniformly 30–40-crenulate-dentate, the dentations 7–8 per cm, conspicuous, 1–1.5 mm wide. Lateral nerves 8–13 each side, impressed or subelevated and more conspicuous on the upper side, scarcely evident beneath, ascending at an angle of 45–50°, anastomosing 3–6 mm from the margin. Petioles 6–9 mm long.

This taxon differs from some of the variations of *Maytenus guianensis* Kl. and *M. ficiformis* Reiss. with crenulate margins, in the smaller, differently shaped leaf blades with more numerous teeth per centimeter.

Maytenus pustulata Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Cerro de la Neblina, north branch of river in canyon, Camp IV, 15 km NNE of Pico Phelps, 0°51′N, 65°57′W, 780 m, 5 Mar. 1984, *Ronald Liesner 16720* (holotype, MO; isotype, VEN).

Arbor 5-metralis; foliis elliptico-oblongis apice obtusis, acumine 3–4 mm lato, basi obtusis vel subacutis 14–17 cm longis 6–7.5 cm latis integerrimis; nervis lateralibus utroque latere 9–13 supra paullo elevatis subtus obsoletis; venatione tertiaria ubique obsoletis, in superficie inferiori folii pustulatis; petiolis 11–18 mm longis; pedicellis fructiferis 6–10 mm longis; fructu ellipsoideo-obovoideo 15–16 mm longo 8–9 mm lato, apice rotundato.

Tree 5 m tall. Leaf blades coriaceous, 14–17 × 6–7.5 cm, elliptic-oblong, narrowed to an obtuse apex with an acumen 3–4 mm wide, obtuse to subacute at base, decurrent on the petiole; lateral nerves 9–13 on each side, slightly elevated on upper surface, obsolete on lower surface; tertiary veins obsolete both sides, the lower surface pustulate. Petiole 11–18 mm long, strongly canaliculate, 2–2.5 mm wide. Fruiting calyx lobes 0.5 mm long, rounded, unequally long-ciliolate around apex. Fruiting pedicels 6–10 mm long, 1–1.5 mm wide. Fruit ellipsoid-obovoid, 15–16 mm long, 8–9 mm wide toward summit, narrowed to 2.5 mm wide basally, rounded at summit.

The pustulate lower leaf surface, obsolete tertiary venation, large leaf blades, and stout pedicels distinguish this species from *Maytenus huberi* Steyerm., in which the tertiary and lateral nerve venation is insculpted.

ZINOWIEWIA

Zinowiewia aymardii Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Dist. Sifontes: bosques húmedos intervenidos por actividades mineras del sector "La Hoya" (Peray-tepuy), 7 km NW of Caserio El Pilón, 58 km W of Sta. Elena de Uairén, 4°40′N, 61°33′W, 850 m, 21 Oct. 1986, *Gerardo Aymard 4631* (holotype, MO; isotype, PORT).

Arbor 10–45 metralis, foliorum laminis ovatis vel lanceolato-ellipticis apice obtuse acuminatis basi attenuato-acutis vel acuminatis decurrentibus 5.5–10 cm longis 2.5–3.5(–4.5) cm latis; nervis lateralibus utroque latere (5–)8–12 supra subelevatis, venatione tertiaria ubique manifestis grosse reticulatis; petiolis 4–10 mm longis; inflorescentia cymosa axillari terminalique 5–6-plo ramosa 2.5 cm longa 4–6 cm lata, axibus primariis 3–9 mm longis; floribus 5-meris; pedicellis 1–1.5 mm longis; calycis lobis suborbicularibus rotundatis 0.5 mm longis 0.7 mm latis; fructu oblique obovato 14–20 mm longo apicem versus 7–9 mm lato arcte venoso; seminibus anguste ellipsoideis 6.5–7 mm longis 2–3 mm latis.

Tree 10–45 m tall. Leaf blades ovate or lance-elliptic, obtusely acuminate at apex, narrowly acute to acuminate at the shortly decurrent base, 5.5–10 cm long, 2.5–3.5(–4.5) cm wide; lateral nerves (5–)8–12 each side, ascending at an angle of 45–60°, anastomosing 3–5 mm from margin, conspicuous and impressed or subelevated above, less conspicuous below; tertiary venation manifest both sides, grossly reticulate, more conspicuous below; midrib impressed above with a slender narrow ribbonlike border on each side. Inflorescence cymose, axillary and terminal, 5–6 times branched, 2.5 cm long, 4–6 cm wide, the primary axes 3–9 mm long. Flowers 5-merous, the pedicels 1–1.5 mm long. Bracts subtending opposite pairs of the dichotomous axes. Calyx papillose-pustulose without, the lobes suborbicular, rounded, 0.5 mm long 0.7 mm wide, margins slightly uneven but eciliate, the apex ending slightly higher than the lateral margins and crowned by 3 darker minute appendages. Petals broadly ovate-oblong, rounded at apex, 1.1 mm long, 0.5–0.8 mm wide. Anthers orbicular, 0.2–0.3 mm × 0.2–0.3 mm; filaments 0.3–0.4 mm long, slightly wider basally. Disk annular-cupuliform, lance-deltoid, acute, 0.5–1 mm long, the margins with dark squamellate appendages. Fruit obliquely obovate, broadly rounded at apex, 14–20 mm long, 7–9 mm wide toward the distal end, about 3 times longer than broad, strongly venose, the main nerves at first parallel. Seeds narrowly ellipsoid, 6.5–7 mm long, 2–3 mm wide.

Paratype. VENEZUELA. BOLÍVAR: lower portion of Quebrada Oparumá, tributary to Río Pacairao, below Santa Teresita de Kavanayén, 915–1,065 m, 25 Nov. 1944, *Steyermark 60580* (F, VEN). T. F. DELTA AMACURO: bosque pluvial, E of Río Grande, ENE of El Palmar, near limits of Bolívar, 13 Jan. 1965, *Marcano Berti 562* (MER, MO, NY, VEN).

Common names. Ata-caramá-yek (Arekuna); guatacare montanero.

This taxon differs from *Zinowiewia australis* Lundell of the northern Coastal Range of Venezuela in the more numerously flowered, larger inflorescence with longer primary and secondary axes, and especially in the shorter seed body and shorter fruit with the wing narrower in proportion to the width. Also the leaf blades are more shortly and less abruptly decurrent.

RHAMNACEAE

GOUANIA

Gouania wurdackii Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Dist. Cedeño: Cerro San Borja, middle Orinoco River, 100–300 m, 12 Dec. 1955, *J. J. Wurdack & J. V. Monachino 39810* (holotype, MO; isotypes, NY, VEN).

Frutex scandens; foliorum laminis discoloribus anguste ovatis vel oblongo-ovatis apice acutis vel subacutis basi cordatis vel subcordatis 4–7 cm longis 2.5–4 cm latis supra tenuiter rugulosis sulcinerviis sulcis adpresso-pubescentibus subtus densissime arcte cinereo-vel stramineo-tomentellis, marginibus arcte serratis, dentibus utroque margine 15–20 late deltoideis subacutis apice in glandulis callosis obtusis parvis paullo incrassatis terminantibus; costa media supra nervis lateralibus tertiariisque sulcatis subtus manifeste elevatis, nervis lateralibus utroque latere 6–8; petiolis 5–10 mm longis; floribus extus dense cinereo-tomentosis; calycis lobis ovatis subacutis 1.2 mm longis extus albido-pilosis intus glabris; disco dense minuteque pubescenti, circa stylum elevato pilis setosis munito, lobis triangulari-lanceolatis ad apicem attenuatis subemarginatis subobtusis 0.5 mm longis; capsulis suborbicularibus alatis 9–10 × 9–10 mm, omnino dense pilosulis alis sublunatis longioribus quam latioribus 9–10 mm longis 2.5–4 mm latis.

Woody vine or climbing shrub with striate, densely fulvous-tomentellose branches. Leaf blades discolored (dry), olive green above, cinereous or stramineous below, narrowly ovate or oblong-ovate, acute to subacute at apex, cordate or subcordate at base, 4–7 cm long, 2.5–4 cm wide, finely rugulose and sulcate-nerved above, minutely appressed-pubescent in the sulcations, below densely tomentellose with cinereous or stramineous hairs completely covering the surface and nerves, the hairs on the lower surface densely intertwining and matted, the margins closely and rather uniformly serrate with 15–20 broadly deltoid, subacute teeth 2–4 mm wide and averaging 4 per cm, terminating in a small, brown or maroon-brick-colored, thickened callosity, glabrous on the lower side and with axillary hairs on the upper leaf surface; lateral nerves 6–8 each side, sulcate above; midrib and lateral and tertiary nerves conspicuously elevated, the tertiary ones conspicuously transverse between the finer elevated veinlets. Petioles 5–10 mm long, densely pubescent with stramineous or pale yellow-brown hairs. Inflorescence interruptedly spiciform, the lower inflorescences simple and axillary, the upper becoming paniculately branched; rachis deeply stramineous or pale brown pubescent. Flowers sessile or nearly so. Calyx lobes ± densely pilose without, with pale hairs, ovate, subacute, 1.2 mm long, 1.2–1.3 mm wide at the base, glabrous within; hypanthium obconic, 1.2 mm long, densely pubescent. Petals cucullate, about length of calyx lobes. Disk completely and densely short pubescent, elevated into an annulus near the style, where densely setose; disk lobes triangular-lanceolate, attenuate to a subobtuse subemarginate apex ca.0.5 mm long, about ⅓ the width of the calyx lobe. Capsules fulvous brown or gray-brown, sessile or up to 2 mm pedicellate, suborbicular, about as broad as long, 9–10 × 9–10 mm, ± densely pilosulous throughout; axis of fruit 7–9 mm long, the wings sublunate, longer than broad, 9–10 mm long, 2.5–4 mm wide, about as wide as the central body.

Paratypes. VENEZUELA. BOLÍVAR: Dist. Cedeño: east slopes of Cerro Pijiguao, N end of Serranía Suapure, above Pijiguao, ca. 70 km from mouth of Río Suapure, 110–520 m, 19 Jan. 1956, *Wurdack & Monachino 41310* (MO, NY, VEN). T. F. AMAZONAS: Dpto. Atures, 18 km al SE de Puerto Ayacucho, laja cerca de la Piedra con Petroglifos, ± 2 km al N del pueblo de Pintado, 5°32′N, 67°32′W, 1,000 m, 8 Dec. 1977, *Huber 1370* (NY, VEN).

This taxon is distinguished vegetatively from the common and widely distributed *Gouania mollis* H.B.K. by the narrowly lance-ovate, acute leaves with conspicuous discolored nerves on the stramineous lower surface and by the finely rugulose sulcate nerves of the upper surface. Also, the tertiary venation abaxially is conspicuously elevated and prominent transversely and the marginal teeth are closer together, shorter, narrower, and terminate more abruptly in smaller callosities. The taxon is restricted to the granitic sector of the Distrito Cedeño of northwestern Estado Bolívar and adjacent northwestern Territorio Federal Amazonas, a region of high endemism.

RHAMNUS

Rhamnus longipes Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Serranía Parú, cumbre, SSE to edge of descent, to tributary of Caño Asisa, mostly rocky sabanita open areas, 2,000 m, 10 Feb. 1951, *R. S. Cowan & John J. Wurdack 31388* (holotype, NY).

Frutex 2-metralis, ramulis juvenilibus sparsim pilosulis; foliorum laminis ovatis vel oblongo-ovatis apice acutis vel subacuminatis basi obtusis majoribus 5–6.5 cm longis 2.5–3.2 cm latis obscure repando-crenulatis, costa media subtus sparsim pilosula, aliter ubique glabris; nervis lateralibus utroque latere 5–8; petiolis 4–8 mm longis paullo pilosulis; calyce fructifero sparsim pilosulo pilis adpressis munito; infructescentia 1–2-fructifera; pedunculo fructifero maturo 10–15 mm longo sparsim pilosulo; pedicellis fructiferis maturis 10–15 mm longis sparsim pilosulis; fructibus subglobosis 5–7 mm longis 6–7 mm latis.

Shrub 2 m tall. Young stems sparsely pilosulous with pale hairs. Leaf blades ovate or oblong-ovate, acute to subacuminate at apex, obtuse at base, the larger ones 5–6.5 cm long, 2.5–3.2 cm wide, the margins subrevolute, obscurely repand-crenulate with ca. 3 depressed crenulations per cm, the leaf surface glabrous both sides; midrib above sulcate, glabrous, below sparsely pilosulous with pale hairs. Principal lateral nerves 5–8 each side, inconspicuous above, slightly elevated below; tertiary venation slightly sulcate above, more conspicuously so below. Petiole 4–8 mm long, slightly pilosulous with pale hairs. Fruiting calyx sparsely pilosulous, the lobes triangular-lanceolate, subacute, 1.3 mm long. Infructescence with 1–2 fruits; mature fruiting peduncle and pedicels 10–15 mm long, pilosulous with pale hairs. Fruit subglobose, 5–7 mm long, 6–7 mm broad, glabrous.

This species is characterized by the relatively elongated, sparsely pilosulous fruiting peduncle with 1–2 elongate, sparsely pilosulous pedicels 10–15 mm long; subrevolute, shallowly repand-crenulate leaf margins with an average 3 crenulations per cm; and the slightly elevated tertiary venation of the lower leaf surface.

Rhamnus sipapoensis Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Cerro Sipapo (Paraque), rim head of South Basin, occasional in woodland, rugged terrain, 1,970 m, 26–28 Jan. 1949, *Bassett Maguire & Louis Politi 28656* (holotype, NY; isotype, MO).

Arbor 3-metralis, ramulis junioribus dense brunneo-tomentosis; stipulis haud persistentibus; foliorum laminis oblongis elliptico-oblongis vel ovato-oblongis apice obtuse acutis vel abrupte breviter acutis mucronatis basi rotundatis vel obtusis 2.5–7.5 cm longis 1.5–3.8 cm latis, supra glabris subtus pallido-stramineis dense velutinis, marginibus revolutis integerrimis vel fere integerrimis; costa media nervisque supra sulcatis subtus dense tomentellis; nervis lateralibus utroque latere 7–11; petiolis 4–10 mm longis dense tomentellis; inflorescentia epedunculata vel pedunculo usque ad 6 mm longo; pedicellis sub anthesi 6–9 mm longis post anthesim usque ad 11 mm longis dense brunneo-pubescentibus; calyce 3.5–4 mm longo extus dense brunneo-tomentelloso; ovario dense pubescenti.

Tree 3 m tall, the young branches densely dull brown tomentellous. Stipules not persistent. Leaf blades oblong, elliptic-oblong, or ovate-oblong, mucronate at the obtusely acute to abruptly short acute apex, obtuse to rounded at base, 2.5–7.5 cm long, 1.5–3.8 cm wide, glabrous above, densely pale buff velutinous below with the tomentum concealing the leaf surface; margins revolute, entire or nearly so; midrib and lateral nerves sulcate above, below densely brown tomentellous. Lateral nerves 7–11 each side, spreading-ascending at an angle of 25–45°, ending at margins. Petioles 4–10 mm long, densely tomentellous. Inflorescence epedunculate or with a peduncle up to 6 mm long. Pedicels 6–9 mm in anthesis, up to 11 mm long after anthesis, densely brown pubescent. Calyx campanulate, 3.5–4 mm long, 3.2–3.5 mm broad, densely brown tomentellous; lobes 5, lanceolate-ovate, acute, 1.5–2.1 mm long, 1–1.5 mm wide. Petals unguiculate, bilobate, 1.5 mm long, the lamina suborbicular-obovate, 0.8 mm long, 1.3 mm wide. Anthers oblong-subquadrangular, 0.5 mm long; filaments 1 mm long, glabrous. Ovary subglobose, 1.5 mm long, densely pubescent; style 0.4 mm long, glabrous.

This species has a close affinity with *Rhamnus marahuacensis* Steyerm. & Mag., from which it differs in the mainly epedunculate inflorescence, or the peduncle may be developed to 6 mm in length. It differs further in the densely tomentose calyx, pedicels, and stems; the mainly entire leaf margins; the obtusely acute to abruptly short-acute, mucronate leaf blades; and the more densely tomentose lower leaf surface.

SAPINDACEAE

MATAYBA

Matayba affinis Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Dept. Atabapo. Cucurital de Caname, southern bank of the middle part of Caño Caname, 3°40′N, 67°22′W, 100 m, 30 Apr.–1 May 1979, *Gerrit Davidse, Otto Huber & Stephen Tillett 17011* (holotype, MO; isotype, VEN). Figure 4.

Arbor 4-metralis; foliis 3 dm longis, foliolis 3–5 oblongo-obovatis vel elliptico-oblongis apice rotundatis vel obtuse acutis basi acutis majoribus 14–15 cm longis 6–7 cm latis, praesertim secus costam mediam nervos lateralesque glandulis microscopicis rufis obsitis aliter glabris integerrimis; calycis lobis late suborbicularibus apice rotundatis vel subacutis 1–1.2 mm longis 1.2–1.5 mm latis; antheris pilosis; disco sparsim piloso; stylo elongato 1.2 mm longo; ovario 3-loculari.

Tree 4 m, the branches strongly lenticellate. Leaves, including the petiole, 3 dm long. Petioles 3–4 cm long, microscopically puberulent. Leaflets 3–5, alternate, oblong-obovate to elliptic-oblong, rounded to obtusely acute at apex, acutely narrowed at the base, the upper larger ones 14–15 cm long, 6–7 cm wide, the lower smaller ones 7–11 cm long, 3–5 cm wide, glabrous except for the microscopic rufous glands especially abundant along the midrib and lateral nerves, entire; lateral nerves 6–8 on each side, inconspicuous, ascending at an angle of 45–50°; tertiary venation finely and obscurely reticulate both sides; petiolule 5–6 mm long, glabrous. Panicle terminal, 15–18 cm long; rachis moderately puberulent with 2–4 unbranched axes 2.5–7 cm long, bearing numerous sessile clusters of pedicellate flowers. Pedicels 1.5–3 mm long, densely puberulous. Calyx moderately appressed-puberulous without, the margins cut ⅔ the length; calyx lobes broadly suborbicular-deltoid, rounded or subacute at apex, 1–1.2 mm long, 1.2–1.5 mm wide at the base. Petals narrowly oblong-ovate, obtuse, 1.2 mm long, 0.4 mm wide; petaliferous scales rhomboid-oblong, rounded, slightly exceeding the petal, 1.3–1.5 mm long, 0.5 mm wide, densely villous as is the petal. Anthers suborbicular, 0.5 × 0.5 mm, densely pilose; filaments 2 mm long, pilose except in uppermost portion. Disk sparsely pilose. Style 1.2 mm long, elongated, sparsely strigillose. Ovary ovoid-subglobose, trigonous, 2 mm long, 1.5 mm wide, 3-celled, moderately strigillose.

This species is allied to *Matayba macrostylis* Radlk., but the anthers are pilose, the disk is sparsely pilose, the calyx lobes are rounded or subacute, the ovary is 3- instead of 2-celled, the petals are shorter, and the leaflets are rounded or obtusely acute, and only 3–5.

Matayba longipes Radlk., Sitzungsber. Bayer. Akad. IX. 536. n. 479. p. 626. n. 7. 1879; in Engler, Das Plfanzenreich, Heft 98e (IV. 165). Sapindaceae. 1085. 1933. *Matayba tovarensis* Radlk., Sitzungsber. Bayer. Akad. IX. 536. n. 494. p. 626. n. 8. 1879.

Radlkofer (1933) distinguished *Matayba tovarensis* Radlk. from *M. longipes* Radlk., both described from the area of Colonia Tovar, Venezuela, on vegetative characters only, such as supposed differences in texture (membranous in *M. longipes* contrasted with coriaceous in *M. tovarensis*), leaf shape (oblong- or subacute-lanceolate in *M. longipes* vs. lanceolate in *M. tovarensis*), and degree of narrowing of the base of the leaflet blade into the petiole (abruptly attenuate in *M. longipes*, but gradually narrowed in *M. tovarensis*). Study of type material and of additional col-

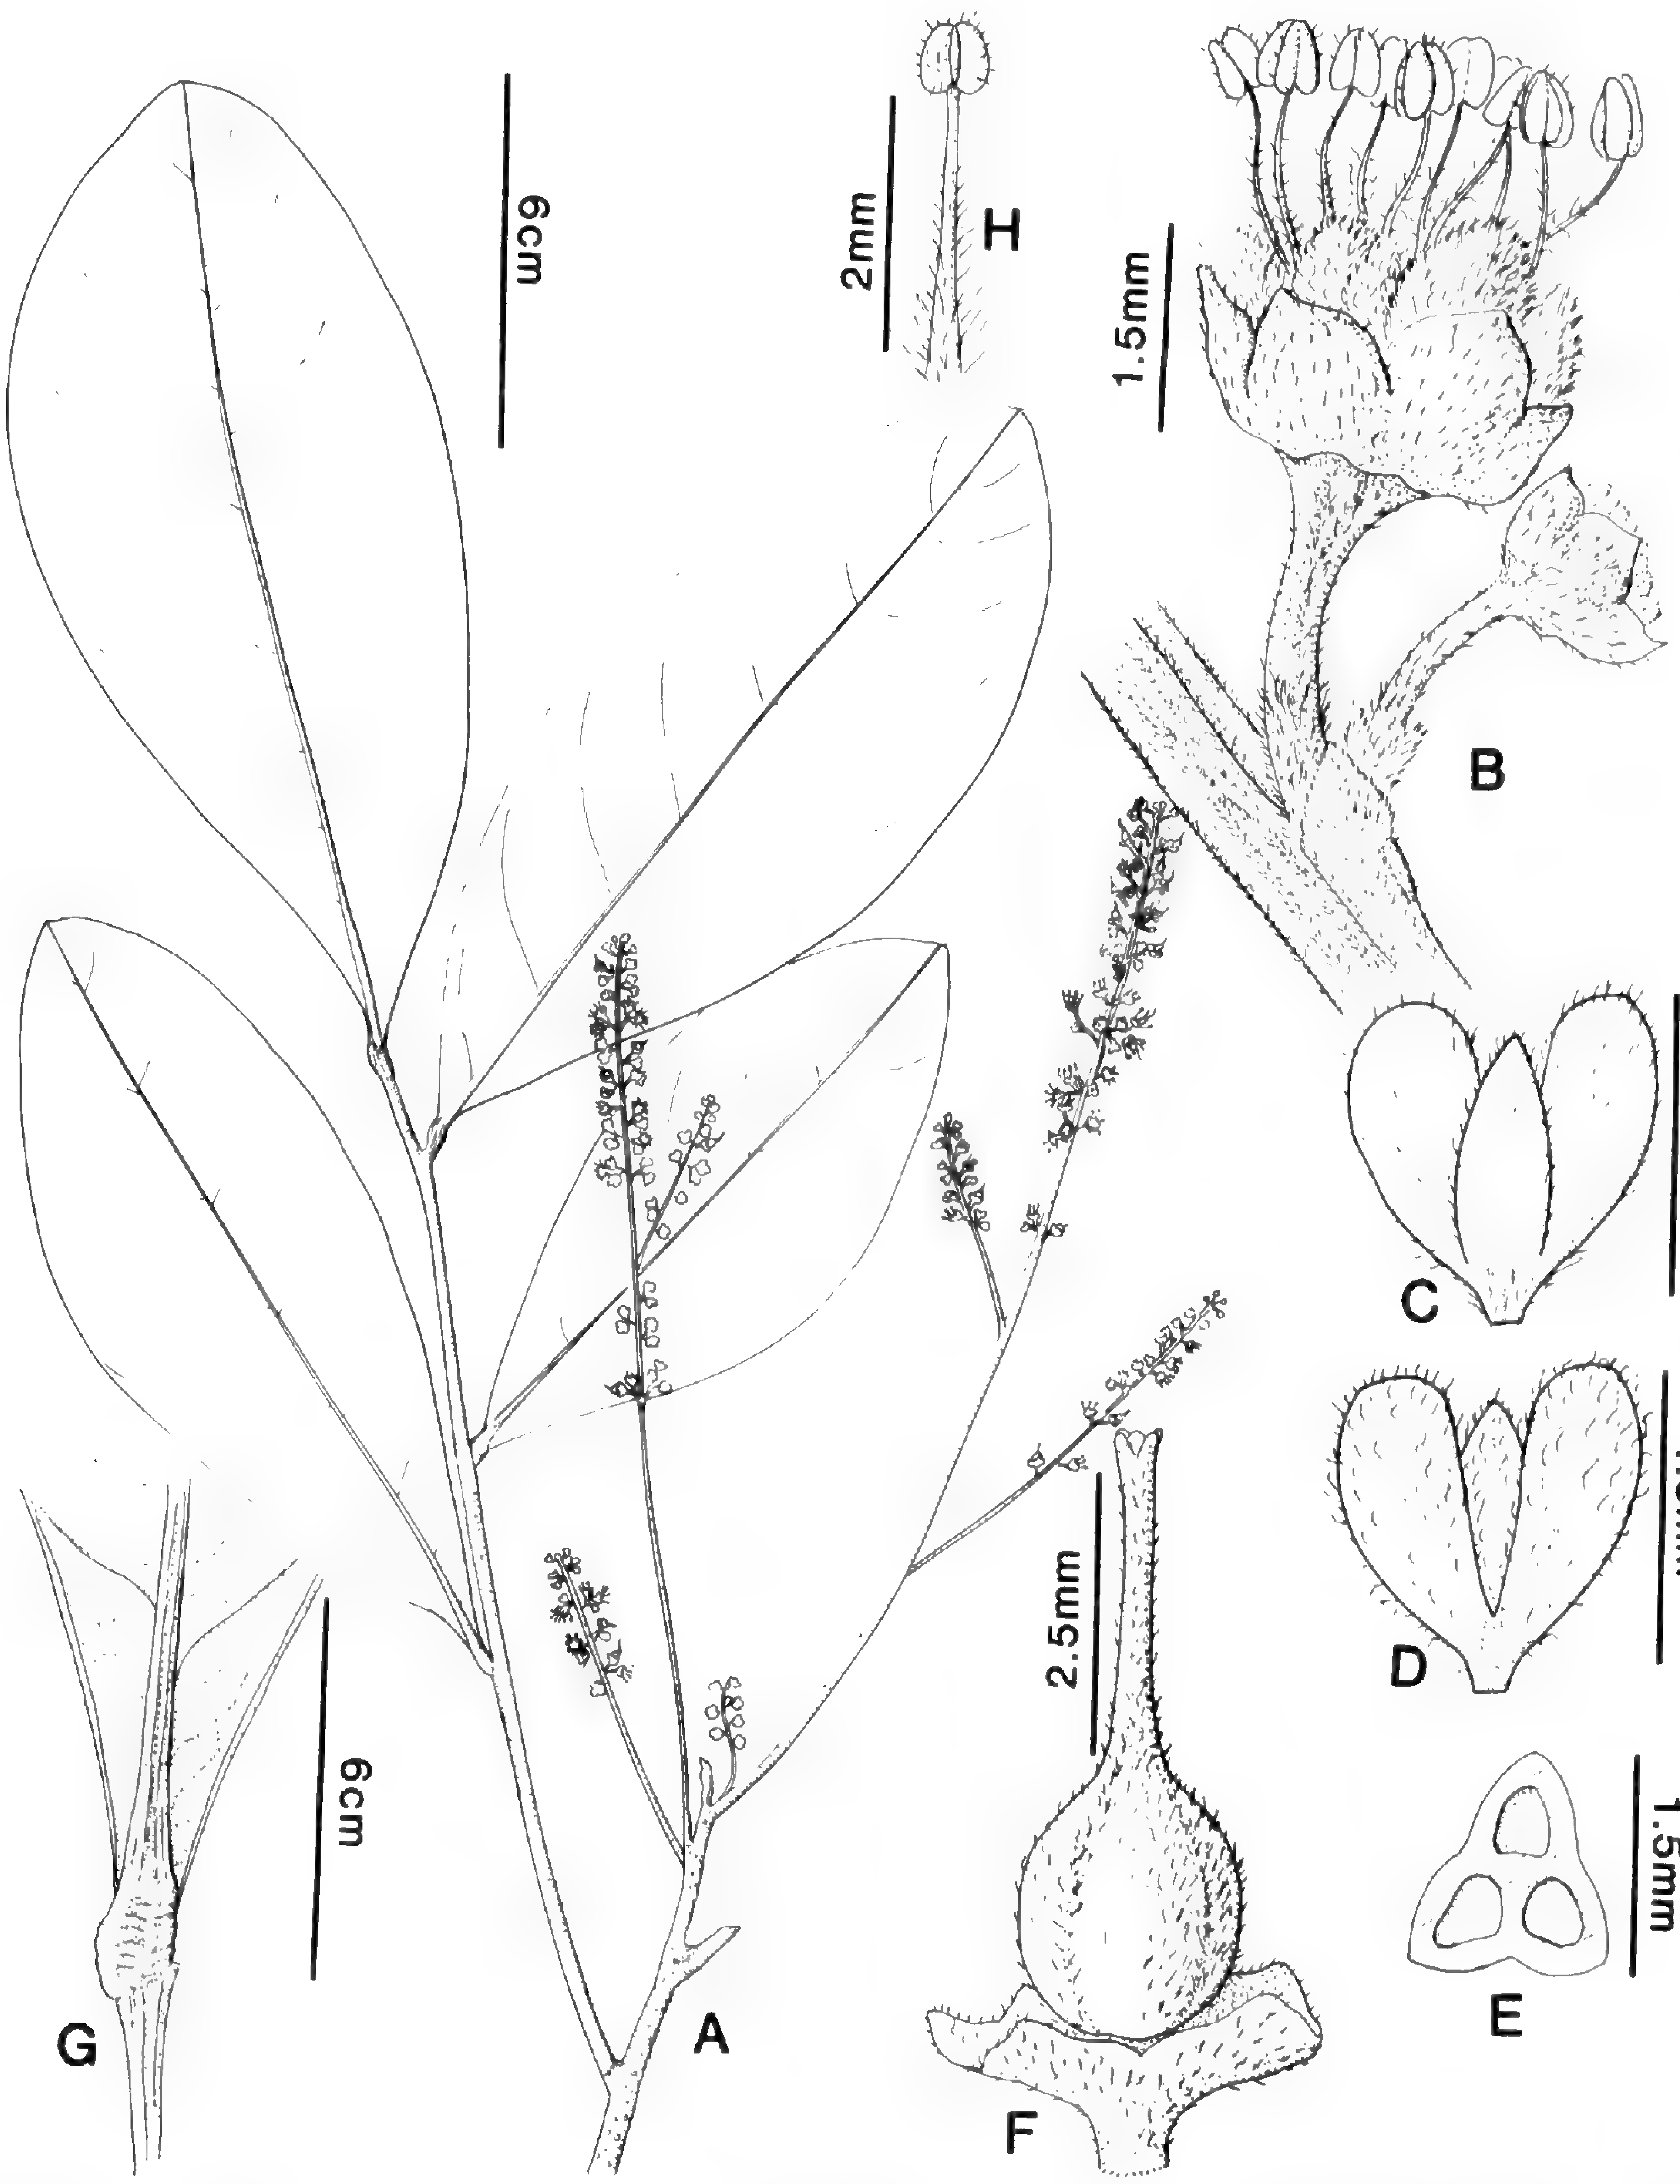

FIGURE 4. Matayba affinis.—*A. Habit of flowering branch.—B. Detail of small portion of flowering rachis.—C. Petal, dorsal view.—D. Petal, ventral view.—E. Diagrammatic transverse section through ovary.—F. Pistil and calyx.—G. Basal portion of leaf blade, abaxial view, with portion of petiole.—H. Stamen.*

lections from near the type locality and elsewhere in the coastal mountains of northern Venezuela indicates that these differences break down and that the two taxa must be united. Even on the type specimen of *M. longipes* (*Fendler 1748*), a few leaflets show their bases gradually tapering into the petiole as in *M. tovarensis*. The leaflet shape varies within a given population, and there appears to be no difference in the texture of the two taxa. I am uniting them under *M. longipes*.

The fruit of *Matayba longipes* has a stipe described as being 1.8–2 cm long (Radlkofer, 1933). However, an isotype specimen at MO has stipes mostly only 1.5 cm long.

Fruiting specimens collected in the Venezuelan Guayana from Cerro Yutaje, Serraní Parú, and the Brazilian side of the Cerro de La Neblina in Territorio Federal Amazonas agree in all essential respects with *Matayba longipes* of the Venezuelan coastal mountains, except for the constantly shorter fruiting stipe, only 5–9 mm long, whereas in typical *M. longipes* the length varies from 9–18 (−20) mm. Other minor differences are in the sometimes smaller number of leaflets, relatively larger length and width of the leaflets, and in their slightly longer, more slender leaf apex. This difference in foliage is somewhat more marked in the specimens from Serranía Yutaje and Neblina than those from the vicinity of Cerro Yutaje.

In view of the differences in stipe length and the geographically isolated distribution on the sandstone mountains of the Venezuelan Guayana, together with some tendency in foliar divergence, I consider that the Guayana population shows a sufficient degree of separation as to warrant a subspecific status.

RADLKOFER, L. 1933. Sapindaceae. *In:* A. Engler, Das Pflanzenreich IV. 165:1085. (Heft 98e).

Matayba longipes Radlk. subsp. **tepuiensis** Steyerm., subsp. nov. TYPE: Venezuela. T. F. Amazonas: Serranía Parú, Caño Asisi, Top Camp to Caño Camp, talus slopes, 1,400 m, 13 Feb 1951, *R. S. Cowan & J. J. Wurdack 31450* (holotype, MO, as 2997923; isotype, NY).

A *M. longipes* praesertim fructus stipite 5–9 mm longo recedit; foliolis quattuor quinque vel sex 9–21 cm longis 3–8 cm latis; infructescentiis 2–12 cm longis.

Tree 8–20 m tall. Leaves 4–6-foliolate; leaflets elliptic-ovate to oblong-lanceolate, obtusely to slenderly acutely acuminate, 9–17(−21) cm long, 3–6.5(−8) cm wide, the acumen 1.5–2.5 cm long, abruptly to gradually acutely narrowed to the base; main lateral nerves 8–10(−12) each side, elevated below; tertiary venation prominently reticulate. Petiole 4–8 cm long; petiolule 2–10 mm long. Disk tomentose. Infructescence 2–12 cm long, the peduncle and rachis mostly densely strigose-pubescent. Fruiting pedicel 4–7 mm long, sparsely strigillose. Stipe of fruit 5–9 mm long, sparsely strigillose. Fruiting capsule lobed, horizontally divaricate, 7–12 mm high, 1.5–2.2 cm broad, glabrous or very sparsely puberulent without, the valves densely tomentose within. Style persistent in fruit, 2–3 mm long.

Paratypes. VENEZUELA. T. F. AMAZONAS: Depto. Atures, valley of Río Coro-Coro, west of Serranía de Yutaje, east base of forested mountain 5 km W of river, 5°41′N, 66°9′30″W, 1,100 m, 10 Mar. 1987, *Holst & Liesner 3405*. Matayba oligandra Sandwith var. **oligandra**

Matayba oligandra Sandw., Kew Bull. 1935: 123. 1935.
Trichilia ptariana Steyerm., Fieldiana, Bot. 28(2): 278. 1952.
Matayba oligandra var. *ptariana* (Steyerm.), Bol. Soc. Venez. Ci. Nat. 26: 426. 1966.
Matayba jauaensis Steyerm., Bol. Soc Venez. Ci. Nat. 33 (132/133): 347, fig. 15. 1976.

Matayba oligandra Sandw. var. **occidentalis** Steyermark, var. nov. TYPE: Venezuela. T. F. Amazonas: West Mountain Caño Grande, Río Cuao, Río Orinoco, 125 m, 17 Jan. 1949, *Bassett Maguire & Louis Politi 28399* (holotype, MO; isotype, NY).

A *M. oligandra* foliolis ovatis elliptico-ovatisve 2.5–4.5 cm latis (2.8–)3–3.6-plo longioribus quam latioribus, acumine longitudine ¼–⅙ laminae partes aequanti recedit.

Leaves 10–12-foliolate. Leaflets ovate or elliptic-ovate, abruptly slenderly and obtusely acuminate at apex, acute at base, 5.5–10.5 cm long, 2.5–4.5 cm wide, (2.8–)3–3.6 times longer than broad, the acumen 10–20 mm long, ¼–⅙ the length of the leaf blade; petiolules 5–10 mm long. Petioles (3–)5.5–8 cm long. Infructescence 9–17 cm long. Fruit 1.5–1.8 cm long, 1.5–2 cm diam., the valves glabrous without and within.

Paratypes. VENEZUELA. T. F. AMAZONAS: Cerro Sipapo, Campo Grande, 1,500 m, 8 Dec. 1948, *Maguire & Politi 27558* (MO, NY); Cerro Arauicaua, Río Yatua, 1°35′N, 66°10′W, 125–150 m, 12 Apr. 1970, *Steyermark & Bunting 102560* (VEN).

Matayba oligandra Sandw. var. *oligandra*, described from Guyana (Sandwith, 1935: 123), has the leaflets principally oblong or oblong-lanceolate, 2–3.8 cm wide, chiefly 2.2–3 times longer than broad, and with an acumen ⅙–⅐ the length of the leaf blade. It is confined to Estado Bolívar in the eastern half of the Venezuelan Guayana. Var. *occidentalis*, on the other hand, is restricted to the western part of the Venezuelan Guayana in Territorio Federal Amazonas. *Matayba jauaensis* Steyerm. and *M. oligandra* var. *ptariana* Steyerm. appear to represent merely minor variations of leaflet size and cannot be maintained apart from var. *oligandra*.

The type collection of *Matayba oligandra* and *M. chimantensis* Steyerm., the latter possibly synonymous with *M. oligandra*, have only 4–6 stamens, whereas *M. jauaensis* Steyerm. and *M. oligandra* var. *ptariana* have 8 stamens. However, no additional characters have been found to separate those collections having 8 stamens from typical *M. oligandra*.

SANDWITH, N. Y. 1935. Contributions to the Flora of Tropical America: XXIII. Bull. Misc. Inform. 1935: 117-132.

Matayba yutajensis Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Serranía Yutaje, Northwest Ridge, 1,400 m, 11 Feb. 1953, *Bassett & C. K. Maguire 35143* (holotype, MO; isotypes, NY, VEN). Figure 5.

Arbor 3-5-metralis; foliis 2-4-foliolatis; foliolis alternis, oblongis vel oblanceolato-oblongis apice rotundatis retusisque 10-18 cm longis 2.5-8 cm latis; nervis lateralibus principalibus utrinque latere 8-15; venulis tertiariis utrinque conspicue elevatis reticulatisque; petiolis 1-1.7 cm longis; calyce 3.5-4 mm lato extus glabro; filamentis ubique dense pilosis; fructu 2 cm longo 2.3 cm lato extus glabro; endocarpio intus glabro.

Tree 3-5 m. Leaves 2-4-foliolate. Leaflets alternate, oblong to oblanceolate-oblong, rounded and retuse at apex, subacute to acute at base, 10-18 cm long, 2.5-8 cm wide, glabrous throughout; principal lateral nerves rather inconspicuous, 8-15 each side, spreading at an angle of 10-20°; tertiary venation prominently elevated and reticulate on both sides. Petioles 1-1.7 cm long, glabrous; petiolules 3-8 mm long, glabrous. Inflorescence terminal or subterminal, including the peduncle, 15-18 cm high, 5 cm wide, sparsely branched, the individual axes ascending, 2-5 cm long, sparsely strigillose. Rachis sparsely strigillose to glabrescent. Flowers pedicellate. Pedicels 1-1.5 mm long, sparsely strigillose. Bract subtending pedicels and axes lanceolate, acute, 0.7-1 mm long, sparsely strigillose. Calyx 3.5 mm long, 3.5-4 mm wide, glabrous without or sparsely strigillose near base; lobes suborbicular, rounded with narrowed to subacute apex, 1 mm high, 2 mm wide. Petal suborbicular-flabelliform, 1.5 mm long, 1.6-1.7 mm wide, glabrous without, pilose within; petaliferous scales obovate-oblong, rounded-truncate at summit, 1 mm long, 0.5 mm wide, with long brownish hairs, the margins (especially around the apex) laciniate-pectinate, pubescent both sides. Anthers suborbicular, basally bilobed, 0.7 × 0.7 mm; filaments 3 mm long, 0.3 mm wide at base, densely pilose throughout. Fruit 3-lobed, shortly stipitate, the stipe 3 mm long, 4 mm wide; fruit body 2 cm long, 2.3 cm wide, glabrous without; endocarp glabrous within.

Paratypes. VENEZUELA. T. F. AMAZONAS: Serranía Yutaje, Cerro Yutaje, left hand fork of Caño Yutaje, 1,300-1,400 m, 15 Feb. 1953, *B. & C. K. Maguire 35242* (MO, NY); 1-2 km E of Río Coro-Coro, W of Serranía Yutaje, 9 km N of Yutaje settlement, 5°42'N, 66°07'30"W, 500-730 m, 28 Feb. 1987, *Liesner & Holst 21484* (MO, NY, VEN); valley of Río Coro-Coro, W of Serranía Yutaje, W of valley, 5°42'30"N, 66°10'W, 1,300 m, *Holst & Liesner 3368* (MO, NY, VEN); Dept. Atabapo, Cerro Marahuaca, above branch of Caño Negro, S-central part of meseta, downstream from "Sima" camp, 3°43'N, 65°31'W, 1,220-1,350 m, 23-24 Feb. 1985, *Steyermark & Holst 130642, 130671* (MO, VEN); Cerro Marahuaca, Río Yameduaka, 3°38'N, 65°28'W, 1,225 m, 17-18 Feb. 1985, *Liesner 17614* (MO, VEN).

This species is related to *Matayba atropurpurea* Radlk., from which it differs in the retuse, rounded apex of the leaflets; fewer leaflets; shorter petioles; filaments densely pilose throughout their length; and the much larger fruit. Further, *Matayba yutajensis* occupies higher altitudes of montane forest of the sandstone table mountains, whereas *M. atropurpurea* is a lowland tree.

TALISIA

Talisia amaruayana Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Amaruay-tepui, 5°54'N, 62°15'W, 550-810 m, 26 Apr. 1986, *Ronald Liesner & Bruce Holst 20394* (holotype, MO; isotype, VEN).

Arbor 3-metralis; foliis 12-foliolatis; foliolis lanceolatis apice acuminatus basi acutis vel subacutis 26-38 cm longis 4-8 cm latis praeter costam mediam subtus sparsim puberulentam glabris; nervis lateralibus utroque latere 16-25; panicula usque 8.5 dm longa; calycis lobis intus glabris extus puberulis longiciliatis; petalis 6 mm longis 2.5-2.8 mm latis longiciliatis; squamis petaliferis parte dorsali praeter margines inferiores dense sericeos glabra; staminibus 5; filamentis praeter partem superiorem pilosis; disco hirsutulo.

Tree 3 m, with simple unbranched stem. Leaves 12-foliolate. Leaflets chartaceous, lanceolate, acuminate at apex, acute to subacute at base, 26-38 cm long, 4-8 cm wide, glabrous except sparsely puberulent on the midrib below; lateral nerves 16-25 each side, conspicuously elevated beneath, impressed above, anastomosing 4-7 mm from margin; tertiary venation minutely reticulate above, grossly reticulate below with elevated veins. Petiolules 7-9 mm long, hirtellous. Panicle terminal, up to 8.5 dm long, the rachis and axes hirtellous. Axes simple or branched, 12-20 cm long. Flowers crowded in several-flowered fascicles, sessile. Calyx

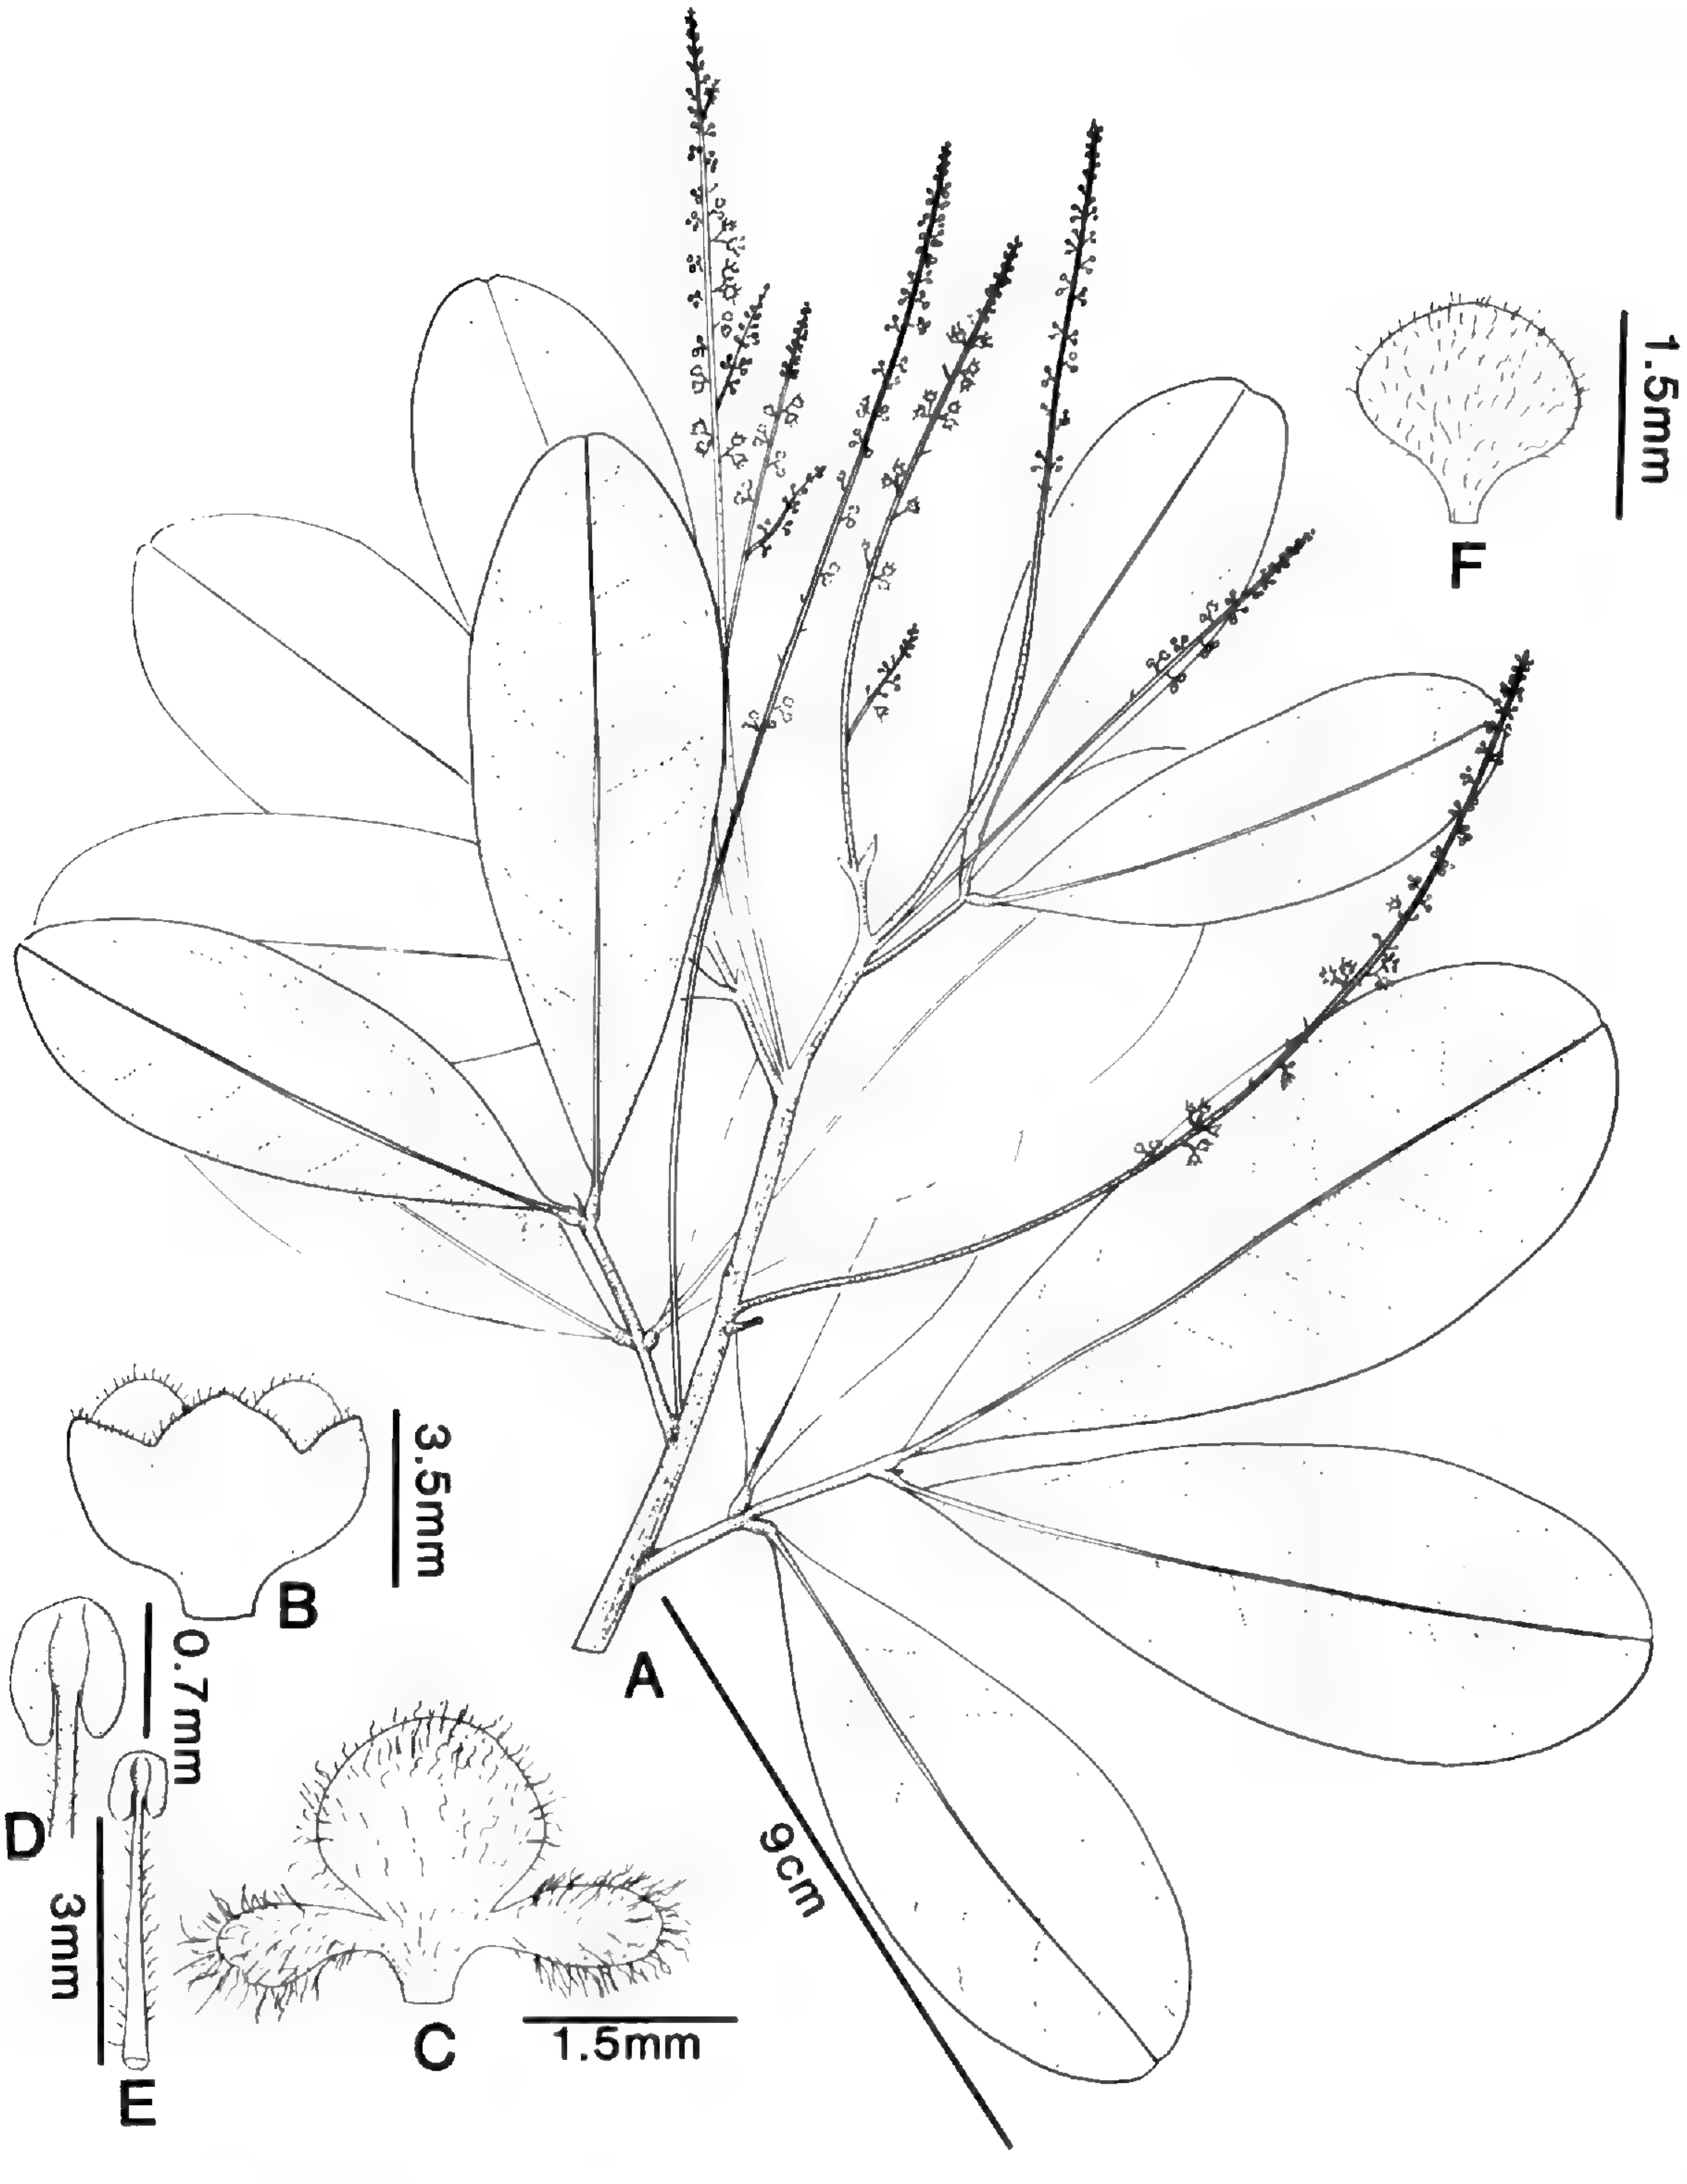

FIGURE 5. Matayba yutajensis.—*A. Habit of flowering branch.—B. Calyx.—C. Petal with 2 scales spread out, ventral view.—D. Upper portion of stamen.—E. Stamen.—F. Petal, dorsal view.*

3.5 mm long, cut ⅔ way down; lobes ovate-oblong, rounded at summit, 2 × 2 mm, puberulous without, glabrous within, long-ciliate. Petals lance-oblong, obtuse at summit, 6 mm long, 2.5–2.8 mm wide below the middle, glabrous both sides, long-ciliate. Petaliferous scales lanceolate, obtuse-subtruncate, slightly shorter than the petal, 3–3.5 mm long, 2 mm wide at base, the ventral portion densely sericeous above the glabrous basal sector, the dorsal portion densely sericeous along the lower margins, glabrous elsewhere. Stamens 5; filaments 1.3 mm long, pilose except in the uppermost part; anthers linear-oblong, 1.5–1.8 mm long, 0.2 mm wide, the appendage broadly lanceolate, acute, 0.3 mm long, the base bilobed. Disk shallowly undulate-lobulate, 2.8 mm diam., hirsutulous except on the outer concavities. Style 3 mm long, strigose. Fruiting pedicels 2 mm long, densely pubescent. Fruit ovoid-subglobose, 2 cm long, 1.7–1.8 cm wide, minutely appressed-puberulent.

Paratype. VENEZUELA. BOLÍVAR: Amaruay-tepui, 5°55′N, 62°15′W, 550–800 m, 20 May 1986, *Liesner & Holst 20935* (MO, VEN).

From the closely related *Talisia tiricensis* Steyerm., *T. amaruayana* differs by having ciliate petals and puberulous lower midrib.

Talisia caudata Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Cerro Sipapo, trail from Base Camp, 125 m, 25 Jan. 1949, *Bassett Maguire & Louis Politi 28615* (holotype, MO; isotype, NY). Figure 6.

Arbor 2-metralis; foliis 6 dm longis, 25-foliolatis; foliolis alternis lanceolatis apice longicaudatis basi acutis 9.5–14 cm longis 2.5–3 cm latis, acumine 17–25 mm longo, subtus praeter costam mediam dense hirtellam glabris eglandulosis; nervis lateralibus utroque latere 14–17; rachidi dense puberula pilis divaricatis munita haud glandulosa; petiolulis 7–10 mm longis minute denseque puberulentibus pilis divaricatis praeditis; infructescentia paniculata 14 cm longa 7 cm lata, axibus 8–9 simplicibus 0.5–3 cm longis adpresso pubescentibus; fructibus obovoideo-oblongis apice rotundato-subtruncatis basi rotundatis 2.2–2.4 cm longis 1–1.2 cm latis obtuse trigonis adpresso puberulis; stylo sub fructu deciduo vel persistenti 2 mm longo dense strigoso.

Tree 2 m. Leaves 6 dm long, petiolate. Petiole 17 cm long, minutely and densely puberulent with divaricate hairs. Leaflets mainly alternate, 25, lanceolate, long-caudate at apex, asymmetrically acute at base, 9.5–14 cm long, 2.5–3 cm wide, the caudate portion 17–25 mm long, 3 mm wide at base, the upper surface glabrous with impressed or slightly raised, minutely puberulent midrib, the lower surface glabrous except for the densely minutely hirtellous, eglandular midrib. Lateral nerves 14–17 each side, slightly sulcate above, elevated below, slightly ascending at an angle of 25–30°, strongly anastomosing below 3–5 mm from margin; tertiary venation reticulate below, slightly elevated, inconspicuous and scarcely manifest on upper side. Leaf rachis densely puberulous with divaricate nonglandular hairs. Petiolules 7–10 mm long, minutely and densely puberulent with divaricate hairs. Infructescence paniculate, 14 cm long, 7 cm wide, the rachis densely appressed-pubescent; axes 8–9, unbranched, the lower and middle ones 2–3 cm long, the upper ones 0.5–1 cm long, densely appressed-pubescent. Fruit obovoid-oblong, rounded-subtruncate at summit, rounded at base, 2.2–2.4 cm long, 1–1.2 cm wide, obtusely trigonous, appressed-puberulous. Style in fruit deciduous or persistent, 2 mm long, densely strigose. Calyx lobes in fruit persistent, strigose without, ciliate.

This taxon differs from the related *Talisia erecta* Radlk. in the much longer caudate, lanceolate leaflets with longer petiolules, more numerous lateral nerves, and eglandular pubescence without stipitate glands. The leaflets are longer than broad, but less so than in *T. erecta*, which has more closely spaced leaflets.

Talisia glandulifera Steyermark, sp. nov. TYPE: French Guiana. Saul: Monte La Fumée, 3°37′N, 53°12′W, 200–400 m, 1 Oct. 1982, *Scott Mori et al. 15027* (holotype, MO; isotype, NY). Figure 7.

Arbor usque 15 m altis; foliis 25–40 cm longis; foliolis 4–7-jugis plerumque oppositis elliptico-lanceolatis apice longiacuminatis basi acutis majoribus 10–18 cm longis 3.5–5 cm latis, costa media supra impressa subtus elevata minute puberulenti pilis divaricatis praedita; petiolulis 2–5 mm longis; calyce 3.5 mm longo extus dense glanduloso-piloso, lobis ovato-oblongis apice rotundatis; petalis subovato-oblongis apice rotundatis extus glabris intus sparsim prope basim secus mediumque sparsim adpresso-glanduloso-puberulentibus; filamentis glabris; disco dense hispido.

Tree 15 m tall. Leaves 25–40 cm long, the petiole 6.5–10 cm long. Leaflets 4–7 pairs, mainly opposite, elliptic-lanceolate, long-acuminate at apex, asymmetrically acute at base, the larger ones 10–18 cm long, 3.5–5 cm wide, the midrib impressed above, elevated below, minutely puberulent with short, divaricate hairs, otherwise glabrous; lateral nerves 13–18 each side, conspicuous and elevated below, slightly ascending at an angle of 15–25°; tertiary venation finely reticulate above, more grossly reticulate below; rachis terete, minutely puberulent with a few glandular hairs; petiolule 2–5 mm long. Inflorescence subterminal, paniculate, densely flowered, 13–23 cm long, 8–20 cm wide, with 6–12 ascending axes, the lower ones 4–15 cm long, densely hirtellous intermixed with glandular hairs. Peduncle 1 cm long or none. Flowers pedicellate or subsessile; pedicels 1.5 mm long, densely hispidulous. Bracts ovate-lanceolate, acute, 0.75–1.5 mm long, densely hirtellous with some glandular hairs. Calyx 3.5 mm long, cut ⅔ distance, densely glandular-pilose; calyx lobes ovate-oblong, rounded at summit, 2.5 mm long, 1.5–1.8 mm in upper half, ciliate. Petals subovate-oblong, rounded at summit, 5.5 mm long, 2.2 mm wide in upper half, glabrous without, ciliate in lower half, within sparsely appressed-glandular-puberulent near base and along median line; petaliferous scale about equaling or slightly shorter than petal, 3.5 mm long, 1.5 mm wide, densely barbate-villous for most of length on inner face, the outer face glabrous basally, pubescent in upper half, densely appressed-ciliate. Stamens 8; anthers oblong, obtusely apiculate, 1.3–1.4 mm long; filaments 3.8 mm long,

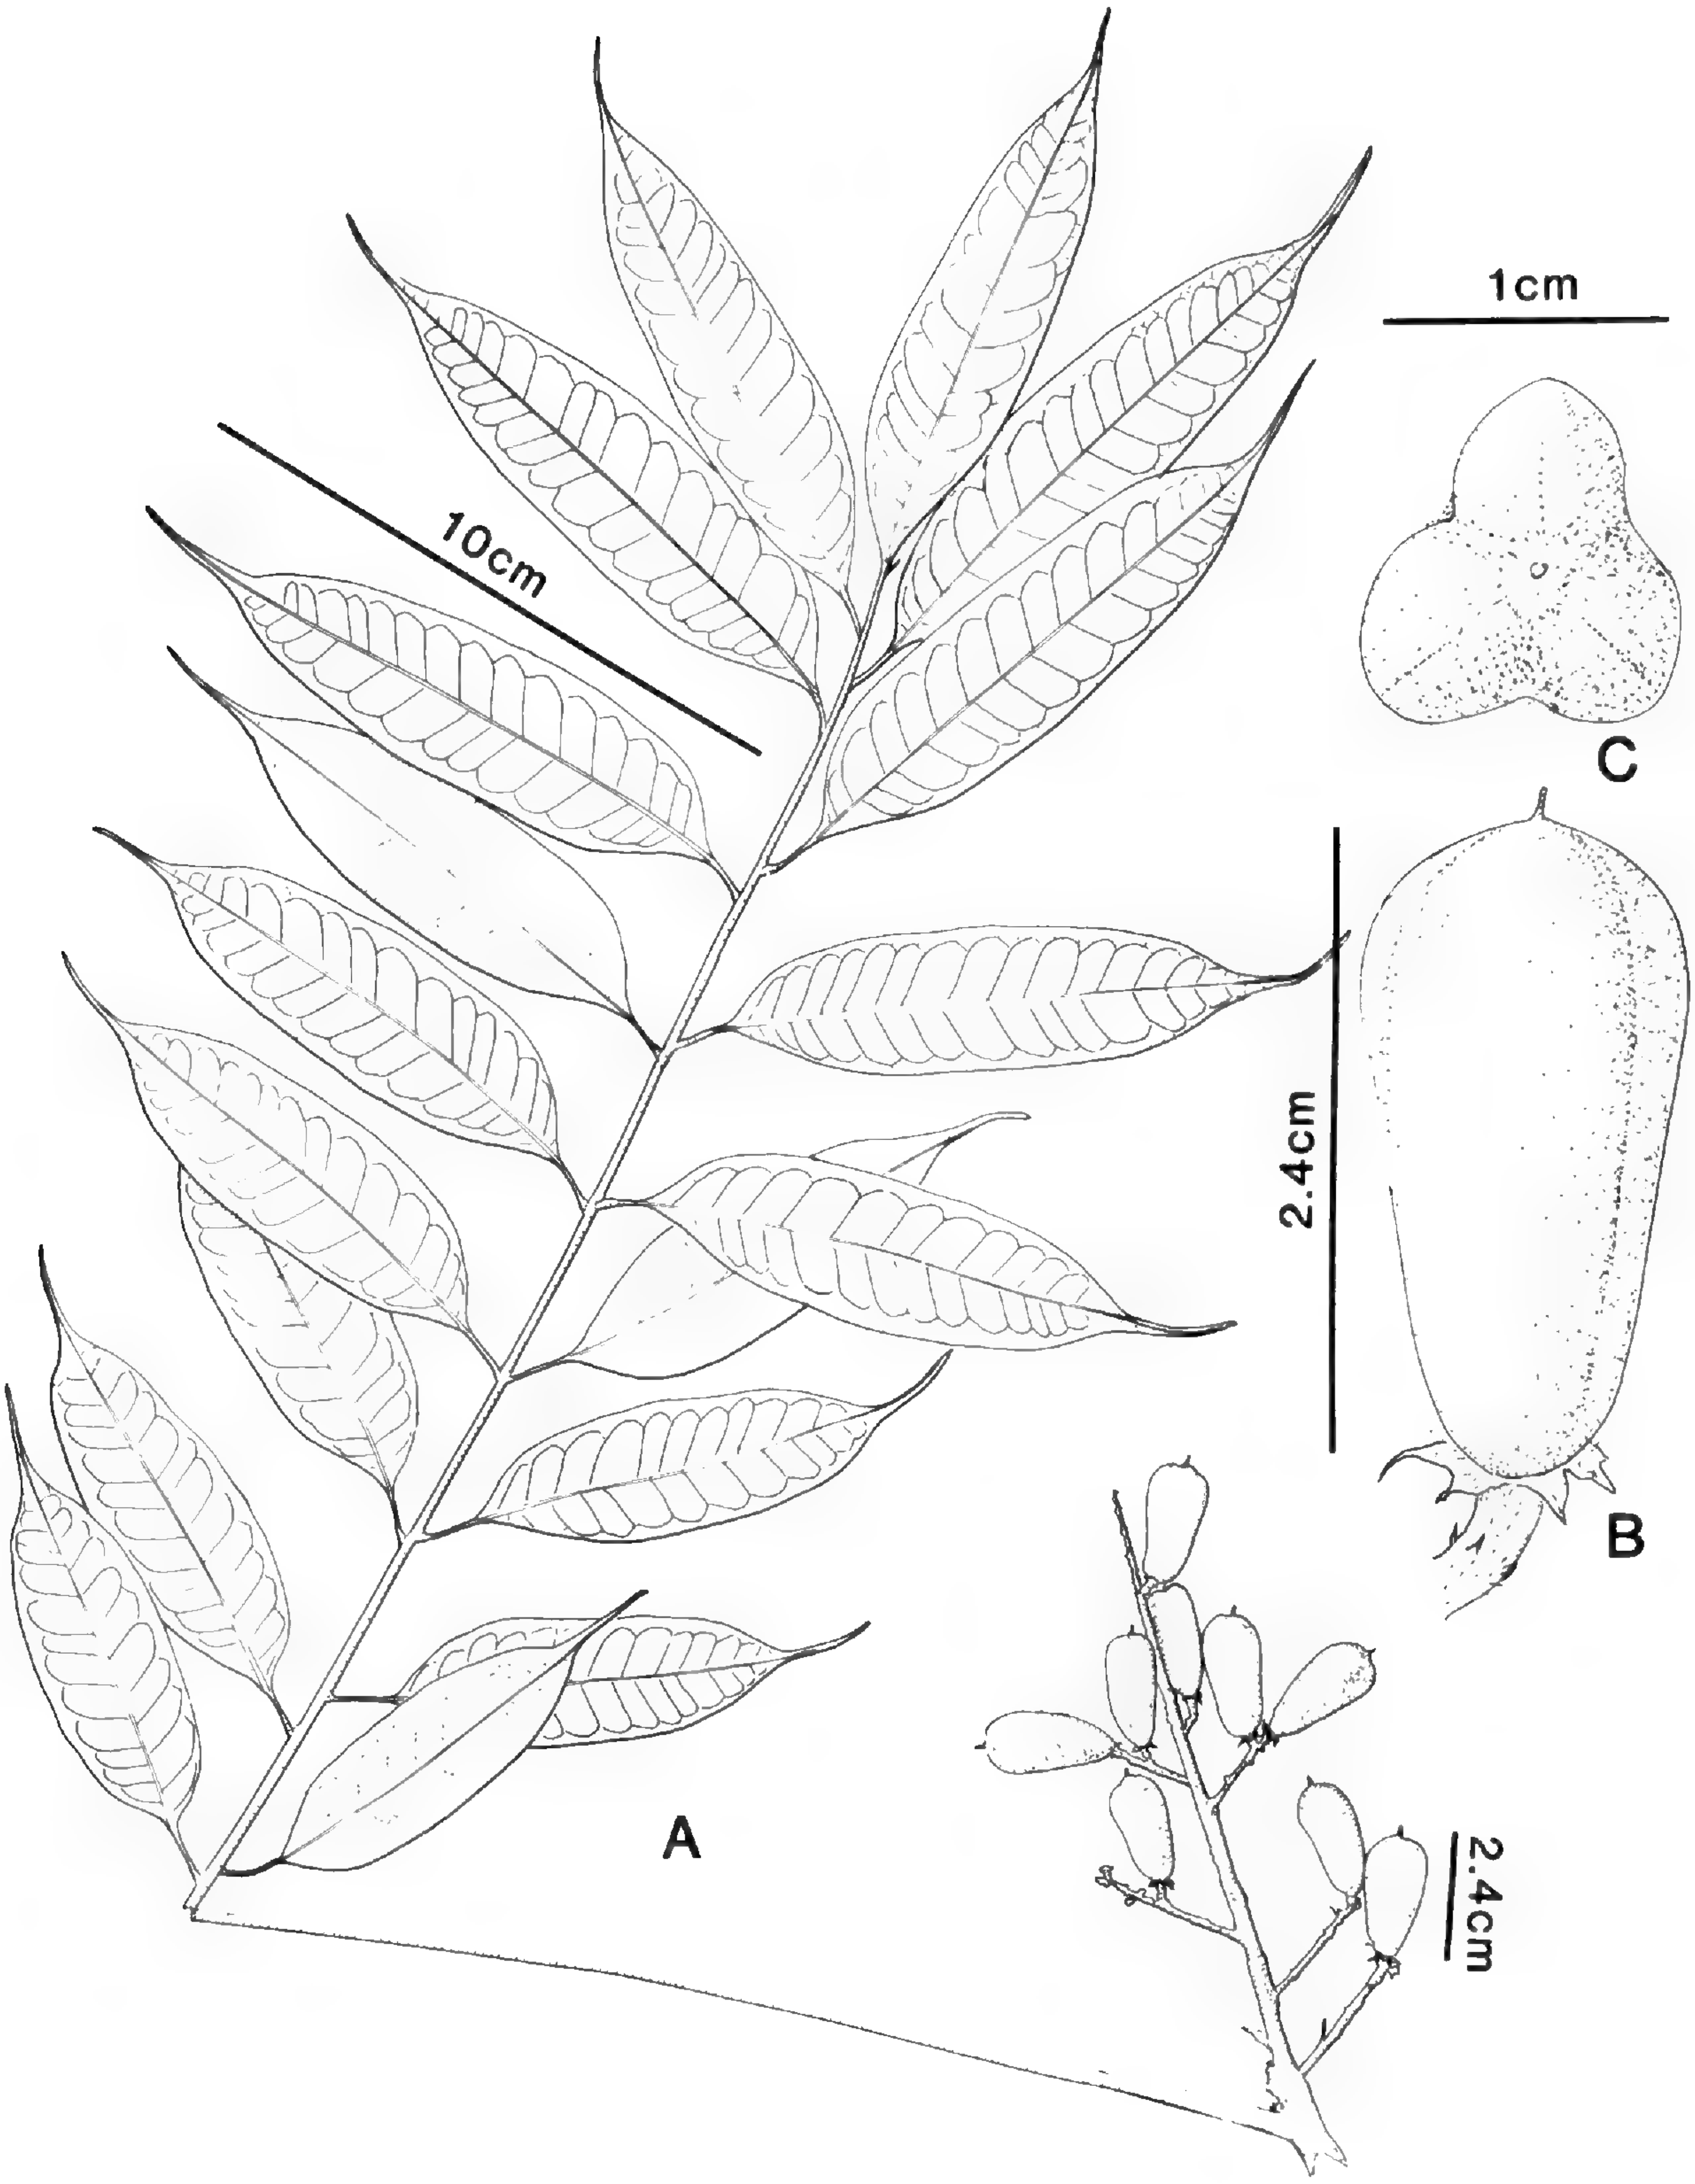

FIGURE 6. Talisia caudata.—*A. Habit of fruiting branch.—B. Fruit, lateral view.—C. Fruit, apical view.*

glabrous. Disk lobulate, 2 mm diam., densely hispid. Fruit not seen.

Paratypes. VENEZUELA. BOLÍVAR: El Paraiso Camp, 53 km NE of caserío Los Rosos, San Félix, 1–10 June 1965, *Luis Marcano-Berti 677* (MER). FRENCH GUIANA. SAUL: Monte La Fumée, 3°37′N, 53°12′W, 200–400 m, 24 Sep. 1982, *Mori et al. 14988* (MO, NY).

This species is apparently most closely related to *Talisia cupularis* Radlk. within the group of species 32–36 of Radlkofer's sect. III "*Eutalisia*" (sect. *Talisia*). It is characterized by calyx lobes densely glandular externally, minutely puberulent rachis with a few gland-tipped hairs, glabrous outer surface of the petals, glabrous filaments, densely hirsutulous disk, and petals glandular on the inner surface. From *T. cupularis* Radlk. it may be differentiated by the glandular-puberulent inner surface of the petals and the strongly glandular pubescent outer surface of the calyx lobes.

Talisia heterodoxa Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Represa Guri, islands 6–

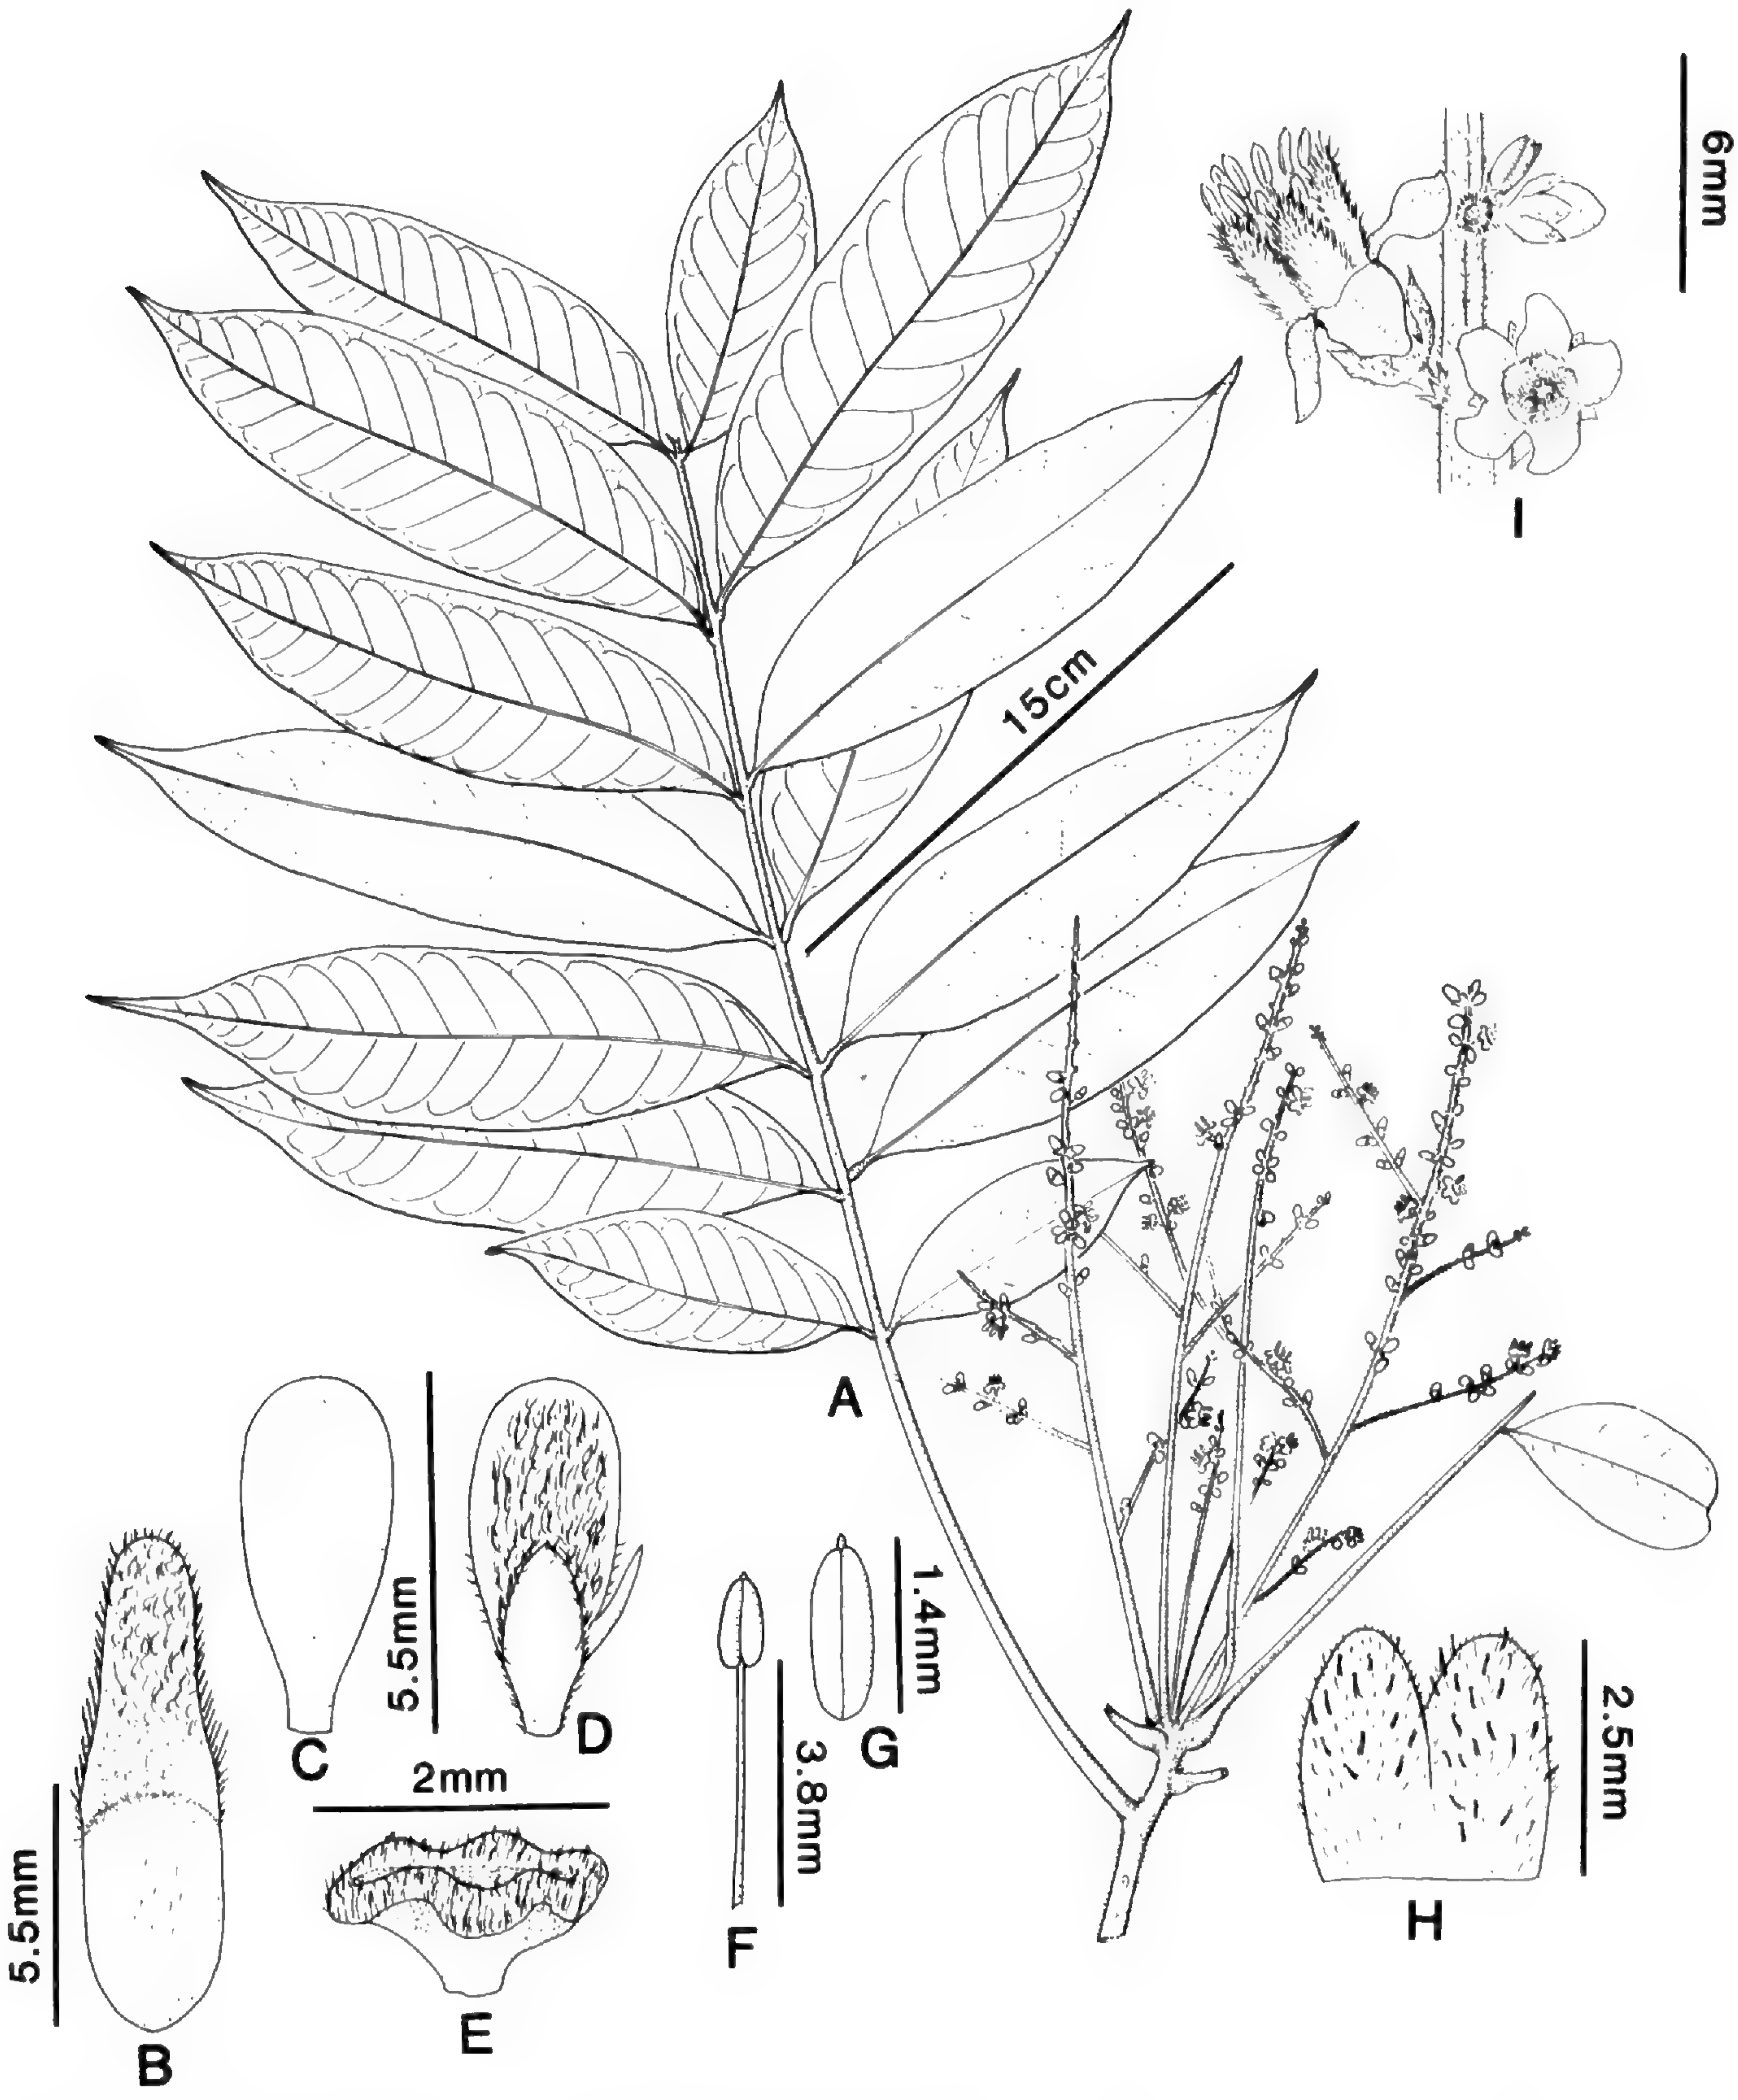

FIGURE 7. Talisia glandulifera.—*A. Habit of flowering branch.—B. Pubescent scale with interior surface of petal reflexed.—C. Exterior view of petal.—D. Interior view of petal.—E. Disk.—F. Stamen.—G. 18 km S of dam, 7°38'N, 62°58'W, 220–240 m, *Ronald Liesner & Angel González 11151* (holotype, MO; isotype, VEN).

Arbor 10-metralis; foliolis 6–8 oppositis vel suboppositis elliptico-oblongis vel oblanceolato-oblongis apice rotundatis saepe retusis 9–16 cm longis 3.5–6.7 cm latis glabris; petiolulis 5–6 mm longis glabris; calycis lobulis suborbiculari-ovatis dense ciliatis extus puberulis intus adpresso-puberulis; squamis petaliferis extus in quarta parte superiore pubescentibus prope basim glandulosis; staminibus 8, filamentis glabris; disco glabro.

Tree 10 m tall. Leaves 6–8-foliolate. Leaflets opposite, subopposite, or slightly alternate, elliptic-oblong or oblanceolate-oblong, rounded and often retuse at apex, cuneate at base, 9–16 cm long, 3.6–6.7 cm wide, glabrous; lateral nerves slender, slightly ascending at an angle of 25–45°, 12–13 each side, finely prominulous both sides; intermediate nerves finer; tertiary venation finely reticulate both sides, the reticulations more elevated and larger below; rachis of leaf 7–15 cm long, minutely puberulous to glabrous. Petiolule 5–6 mm long, glabrous. Petiole 4–9.5 cm long. Inflorescence terminal, 38 cm long with 7–8 widely spreading, sparingly branched axes, the lower ones 10–16 cm long, 2 mm wide, minutely puberulous with short spreading hairs; peduncle 3–4 cm long. Calyx cut ¾ distance, the lobes suborbicular-ovate, rounded at summit, 2.2 mm long; 1.5–2 mm wide, densely ciliate, puberulous without, within appressed-puberulous ⅔ distance upwards. Petals ovate-oblong, broadly rounded at summit, 4.5 mm long, 2.5 mm wide, glabrous both sides, the margins slightly papillate. Petaliferous scale ligulate, obtuse, 3.5 mm long, 1 mm wide, densely hirsutulous ventrally, pubescent within dorsally in the upper ¼ and pubescent basally, elsewhere glabrous. Stamens 8; anthers 1.5 mm long with a short, triangular, obtuse apical appendage, rounded at base; filaments 3 mm long, glabrous. Disk lobulate, glabrous. Fruit 3–3.5 cm long, 3 cm wide, subglabrous.

Paratype. VENEZUELA. BOLÍVAR: Represa Guri, islands 6–18 km S of dam, 7°38′N, 62°58′W, 220–240 m, *Liesner & Gonzalez 11116* (MO, VEN).

This species is closely related to *Talisia retusa* Cowan but differs in having the interior of the calyx lobe pubescent only in the middle portion rather than densely sericeous throughout and in having the petals glabrous instead of partly or wholly retrorsely ciliate. Moreover, in *T. retusa* the petiolules are mainly shorter, and the leaflets smaller and narrower.

Talisia pentantha Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Canaima, W of Avensa Camp, gallery forest, 500 m, 4 Oct. 1974, *F. Ehrendorfer 74104-23* (holotype, VEN).

Arbor; foliis 10-foliolate; foliolis oppositis, lanceolato-ellipticis apice acutis basi acutis majoribus 13.5–16 cm longis 3.7–4.5 cm latis, infimis 8.5–10.5 cm longis 3.5 cm latis utrinque glabris; nervis lateralibus principalibus utrinque 8–11; inflorescentia 37 cm longa, pedunculo 8 cm longo; floribus pedicellatis; calyce extus sparsim puberula, lobis intus glabris; petalis minute ciliatis aliter glabris; squamis dorsaliter glabris; staminibus 5; antheris linearibus appendiculatis, apice subacuto 1.8 mm longis; disco profunde lobato glabro.

Tree. Leaves 10-foliolate. Leaflets opposite, lanceolate-elliptic, acute at apex, acute at the slightly asymmetric base, mostly 13.5–16 cm long, 3.7–4.5 cm wide, the lowest smaller, 8.5–10.5 cm long, 3.5 cm wide, glabrous both sides, ascending at an angle of 20–25°; tertiary venation inconspicuous. Inflorescence 37 cm long, bearing interrupted short groups of flowers borne on short axes 5–15 mm long; peduncle 8 cm long; rachis ridged, with vertical lines of spreading pilosity on the angles, 2.5 mm diam. Flowers pedicellate, pedicels 1 mm long, densely pilosulous with spreading hairs. Bracts of inflorescence lanceolate, subacute, 0.75 mm long, puberulous. Calyx 3 mm long, cut ⅔ distance; lobes oblong-lanceolate, subacute or subobtuse, 2 mm long, 1 mm wide, sparsely puberulous without, glabrous within, imbricate, densely ciliate. Petals ligulate, obtuse, 4.5 mm long, 1.3 mm wide in late bud, minutely ciliate on the margins, otherwise glabrous; petaliferous scale 3 mm long, dorsally glabrous, densely sericeous ventrally. Stamens 5; anthers linear, appendiculate with a subacute lanceolate apex 0.2 mm long, 1.8 mm long. Disk deeply 5-lobed, glabrous.

The glabrous disk relates this species to *Talisia guianensis* Aubl., which, however, has eight stamens.

Talisia sancarlosiana Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: between San Carlos and Solano, 11–17 Mar. 1970, *Luis Marcano-Berti & P. Alcedo 119-979* (holotype, MER).

Frutex; foliis 17-foliolatis foliolis suboppositis vel alternis, oblongo-lanceolatis apice acuminatis basi subacutis superioribus 30–35 cm longis 8.5–9 cm latis utrinque glabris; nervis lateralibus utrinque 7–9; petiolulis 3–8 mm longis; inflorescentia 13 cm longa 15 cm lata; calycis lobis ovato-oblongis late obtusis extus sparsim pubescentibus intus glabris manifeste ciliatis; petalis lanceolatis late obtusis 5–6 mm longis 1.5–1.8 mm latis extus glabris intus pilis glandulosis praeditis exterioribus ciliatis; squamis petaliferis ligulatis dorsaliter glabris; staminibus 5; filamentis glabris; antheris linearibus 2 mm longis apice obtuse appendiculatis; disco glabro.

Shrub. Leaves 17-foliolate. Leaflets subopposite or alternate, oblong-lanceolate, acuminate at apex, subacute at the base, the upper leaflets larger, 30–35 cm long, 8.5–9 cm wide, the smaller alternate lower ones 19 cm long, 6 cm wide, glabrous both sides; lateral nerves 7–9 each side, elevated below; rachis glabrous; petiolules 3–8 mm long, glabrous; petiole 13–15 cm long, glabrous. Inflorescence paniculate, widely branching, 13 cm long, 15 cm broad, the rachis minutely pubescent in lines. Calyx lobes ovate-oblong, broadly obtuse, 2.3 mm long, 1.5 mm wide, sparsely pubescent without, glabrous within, conspicuously ciliate. Petals lanceolate, broadly obtuse at apex, 5–6 mm long, 1.5–1.8 mm wide below middle, glabrous without, glandular within, the outer ones ciliate. Petaliferous scale ligulate, 2.5 mm long above the glabrous basal 2-mm portion, densely sericeous ventrally, glabrous dorsally. Stamens 5; filaments 2.5 mm long, glabrous; anthers linear, 2 mm long, the obtusely oblong appendage 0.1 mm long, bilobed at base. Disk glabrous. Ovary obovoid, 3 mm long, glabrous; style 3.5 mm long, mainly glabrous, stigmatic in the apical 1.5 mm.

From *Talisia guianensis* Aubl. this species differs in having five stamens, short inflorescence, fewer lateral nerves, and pubescent inflorescence rachis.

TOULICIA

Toulicia anomala Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Río Suapure, Middle Orinoco, along river between Raudal Budare and Raudal Punta Brava (70–80 km from mouth), 110–120 m, 17 Jan. 1956, *J. J. Wurdack & J. V. Monachino 41253* (holotype, MO; isotype, NY).

Frutex vel arbor 2–3-metralis, ramulis glabris; foliis abrupte pinnatis, 6–10-foliolatis, foliolis oppositis vel alternis subsessilibus vel 1–2 mm petiolulatis lanceolatis apice acutis vel acuminatis basi asymmetricis acutis vel obtusis 4–8.5 cm longis 1.5–2.5 cm latis obscure repando-undulatis glabris; petiolis 1.5–4 cm longis 1 mm latis; inflorescentia 5–7 cm longa 2–3.5 cm lata, axibus 8–12 adpresso-pubescentibus 2–17 mm longis 3–8 floris; pedicellis 0.5 mm longis adpresso-pubescentibus; sepalis 4 inaequalibus, exterioribus minoribus suborbicularibus rotundatis 1–1.2 mm longis 1.2–1.5 mm latis extus glabris intus prope basin pubescentibus marginibus ciliatis; petalis 4 esquamatis obovatis 0.8–1 mm longis 0.7–1 mm latis 0.5 mm unguiculatis integris vel 2–3-lobatis, marginibus conspicue longifimbriatis pilis 0.5 mm longis ornatis; staminibus plerumque 6–7, filamentis 2.5 mm longis parte basali 1 mm pilosa; disco regulari leviter lobulato glabro; pistillodio 1 mm longo; pistillo 3.5 mm long 1.5 mm lato, stylis duobus, ovario 2-loculari, ovulo uno in quoque loculo.

Shrub or tree 2–3 m tall, the branches glabrous. Leaves abruptly pinnate, 6–10-foliolate, the leaflets opposite or alternate, subsessile or 1–2 mm petiolulate, chartaceous, lanceolate, acute to acuminate at apex, acute to obtuse at the asymmetrical base, 4–8.5 cm long, 1.5–2.5 cm wide, obscurely repand-undulate, glabrous; lateral nerves 10–12 each side, ascending at an angle of 15–25°, terminating near the margin, there anastomosing; tertiary venation finely reticulate and prominulous on both sides; midrib elevated below, impressed or sulcate above, bordered by a slender, ribbonlike lateral extension 0.25 mm wide on each side; lower leaf surface often with foveolate depressions at the junction of the midrib and lateral nerves accompanied by thickened portions of the lower epidermis. Rachis glabrous, 1 mm wide. Petioles 1.5–4 mm long, 1 mm wide. Inflorescence paniculate, 5–7 cm long, 2–3.5 cm wide, with 8–12 short axes 2–17 mm long, the rachis and axes appressed-pubescent; axes 3–8-flowered, sparsely branched. Peduncle 0.7–3 cm long. Sepals 4, unequal, the outer ones smaller, suborbicular, rounded, 1–1.2 mm long, 1.2–1.5 mm wide, glabrous without, within pilose near the base, long-ciliate on margins. Petals 4, esquamate, unguiculate, obovate, 0.8–1 mm long, 0.7–1 mm wide, the unguiculate portion 0.5 mm long, entire, 2-cleft or 2–3-lobate, densely long-fimbrillate with elongate hairs 0.5 mm long. Stamens usually 6–7; filaments hypogynous, 2.5 mm long, pilose in the basal 1 mm; anthers dorsifixed, suborbicular, 0.5 × 0.5 mm. Disk contiguous but not adnate to the ovary, regular, shallowly lobulate, glabrous, 2 mm across, 0.1–0.2 mm high. Pistillode ovate-elliptic, 1 mm long, 0.8 mm wide. Pistil 3.5 mm long, 1.5 mm wide; styles 2; ovary 2-locular, with 1 ovule in each cell.

This species is anomalous in having 4 sepals, and usually 6–7 stamens. The esquamate petals align it in the genus to section *Aphanolepis* Radlk. I thank Dr. Aaron Goldberg of the Smithsonian Institution for valuable help in critical observations and for comments.

BOMBACACEAE

POCHOTA

In Steyermark & Stevens (1988), the generic name *Pochota* was shown to have priority over *Bombacopsis*, and *Rhodognaphalopsis* A. Robyns was synonymized with *Bombacopsis*. Thus the following taxa are assigned to *Pochota*.

Pochota amazonica (A. Robyns) Steyerm. & W. D. Stevens, Ann. Missouri Bot. Gard. 75: 396–398. 1988.

Bombacopsis amazonica A. Robyns, Bull. Jard. Bot. Etat 33: 186. 1963.
Bombacopsis wurdackii A. Robyns, Mem. N.Y. Bot. Gard. 17(1): 194. 1967.

Bombacopsis amazonica and *B. wurdackii* intergrade and cannot be maintained as two distinct taxa. In his original description of *B. amazonica*, Robyns (1963: 186) stated that the pedicels vary from 3.5 to 9.5 cm long. This description was based on the US holotype. The isotype (*Foldats 3794*) at VEN, however, has pedicels only 2.5–3 cm long. Moreover, the calyx was described from the US holotype as 1–1.2 cm long and 1.6–1.8 cm wide, whereas the VEN isotype has the calyx only 1.1–1.2 cm wide. This disparity in the measurements of the holotype and isotype is manifested again in the measurements of the calyx of *B. wurdackii*, which are described from the MO holotype as 0.6 cm long, whereas the VEN isotype measures 0.8–1 cm.

Additionally, dimensions of leaflet blades (and their apex shapes), petioles, and petiolules overlap and real differences are not discernable. In both taxa the leaflet blades are thick-coriaceous with a prominent midnerve beneath. Both possess a fine reticulate tertiary venation on the lower surface of the leaflets. One of the principal characters employed by Robyns in separating *Bombacopsis wurdackii* from *B. amazonica* was the presence of glands on the receptacle in the former. Removal of the mass of stamens that had previously hidden the receptacle area on the VEN isotype of *B. amazonica* revealed glandular depressions, thus eliminating one of the key separating characters between the two taxa. Robyns differentiated *B. wurdackii* further from *B. amazonica* by the relatively smaller staminal tube of the former, which is described as "circa 5–7 mm long." Examination of the VEN isotype reveals a length closer to 8 mm.

STEYERMARK, J. A. & W. D. STEVENS. 1988. Notes on *Rhodognaphalopsis* and *Bombacopsis* (Bombacaceae) in the Guayanas. Ann. Missouri Bot. Gard. 75: 396–398.

Pochota ewelii Steyermark, sp. nov. TYPE: Brazil. Dept. Amazonas: near Venezuela frontier, camino al Cerro Neblina desde Rio Tucano (afluente del Rio Cauaburi), 1,250 m, 23 Apr. 1964, *J. Ewel 135* (holotype, MY).

Arbor foliis 5-foliolatis, foliolis coriaceis late elliptico-ovatis apice acutis vel obtuse acutis basi obtusis vel rotundatis majoribus 9.5–12.5 cm longis 4.5–7 cm latis supra sparsim lepidotis basi conspicue petiolatis; petiolulis 9–12 cm longis; pedicellis 3 cm longis lepidotis; receptaculo conspicue glanduloso; calyce 10 mm longo 20 mm lato extus lepidoto intus sericeo-tomentoso; petalis linearibus acutis 12–12.5 cm longis 1.8–1.9 cm latis; staminibus ca. 150, 8 cm longis; staminali tubo 13 mm longo basi glabro deinde superne stellato-piloso; stylo 10 cm longo glabro; ovario lepidoto.

Tree with glabrous branches. Leaves 5-foliolate, the leaflets thick coriaceous, broadly elliptic-ovate, acute to obtusely acute at apex, obtuse to rounded at base, the larger 9.5–12.5 cm long, 4.5–7 cm wide, the upper surface sparsely lepidote except the more densely lepidote midrib, the lower surface and midrib strongly lepidote; primary lateral nerves on each side 12–14, impressed below, inconspicuously above, anastomosing 5–8 mm from margin; tertiary venation reticulate and manifestly impressed or subelevated below, inconspicuous above; midrib prominently elevated below, slightly elevated above. Petiole 3.6 cm long, 3 mm thick; petiolules 9–12 mm long. Flowers solitary, axillary. Pedicels 3 cm long, 3 mm wide, moderately lepidote. Receptacle conspicuously glandular. Calyx 10 mm long, 20 mm wide at subtruncate summit, moderately lepidote without, densely sericeous within. Petals linear, acute, 12–12.5 cm long, 1.8–1.9 cm wide, minutely stellate-squamose without, more densely stellate-puberulent within with slightly longer trichomes. Stamens numerous, ca. 150, 8 cm long, with 10 phalanges 1 cm long; staminal tube 13 mm long, glabrous below, moderately stellate-pilose above. Ovary lepidote; style 10 cm long, glabrous.

This taxon differs from *Pochota gracilis* (Robyns) Steyerm. & W. D. Stevens in the pubescent upper part of the staminal tube, broader and shorter calyx, and the thick-coriaceous, longer and broader, conspicuously lepidote leaves. The leaflets resemble in their size and thickness those of *P. amazonica* (Robyns) Steyerm. & W. D. Stevens, which, however, has narrower leaflets less rounded at the base, and shorter petals. The new species is dedicated to Dr. John Ewel, one of the early explorers of Cerro de La Neblina, who reached the summit from the Brazilian side.

Pochota fuscolepidota Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Dept. Atabapo, Cerro Marahuaca, forested slopes 1–2 km N of Sima Camp, 3°40'N, 65°31'W, 1,100 m, 8–9 Mar. 1985, *Ronald Liesner 18452* (holotype, MO; isotype, VEN).

Arbor 5–8-metralis; foliolis 3–5 oblongo-ovatis vel elliptico-oblongis apice acutis basi obtusis vel subacutis 16–22 cm longis 7–10 cm latis supra glabris subtus densissime fusco-ferrugineo-lepidotis, marginibus subrevolutis; nervis lateralibus principalibus utroque latere 12–15 subtus manifeste elevatis; petiolis 5.5–9.5 cm longis; petiolulis 1–

2.5 cm longis; fructu pedicello fructigero 5 cm longo 5 mm lato densissime fusco-lepidoto; calyce fusco-lepidoto; fructu obovoideo apice rotundato densissime fusco-ferrugineo lepidoto 6 cm longo apice 3 cm lato basi 0.7 cm lato.

Tree 5–8 m tall, the young stems densely ferrugineous-fuscous lepidote. Leaflets 3–5, oblong-ovate or elliptic-oblong, acute at apex, obtuse or subacute at base, 16–22 cm long, 7–10 cm wide, glabrous above, densely dark brown–ferruginous below, glabrous above with impressed nerves, densely and thickly covered below by dark brown, ferruginous lepidote scales, the principal lateral nerves 12–15 each side, prominently elevated, anastomosing 7–15 mm from the margin; margins subrevolute; midrib subsulcate above, prominently elevated below. Petioles 5.5–9.5 cm long; petiolules 1–2.5 cm long, densely fuscous lepidote. Flowers not seen. Fruiting pedicels 5 cm long, 5 mm thick, densely fuscous lepidote. Calyx tube in fruit 10 mm long, 17 mm wide, subtruncate at apex, dark lepidote without, densely buff sericeous within. Fruit obovoid, rounded above, 6 cm long, 3 cm wide at summit, 0.7 cm wide at base.

Paratypes. VENEZUELA. T. F. AMAZONAS: Dept. Atabapo, Cerro Marahuaca, Sima Camp, S-central portion of forested slopes along E branch of Caño Negro, 3°43′N, 65°31′W, 1,140 m, 21–24 Feb. 1985, *Steyermark & Holst 130515* (MO, VEN); 9.2 km NE of San Carlos on Solano road, 1°56′N, 67°3′W, 119 m, *Clark 6920* (MO, NY, VEN).

This species is well characterized by the large leaflets that are densely dark brown-ferruginous lepidote beneath, the prominently elevated lateral nerves on the lower leaf surface, and the densely dark brown lepidote fruits.

Pochota gracilis (Robyns) Steyerm. & W. D. Stevens

This species was originally described (Robyns, 1967) from specimens collected on the Río Pacimoni of the Territorio Federal Amazonas of Venezuela at an altitude of 100–140 meters. Subsequent collections manifest variations in the apex and shape of the leaflets, and in the abundance and distribution of scales on the lower leaflet surface. Specimens collected from the eastern portion of the range in Estado Bolívar, Venezuela, have leaflets narrowly obovate or elliptic-obovate with the apex emarginate and rounded-truncate. Additionally, the scales on the lower surface of the leaflets are dark and close together. Specimens having these characteristics all come from localities associated with the sandstone table mountains at altitudes of 400–1,000 meters. In contrast, the collections originating from the Territorio Federal Amazonas all are found at low elevations of 95–140 meters in usually white sand savannas bordering streams of the lowland areas. The leaflets of these lowland populations are narrowly elliptic-oblong or narrowly oblong with broadly obtuse to rounded, rarely emarginate apex, and the scales on the lower surface are more scattered and less conspicuous than those of the Estado Bolívar populations. Since these differences can be segregated in eastern and western geographically separated populations, they may be considered to represent two subspecies as follows.

Pochota gracilis subsp. **gracilis**

Rhodognaphalopsis maguirei A. Robyns, Mem. N.Y. Bot. Gard. 17: 200. 1967.

Leaflets narrowly elliptic-oblong to narrowly oblong, broadly obtuse to rounded at apex, this rarely emarginate; scales on the lower surface of the leaflets small, scattered, rather noticeably separated.

Distribution. T. F. Amazonas, Venezuela, in usually white sand savannas bordering streams at altitudes of 95–140 meters.

Specimens examined. VENEZUELA. T. F. AMAZONAS: Río Pacimoni, 12 km below mouth of Río Yatua, 100–140 m, *Maguire, Wurdack & C. K. Maguire 41653* (holotype, MO; isotype, NY); Caño Caname del medio Río Atabapo, sabanita, 3°40′N, 67°27′W, 100 m, *Huber, Tillett & Davidse 3747* (VEN); bajo Río Ventuari, 10 km al NE de la desembocadura del Caño Marueta, 4°18′N, 66°16′W, 110 m, *Huber 6116* (MO); sabana, 1 km al E del caserío de Guarinuma, 3°37′N, 67°26′W, 95 m, *Huber 3350* (VEN); sabanita, 10 km al NE del Cerro Moriche, middle Río Ventuari, 4°48′N, 66°17′W, 120 m, *Huber 3437* (VEN); white sand savannas, Caño Caname, opposite Cucurital de Caname, 3°40′N, 67°22′W, 95 m, *Davidse, Huber & Tillett 17035* (MO, VEN); along lower Río Sipapo, *Maguire & Politi 27849* (NY).

Pochota gracilis subsp. **bolivarensis** Steyermark, subsp. nov. TYPE: Venezuela. Bolívar: wooded knoll in savanna, Río Kanarakuni, southern base of Cerro Sarisariñama, Meseta de Jaua, 400 m, 17–29 Mar. 1967, *Julian Steyermark 98206* (holotype, VEN; isotype, NY).

Local name. Wanabana (Maquiritare).

A ssp. *gracilis* foliolis anguste obovatis vel elliptico-obovatis apice subtruncato-rotundatis emarginatis, subtus squamis lepidotis conspicuis fuscatis confertis recedit.

Leaflets narrowly obovate to elliptic-obovate, subtruncate-rounded at the emarginate apex; scales on the lower surface conspicuous, darker, and closer together.

Paratypes. VENEZUELA. BOLÍVAR: Cerro Guaiquinima, summit, riverine forest, Salto de Río Szczerbanari (Río Carapo), 5°44'N, 63°41'8"W, central portion, 750 m, *Steyermark, G. & E. Dunsterville 113236* (VEN); Auyan-tepui, 1,100 m, *Tate 1155* (NY, VEN); upper Caura River, Cerro Marajanu, 550 m, *Cardona 2951* (VEN).

Rhodognaphalopsis maguirei A. Robyns was originally described as having a calyx 15 mm long and 7 mm wide, while *R. gracilis* was described with a calyx 12 mm long and 5 mm wide. Yet on the NY isotype of *R. gracilis* the older calyces attain a width of 6–6.5 mm; those in bud are 4–5 mm wide. In the holotypes of both *R. maguirei* and *R. gracilis* the staminal tubes are glabrous. Although the style in *R. maguirei* is described as glabrous and that of *R. gracilis* as sparsely stellate-puberulous at the base, it is doubtful if this last character can be used to separate the two taxa, since in all other respects they are alike. The type collection of *R. maguirei* from the lower Río Sipapo occurs within the general range of *Pochota gracilis* subsp. *gracilis*.

ROBYNS, A. 1967. *Pochota gracilis. In:* B. Maguire & collaborators, The Botany of the Guayana Highland—Part VII. Mem. N.Y. Bot. Gard. 17: 198.

Pochota liesneri Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Dept. Atabapo, Salto Yureba, Cerro Yureba, lower Ventuari, 4°3'N, 66°1'W, 350 m, 14 Mar. 1985, *Ronald Liesner 18637* (holotype, MO; isotype, VEN). Figure 8.

Arbor 15-metralis; foliis 5–6, foliolis rugulosis elliptico-obovatis apice abrupte acutis basi acutis majoribus 12–26 cm longis 8–11 cm latis supra praecipue per nervos laterales atque costam mediam glandulis fuscis praeditis, subtus molliter pilosis pilis stellatis fuscis 0.5–1 mm longis obtectis; nervis lateralibus principalibus utroque latere 14–20 subtus prominente elevatis supra sulcatis, venulis tertiariis manifeste grosseque reticulatis; petiolis 13–20 cm longis glabris, petiolulis 7–13 mm longis glabris; pedicello 3 cm longo 5–7 mm crasso; calyce 3.5–3.7 cm longo apice 2–2.5 cm lato extus densissime fulvo stellato-tomentoso; petalis 25–31 cm longis 1 cm latis ubique densissime stellato-tomentoso; staminibus numerosis 18–25 cm longis; tubo stamineo 6–7 cm longo parte superiori glabra dimidia parte inferiori 3.5–4.5 cm dense stellulato-tomentoso in 10 phalangibus soluto; stylo 25–30 cm longo inferne dense stellato-villoso superne stellato-tomentoso; ovario conico 17 mm longo conspicue costato, costis dense ferrugineo-squamosis sulcis minute puberulis.

Tree 15 m tall. Leaves 5–6-foliolate, leaflets rugulose, elliptic-obovate, abruptly acute at apex, acute and long decurrent at base, the larger ones 12–26 cm long, 8–11 cm wide, upper surface with dark glandular dots dispersed more commonly along the lateral nerves and midrib, softly pilose below with brown stellate hairs 0.5–1 mm long on both the surface and nerves; principal lateral nerves 14–20 each side; tertiary veinlets prominently grossly reticulate below, subsulcate above. Petioles 13–20 cm long, glabrous; petiolules 7–13 mm long, glabrous. Flowers large, axillary, solitary, opposite on the stem. Pedicels 3 cm long, 5–7 mm thick, densely dark brown stellate-tomentose. Calyx tubular-campanulate, 3.5–3.7 cm long, 2–2.5 cm wide at the subtruncate, scarcely repand apex, densely fulvous stellate-tomentose without, the stellate tomentum with numerous small hairs and a few larger ones, densely buff-sericeous within. Petals tan (fide Liesner), linear, 25–31 cm long, ca. 1 cm wide, on both sides densely stellate-tomentose. Stamens about 50, 18–25 cm long; staminal tube 6–7 cm long, the upper portion glabrous, the lower portion 3.5–4.5 cm long with pale, minute, stellate tomentum, separating above into 10 phalanges 3–4 cm long. Style 25–30 cm long, densely stellate-pilosulous, especially in the lower half. Ovary conic, 17 mm long, 10 mm wide at base, conspicuously 5-costate, the ridges densely ferruginous squamose with minute pale appressed hairs in the sulcations.

This unusual species is at once distinguished by the softly brown long-pilose lower surface of the rugulose leaflets, relatively large flowers with markedly elongated petals and staminal tube, and minutely dense brown-stellate tomentose, elongated calyx tube. The collections of Ronald Liesner have contributed greatly to our knowledge of the rich flora of the Venezuelan Guayana.

Pochota mawarinumae Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Dept. Río Negro, near Cerro de La Neblina Base Camp, Río Mawarinuma, 0°50'N, 66°10'W, 140 m, 2 Mar. 1984, *Ronald Liesner 16355* (holotype, MO; isotype, VEN).

Arbor 15-metralis; foliis 5–7-foliolatis; foliolis coriaceis subtus glaucis argenteis late obovatis apice rotundatis minute mucronatis basi longiattenuatis 20–32 cm longis 8.5–10.5 cm latis subtus minute lepidotis, nervis lateralibus principalibus utroque latere (6–)8–10; petiolis 2.3–3.4 cm longis, petiolulis 1–4 cm longis; pedicellis 1.5–3.5 cm longis dense minuteque fulvo-stellato-puberulo; receptaculo manifeste glanduloso fulvo-stellato-puberulo; calyce breviter campanulato apice truncato 10–13 mm longo 15–20 mm lato extus dense minuteque fulvo-stel-

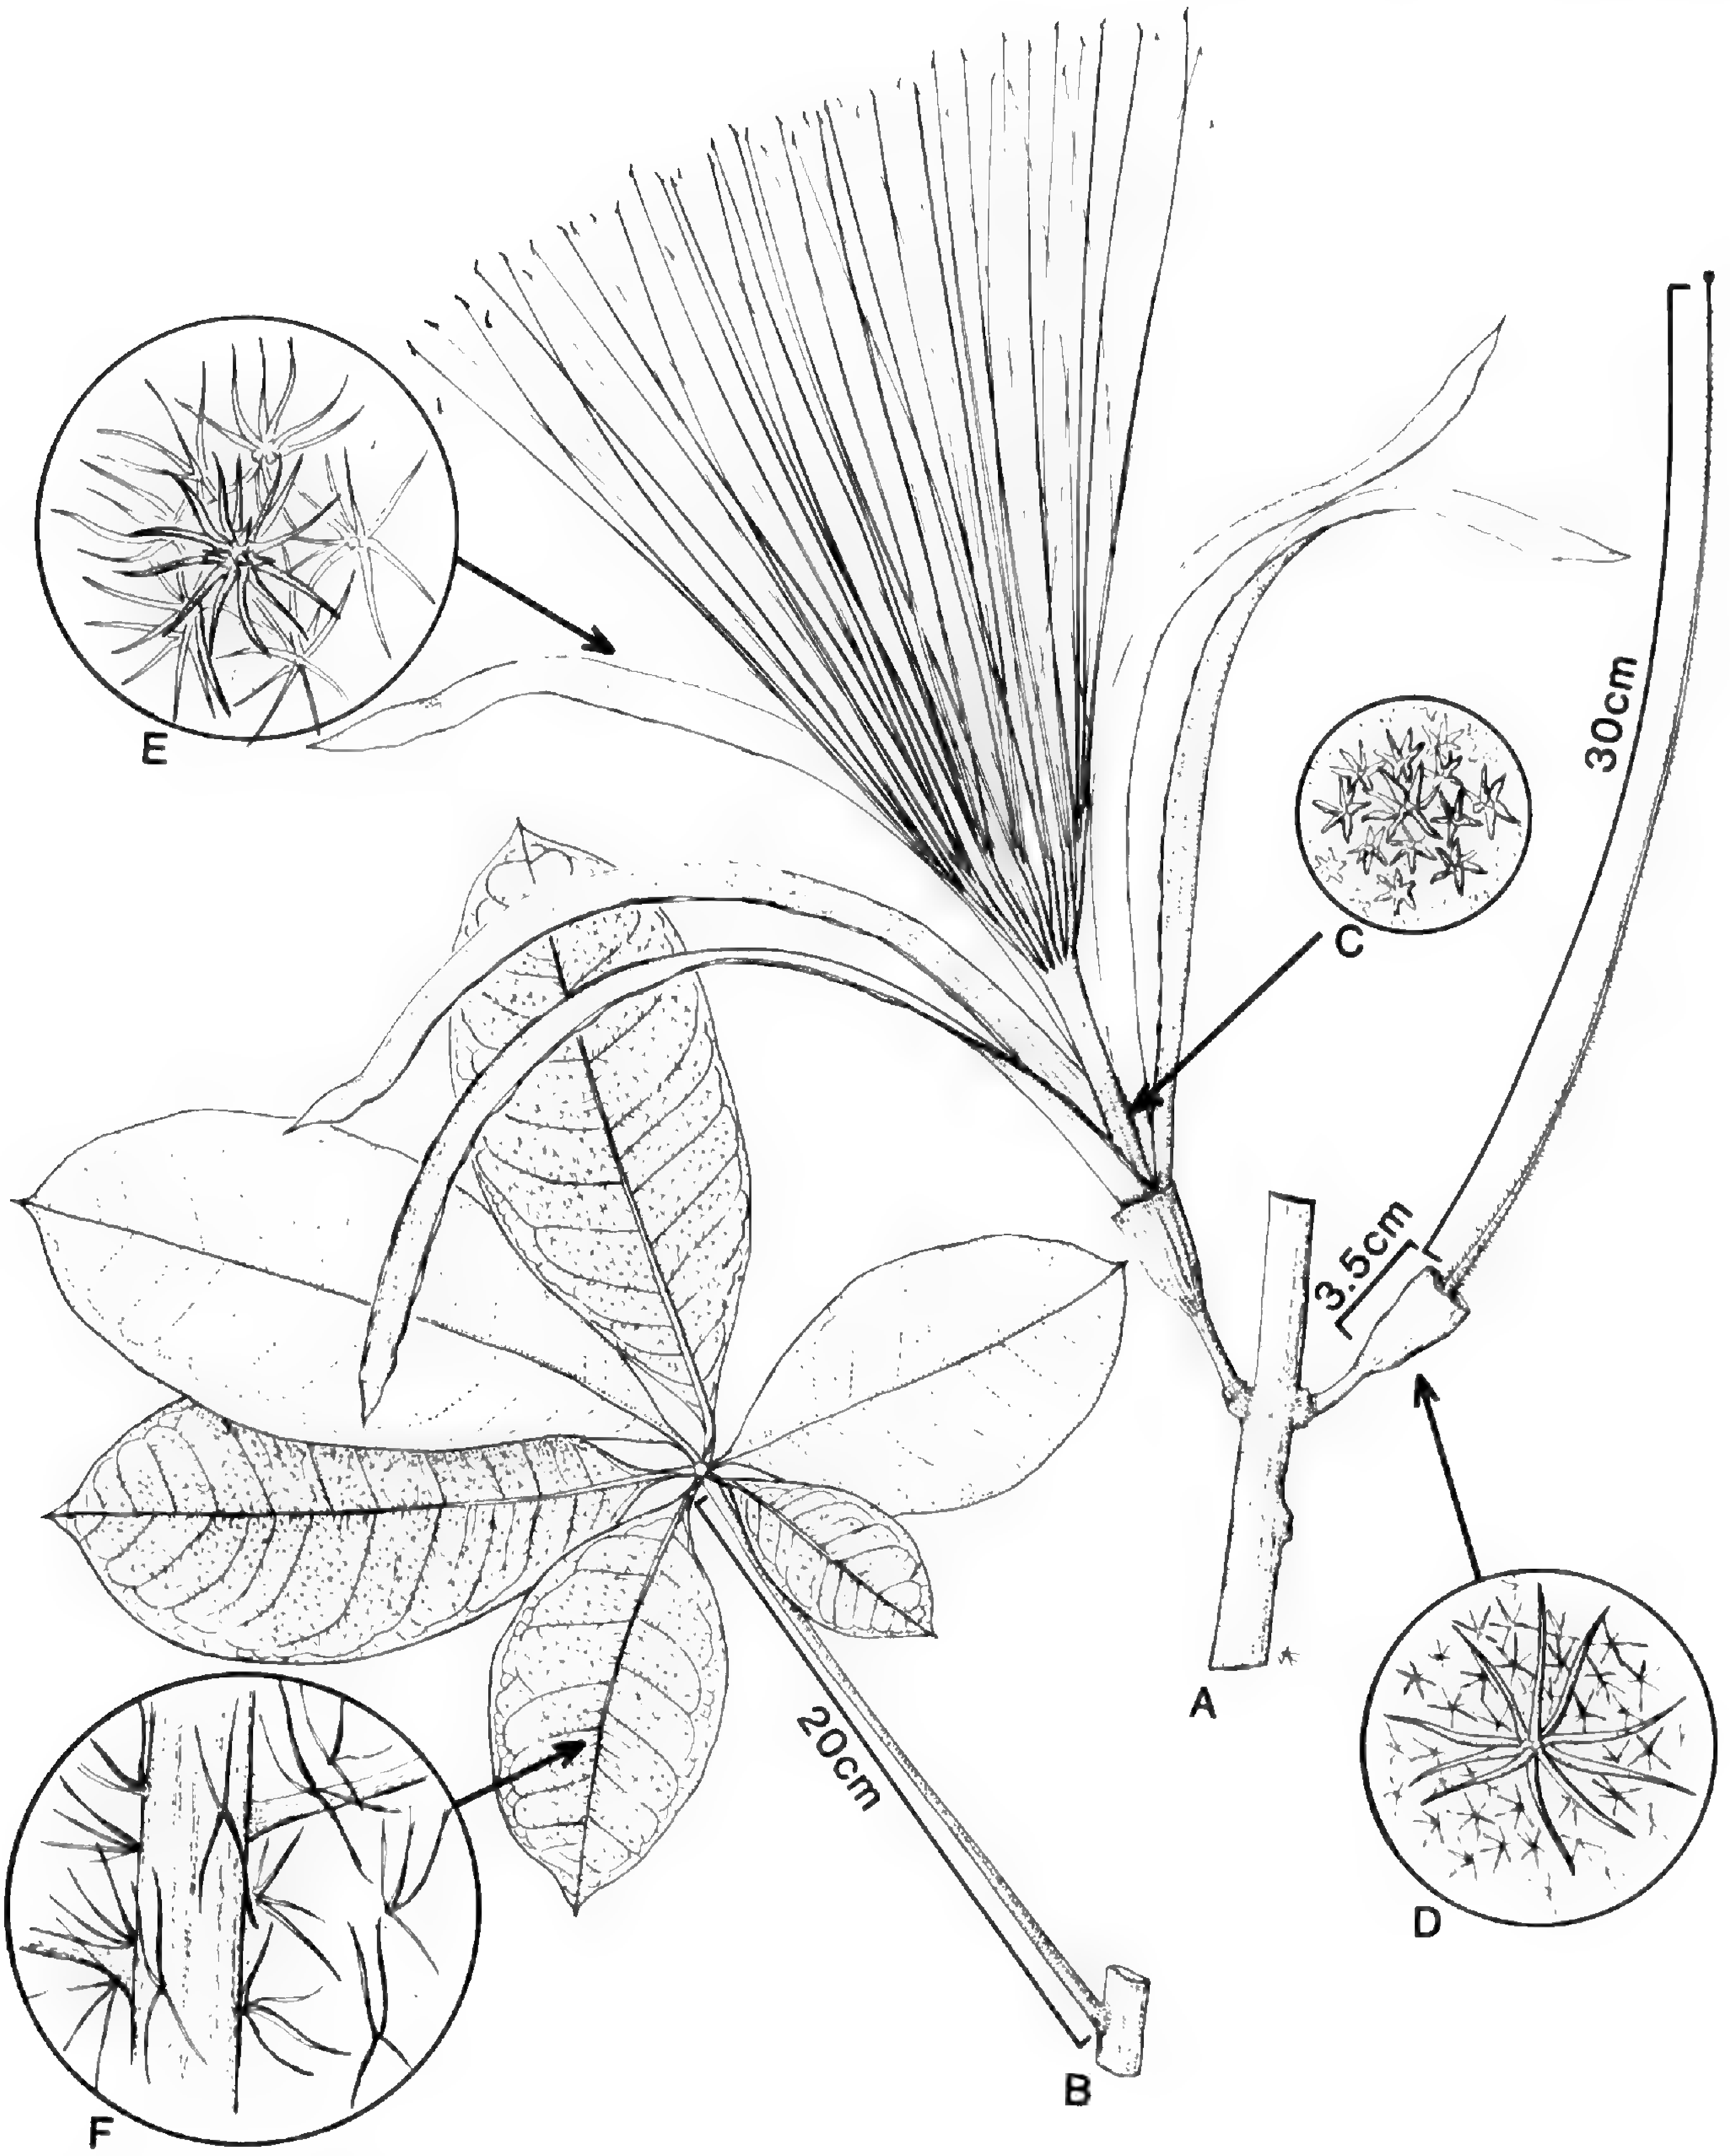

FIGURE 8. Pochota liesneri.—*A. Portion of flowering stem.—B. Single leaf attached to stem.—C. Showing larger and smaller stellulate hairs on staminal tube.—D. Showing one large and numerous smaller stellulate hairs on calyx tube and receptacle.—E. Stellulate pubescence on petal.*

lato-puberulo intus dense sericeo-tomentoso; petalis linearibus 13–16.5 cm longis 1.3–2 cm latis; staminibus 8–13 cm longis, tubo stamineo 20 mm longo dense minuteque cinereo-stellato-puberulo; stylo parte basali 2.5 cm minute stellato-tomentoso aliter glabro; ovario superne dense sericeo tomentoso aliter minute puberulenti; capsula nondum visa.

Tree 15 m tall. Branches robust. Leaves 5–7-foliolate. Leaflets coriaceous, pale or glaucous below, broadly obovate, rounded at the mucronate apex, attenuate to the acute base, the larger ones 20–32 cm long, 8.5–10.5 cm wide, minutely lepidote below. Petioles 2.3–3.4 cm long; petiolules unequal, 1–4 cm long. Principal lateral nerves (6–) 8–10 each side, arcuately ascending, conspicuously elevated on lower surface, subelevated on upper surface, branched, and anastomosing 1–2 cm from margin. Tertiary venation finely reticulate between larger areoles, impressed below. Midribs strongly elevated below. Flowers solitary, axillary. Pedicels in anthesis 1.5–3.5 cm long, densely brown stellate-tomentose. Receptacle conspicuously glandular, brown tomentose, 1 cm long, 1.5 cm wide. Calyx shortly campanulate, 10–13 mm long, 15–20 mm wide, densely brown tomentose without, sericeous within. Petals linear, 13–16.5 cm long, 1.3–2 cm wide, minutely densely tan stellulate-tomentose without, densely and paler stellulate-tomentose within. Stamens 8–13 cm long, numerous, ca. 80 in 10 phalanges 10 mm long; staminal tube 20 mm long, stellate-puberulent most of the length; anthers hippocrepiform-linear, 2.5–3.5 mm long. Style 10.5(immature)–14 cm long, glabrous most of the length, densely pale stellate-tomentose in the basal 2.5 cm. Ovary conic, 5-carinate, densely sericeous-tomentose in the upper ⅓, minutely appressed-puberulent in the lower ⅔ on the ridges and in the sulcations.

Paratype. VENEZUELA. T. F. AMAZONAS: Cerro de La Neblina, same data as type, 6 Mar. 1984, *Liesner 16460* (MO, VEN).

This species is most closely related to *Pochota obovata* (Robyns) Steyerm. & W. D. Stevens but differs in the longer petals, completely stellate-pubescent staminal tube, manifestly glandular receptacle, predominantly larger glabrous portion of the style, and more rounded, merely mucronulate apex of the somewhat narrower leaflets. The Base Camp along the Río Mawarinuma of Cerro de La Neblina served as a working base for the numerous scientists who participated in the recent expedition to that sandstone table mountain, and is the locale of many noteworthy species new to Venezuela or new to science.

Pochota redmondii Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Dept. Atures: stream 0.5–2 km E of Río Coro-Coro, W of Serranía de Yutaje, 3 km N of Yutaje settlement, 5°38′N, 66°30′W, 200 m, 19 Feb. 1987, *Ronald Liesner & Bruce Holst 21248* (holotype, MO; isotype, NY, VEN).

Arbor 6 m; foliolorum laminis late obovatis apice rotundatis 10.5–48 cm longis 5.5–15 cm latis haud manifeste lepidotis subtus haud glaucis; floribus solitariis, pedicellis 1.5–3 cm longis glabris; calyce late campanulato 8–10 mm longo 8–13 mm lato subtruncato; petalis ligulato-spathulatis 8 cm longis superne 9–10 mm latis basi 4.5–5 mm latis; tubo stamineo 13 mm longo 2.5 mm lato lineatis, lineis 5 minute stellato-puberulentibus cum zonis latioribus glabris 0.9–1 mm latis alternantibus munito; ovario dense tomentoso.

Tree 6 m tall, the branches glabrous, the terminal portion 1–1.2 cm diam. Leaves 5-foliolate; leaflets articulate, subcoriaceous, broadly obovate, rounded at apex, sometimes emarginate to abruptly cuspidate, cuneately acute and slightly decurrent at the base, 10.5–48 cm long, 5.5–15 cm wide, glabrous, not manifestly lepidote; lateral nerves 10–16 each side, impressed to subelevated above, subelevated below, anastomosing 5–8 mm from margin; tertiary venation conspicuously reticulate below, the larger areoles enclosing a minute network of elevated veins, less conspicuously reticulate above; petiole 18–22.5 cm long, 4 mm diam., glabrous, terete, not lepidote; petiolules unequal, 1–5 cm long, glabrous, articulate. Flowers solitary; pedicels 1.5–3 cm long, glabrous. Receptacle 5-glandular, glands oval, 1–1.5 mm long. Calyx broadly campanulate, 8–10 mm long, 8–13 mm wide at summit, truncate, densely buff stellate-tomentose without, densely pale sericeous within. Petals cream-tan, subcoriaceous, ligulate-spathulate, subobtuse at apex, 8 cm long, 9–10 mm wide in upper half, 4.5–5 mm wide at base, densely stellate-tomentose within, more densely stellate-tomentellose without. Staminal column 13 mm long, 2.5 mm wide, glabrous above and at base, with 5 vertical minutely stellate-puberulent lines in between alternating with broader glabrous zones 0.9–1 mm wide, branched into 10 phalanges, the main basal branches 10–13 mm long, each main basal branch again branched into several divisions with ultimate 18–24 filaments on each phalange, a total of ca. 240 filaments 4–4.5 cm long. Anthers linear-oblong, 2.5–3 mm long. Stigma 5-lobed, the lobes ovate-lanceolate, 1 mm long, 0.7 mm wide. Ovary suborbicular, densely tomentose.

Paratype. VENEZUELA: T. F. AMAZONAS: Dept. Atures, Río Coro-Coro, river and adjacent forested slopes, W of Serranía de Yutaje, 6–8 km N of Yutaje settlement, 5°41′N, 66°7′30″W, 23 Feb. 1987, 320 m, *Liesner & Holst 21337* (MO, VEN).

This species is related to *Pochota obovata* Robyns but differs in the shorter pedicels, narrower calyx and petals, alternately glabrous and stellate-pubescent vertical zones of the staminal tube, and nonlepidote, nonglaucous lower leaf surface. It is a pleasure to name this species for Parker Redmond, who kindly took care of the logistics for the expedition to the Serranía de Yutaje.

Pochota tepuiensis Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Meseta de Jaua, Cerro Sarisariñama, summit, 4°41′40″N, 64°13′20″W, parte NE, afloramiento arenisco con zanjones en formación de bosque achaparrado y árboles enanos, 1,380 m, 11–12 Feb. 1974, *Julian Steyermark, V. Carreño Espinoza & C. Brewer-Carias 108938* (holotype, VEN).

Arbor 2.5-metralis; foliolis 5 obovatis apice rotundatis emarginatisque basi cuneatim acutis 3–6 cm longis 1.5–2 cm latis subtus cinereis haud lepidotis valde revolutis; nervis lateralibus subhorizontalibus utroque latere 6–10; petiolis 1.3–2 cm longis glabris, petiolulis 2–3 mm longis glabris; pedicellis immaturis 4 mm longis; calycis tubo immaturo 5 mm longo apice 6 mm lato extus dense fusco-tomentoso intus sericeo; receptaculo conspicue glandulari; petalis immaturis dense fusco-sericeis.

Tree 2.5 m tall. Leaves 5-foliolate; leaflets obovate, rounded and emarginate at apex, cuneately acute at base, 3–6 cm long, 1.5–2 cm wide, grayish below, not lepidote below, 1.6–2.7 times longer than broad; lateral nerves subhorizontal, anastomosing near the margin, 6–10 each side, prominently impressed below, slightly sulcate above; tertiary venation prominent and impressed below. Petiole 1.3–2 cm long, 1.5–2.5 mm wide, glabrous, not lepidote; petiolules 2–3 mm long, glabrous, not lepidote. Pedicels (immature) 4 mm long, brown tomentose. Calyx (immature) 5 mm long, 6 mm wide at summit, densely brown stellate-tomentose without, tawny sericeous within. Receptacle (immature) prominently glandular. Petals in early bud densely brown sericeous.

This species is distinguished by the small size of the strongly revolute, apically rounded leaflets; cinereous nonlepidote lower leaf surface; and short petioles, petiolules, pedicels, and calyx. It is known only from the summit of the isolated Cerro Sarisariñama.

ARALIACEAE

SCHEFFLERA

Schefflera simplex Steyermark & Holst, sp. nov. TYPE: Venezuela. T. F. Amazonas: Cerro de La Neblina, ridge line on Venezuela–Brazil border, 1,900–2,100 m, 17 Apr. 1984, *Al Gentry & Bruce Stein 46694* (holotype, MO; isotype, VEN).

Arbor 6-metralis; foliis 4–5-foliolatis, foliolis oblongo-lanceolatis vel anguste elliptico-oblongis apice obtusis vel acutis, basi obtusis vel subobtusis 6.5–12 cm longis 2–5.5 cm latis supra praeter costam mediam minute pubescentem glabris subtus densissime velutinis; nervis lateralibus principalibus utroque latere 15 23; petiolulis inaequalibus 1–3 cm longis minute adpresso-pubescentibus; petiolis 9–14 cm longis minute adpresso-pubescentibus; inflorescentiis 2–4, brevipedunculatis, pedunculis sub anthesi 2.2–5 cm longis densissime tomentosis; inflorescentiis simplicibus solitariis capitatis, capitulis densifloris ca. 20-floris 9–12 mm longis 10–12 mm latis dense tomentosis; floribus sub alabastro sessilibus 2.5 mm longis dense pubescentibus; stylo 3-lobulato.

Tree 6 m tall. Leaves 4–5-foliolate; leaflets coriaceous, oblong-lanceolate to narrowly elliptic-oblong, obtuse to acute at apex, obtuse or subobtuse at base, 6.5–12 cm long, 2–5.5 cm wide, glabrous above except for the minutely pubescent midnerve becoming glabrous except at base, densely velutinous beneath; midrib elevated on both sides; principal lateral nerves 15–23 each side, 4–6 mm apart, extending to margin, subhorizontally spreading to slightly ascending at an angle of 10–20°, subsulcate above; tertiary venation subsulcate, subreticulate above. Petioles 9–14 cm long, 2.5–3 mm wide, minutely appressed-tomentellose. Petiolules unequal, 1–3 cm long, 2–2.5 mm wide, bicarinate above, minutely tomentellose. Peduncles 2–4, in anthesis 2.2–5 cm long, 3–4 mm wide, densely buff-tomentose; inflorescence simple, solitary, capitate, each one terminating a peduncle; heads densely ca. 20-flowered, 9–12 mm long, 10–12 mm wide, densely tomentose. Bracts subtending inflorescence deltoid-ovate, acute, 3–4 mm long, 2.5 mm wide at base, densely gray-buff tomentose without, glabrous within. Flowers in bud 2.5 mm long; calyx teeth acute, unequal, tomentose without, glabrous within; petals 2.5 mm long, 1.7–2 mm wide, ventrally carinate; style 1, shortly 3-lobulate.

This species is unusual among the Venezuelan Guayana taxa of *Schefflera* in having the inflorescence consisting of solitary heads terminating unbranched, short peduncles. *Schefflera globulifera*, a related taxon with capitate flowers, has a long-pedunculate inflorescence with the heads arranged in one or more verticils.

Schefflera yutajensis Steyermark & Holst, sp. nov. TYPE: Venezuela. T. F. Amazonas: Dept. Atures, valley of Río Coro-Coro, west of Serranía de Yutaje, E base of forested mountain 5 km W of river, 5°41′N, 66°9′30″W, 1,100 m, 11 Mar. 1987, *Bruce K. Holst & Ronald L. Liesner 3426* (holotype, MO; isotype, MO).

Arbor 28-metralis; foliis 6–7-foliolatis, foliolis oblongo-lanceolatis vel late elliptico-oblongis apice abrupte breviter caudato-acuminatis, basi obtusis vel subobtusis 15–25 cm longis 7–12 cm latis supra glabris subtus minute densissimeque breviter sericeis; petiolulis inaequalibus 3–9 cm longis minute denseque breviter sericeis; petiolis maturis 49–50 cm longis 6 mm latis dense breviter sericeis; inflorescentiis late racemoso-paniculatis, pedunculis inclusis sub anthesi 15 cm longis 10–12 cm latis sub fructu 22–25 cm longis 14–25 cm latis, axibus lateralibus primariis late divaricatis sub anthesi 5–11 cm longis sub fructu 6–15 cm longis racemose dispositis 15–30 umbellas simplices 10–20-flores gerentibus, omnino ferrugineo-sericeo-tomentellis; axibus umbelliferis sub alabastro 6–9 mm longis 1 mm latis sub fructu 3–6 cm longis; floribus sub alabastro subsessilibus 0.5 mm longis sub fructu 4–6 mm pedicellatis; inflorescentiarum pedunculis rachidibus axibus pedicellisque minute denseque ferrugineo-sericeo-tomentellis; bracteis sub axibus primariis late lanceolato-ovatis acuminatis 3–5 mm longis extus dense ferrugineo-sericeo-tomentellis; stylis sub fructu 5; fructibus globosis in sicco conspicue 5-carinatis maturis 1.5 × 1.5 cm praeter apicem minute pubescentem glabris.

Tree 28 m tall, the bark slightly rough with longitudinal rows of elevated brown lenticels and widely separated petiolar scars. Leaves 6–7-foliolate; leaflets coriaceous, dark green and shining above, bright copper-colored below when young, turning gray in age, oblong-lanceolate to broadly elliptic-oblong, abruptly short caudate-acuminate at apex, obtuse to subobtuse at base, 15–25 cm long, 7–12 cm wide, glabrous above, minutely and densely ferruginous-sericeous beneath. Lateral nerves 8–11 each side, forking 5–16 mm before reaching the margin. Petiolules unequal, 3–9 cm long, minutely and densely ferruginous-sericeous. Petioles of mature leaves 49–50 cm long, 6 mm wide, densely and minutely ferruginous-sericeous. Inflorescence paniculately branched with 10–13 widely spreading primary axes bearing 15–30 racemosely arranged, simple umbels, each of these 10–20-flowered; inflorescence pedunculate, including the peduncle, 15 cm long, 10–12 cm wide in anthesis, 22–25 cm long, 14–25 cm wide in fruit, the peduncular portion 7.5 cm long in anthesis, 14–15 cm long in fruit, all parts of the inflorescence and infructescence densely ferruginous-sericeous. Primary lateral axes alternate to subverticillate, widely spreading, 5–11 cm in bud, 6–15 cm long in fruit; bracts subtending primary axes broadly lance-ovate, acuminate, 3–5 mm long, ferruginous-sericeous, umbelliferous secondary axes 6–9 mm long, 1 mm wide in bud stage, 3–6 cm long, 1–2 mm wide in fruit; umbels simple, 10–20-flowered. Flowers (staminate) subsessile in bud, 4–6 mm-long pedicellate in fruit; calyx in bud shallowly 5-denticulate, the teeth deltoid, acute, densely ferruginous-sericeous. Styles 5, in fruit spreading over the summit and appressed, 1 mm long. Fruit pale green when mature, globose, sharply 5-carinate when dried, 1.5 × 1.5 cm, the apex minutely pubescent, elsewhere glabrous, 5-celled.

Schefflera yutajensis of Territorio Federal Amazonas is allopatric with *S. quinquecarinata* Steyerm. of eastern Venezuelan Guayana, having similar 5-carinately angled fruits with 5 styles and a paniculately branched inflorescence. The former differs by having the primary axes bearing numerous racemosely arranged many-flowered umbels, fruiting pedicels 4–6 (vs. 18–25) mm long, mostly glabrous (vs. tomentose) fruits, obtuse or subobtuse leaflet bases, and oblong-lanceolate or elliptic-oblong leaflets. The species inhabits seasonally dry, evergreen forested slopes of the Serranía Yutaje.

GENTIANACEAE

SYMBOLANTHUS

Symbolanthus huachamacariensis Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Cerro Huachamacari, diagonal ledge, cumbre, 1,700 m, 4 Dec. 1950, *B. Maguire, R. S. Cowan & John J. Wurdack 29859* (holotype, VEN; isotype, NY).

Planta herbacea 1-metralis, caulibus quadrangularibus; foliorum laminis lanceolato-ellipticis apice tenuiter acuminatis basi longiattenuatis cuneatis, majoribus 8.5–14.5 cm longis 3–5 cm latis; nervis lateralibus principalibus utroque latere duobus; petiolis 10–17 mm longis; bracteis sub pedicellis subulatis 9–13 mm longis 1–1.5 mm latis; calyce 30–32 mm longo, lobis lanceolatis acuminatis vel breviter caudatis sub anthesi 25–27 mm longis sub fructu usque ad 35 mm longis basi 10 mm latis; corolla hypocrateriformi 5.2–5.5 cm longa, tubo 3–4 cm longo 8–10 mm lato; lobis late ovato-suborbicularibus acutis 15–17 mm longis prope basin 15 mm latis.

Perennial herb 1 m tall. Stems quadrangular. Leaf blades lance-elliptic, slenderly acuminate at apex, long-attenuate cuneate at base, long-petiolate, the larger 8.5–14.5 cm long, 3–5 cm wide; main lateral nerves 2 on each side, the uppermost pair arising about ⅜ of the length of the leaf blade above its base; midrib and lateral nerves inconspicuous, at most impressed. Petiole 10–17 mm long. Flowers 2, terminal; pedicels slender, 15–35 mm long. Bracts at base of pedicels subulate, caudate at the apex, 9–13 mm long, 1–1.5 mm wide. Calyx 30–32 mm long, the lobes lanceolate, acuminate, or shortly caudate, 25–27 mm long in anthesis, elongating in fruit to 35 mm with caudate tips, 10 mm wide near the base. Corolla magenta-rose red with purple lines in the white throat, salverform, 5.2–5.5 cm long, the tube 3–4 cm long, 8–10 mm wide; lobes broadly ovate-suborbicular, acute, 15–17 mm long, 15 mm wide near the base. Anthers, including the subulate appendage, 7–8 mm long. Ovary lance-ovate, 11 mm long, 5 mm wide, with 5 squamellate truncate scales 1.5 mm long, 1.2 mm wide at base of ovary; style 3 cm long; stigmas ovate, obtuse, 3 mm long.

Paratype. VENEZUELA. T. F. AMAZONAS: Cerro Huachamacari, upper escarpment, 3 Dec. 1950, *Maguire, Cowan & Wurdack 29801* (NY, VEN); above diagonal ledge, Cerro Huachamacari, Camp II to escarpment and return, 1,200–1,500 m, 5 Dec. 1950, *Maguire, Cowan & Wurdack 29879* (NY, VEN).

This species is distinguished in having attenuate-acuminate calyx lobes that attain ⅔–¾ the length of the corolla tube, and in having a relatively small, tubular corolla.

Symbolanthus yaviensis Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Dept. Atures, summit of Cerro Yaví, headwaters of Río Parucito, eastern affluent of Río Manapiare, 5°43′N, 65°52′W, 100 m, 24 Oct. 1986, *Otto Huber 11849* (holotype, MO; isotype, VEN).

Suffrutex 1–1.5-metralis, caule quadrangulari 4–4.5 mm diam. glabro; foliorum laminis elliptico-ovatis apice subacutis basi cuneatim acutis 3–3.8 cm longis 1.2–1.6 cm latis ubique glabris; nervis lateralibus utroque latere duobus subtus elevatis in parte inferiori ¼ laminae exorientibus; petiolis 6–7 mm longis; floribus terminalibus solitariis, pedicello 6 mm longo; calyce 18 mm longo, tubo 4 mm longo 10 mm lato, sepalis late ovatis apiculatis appendice 0.2 mm longa praeditis, 15 mm longis 14 mm latis, marginibus scariosis integerrimis; corolla parte inferiori ⅔ pallido verde, tubo intus roseato, lobis cremosis, late infundibuliformi 6.4 cm long (tubo 4.7 cm longo, parte basali angusta 12 mm longa 5 mm lata; lobis suborbicularibus minute cuspidatis 17 mm longis in medio 21 mm latis); tubo staminali 17 mm longo supra basin corollae 10–11 mm longo inserto, libero 5–6 mm; filamentis paullo inaequalibus 3–3.5 cm longis glabris, squamis late ligulatis apice truncatis late 2-denticulatis 4 × 4 mm; antheris 7 mm longis, appendicibus 0.5 mm longis; stylo 3.8 cm longo; ovario lanceolato-ovoideo 9 mm longo 4.5 mm lato.

Suffruticose plant with subherbaceous stems, 1–1.5 m tall; stems quadrangular, 4–4.5 mm diam., glabrous. Leaves short-petiolate; leaf blades firmly membranous, elliptic-ovate, subacute at apex, cuneately acute at base, 3–3.8 cm long, 1.2–1.6 cm wide, glabrous both sides, decurrent; midrib sulcate above, elevated below; lateral nerves 2 on each side, arising within the lower ⅓, elevated below, obsolescent above; tertiary venation obscure or obsolescent. Petioles 6–7 mm long. Flowers terminal, solitary; pedicel 6 mm long, 3 mm wide. Calyx 18 mm long; tube 4 mm long, 10 mm wide; sepals broadly ovate, apiculate with a minute appendage 0.2 mm long, 15 mm long, 14 mm wide, scarious-margined, entire. Corolla pale green in lower ⅔, roseate within, creamy white on lobes, broadly infundibuliform, 6.4 cm long (tube and limb 4.7 cm long, the constricted basal portion 12 mm long, 5 mm wide; lobes depressed-suborbicular, minutely cuspidate, 17 mm long, 21 mm wide at middle). Staminal tube 17 mm long, attached 10–11 mm above the base of the corolla tube, free 5–6 mm above the attachment; filaments somewhat unequal, the longer ones 3.5 cm long, the shorter 3 cm long, glabrous. Squamellate scales at base of filaments broadly ligulate, 2-denticulate at the truncate summit, 4 mm long, 4 mm wide. Anthers curved, 7 mm long, 1.7–1.8 mm wide, dorsifixed in the lower ⅓, terminating in an attenuate appendage 0.5 mm long. Ovary lance-ovoid, 9 mm long, 4.5 mm wide; squamellate scales at base of ovary truncate, 1.5 mm long; style 3.8 cm long; stigmas ovate, 3 mm long.

From *Symbolanthus sessilis* Steyerm. & Mag. of the Meseta de Jaua (Cerro Sarisariñama) of Estado Bolívar, Venezuela, this species differs in the smaller corolla, calyx, and leaves; shorter pedicels; entire calyx margins; corolla color; and leaf shape. It is distinguished from *S. calygonus* (R. & P.) Griseb. by the smaller corolla, calyx, and leaves; shorter pedicels and petioles; and minutely mucronate corolla lobes.

RUBIACEAE

REMIJIA

Remijia sessilis Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: southwest side of Cerro de La Neblina, hills 2.5 km SW of Base Camp, 00°49′N, 66°10′W, 400–500 m, 20 Feb. 1985, *M. Nee 30967* (holotype, MO; isotypes, NY, VEN). Figure 9.

Frutex 2-metralis, ramulis petiolis foliorum laminisque longihirsutis pilis brunneis praeditis; petiolis alatis inflatis bulliformibus 2.5–3 cm longis; laminis supra rugosis late obovatis apice breviter acuminatis basi conspicue attenuatis 36 cm longis 16 cm latis utrinque longihirsutis pilis 2.5–4.5 mm longis; nervis lateralibus utroque latere 13–14; inflorescentia sessili dense multiflora 2 cm longa 1.5–2 cm lata; floribus sessilibus; calycis tubo tubuloso-campanulato 3.5–5 mm longo 3.5–5 mm lato extus hirsuto, lobis lato triangularibus attenuatis 1–1.2 mm longis hirsuto-ciliatis; hypanthio obconico 5 mm longo 2–2.5 mm lato dense brunneo-hirsuto; capsulis loculicide dehiscentibus, valvis lineari-oblongis 3.2–3.8 cm longis 5–11 mm latis extus hirsutis intus glabris.

Hollow-stemmed shrub 2 m tall, the branches brown-hirsute. Petioles winged, inflated-bladdery, 2.5–3 cm long with long, brown hairs. Leaf blades rugose, especially above, firmly membranous, broadly obovate, shortly acuminate at apex, conspicuously attenuate to the base, 36 cm long, 16 cm wide, brown hirsute with spreading hairs 2.5–4.5 mm long; lateral nerves 13–14 each side. Inflorescence sessile, densely many-flowered, 2 cm

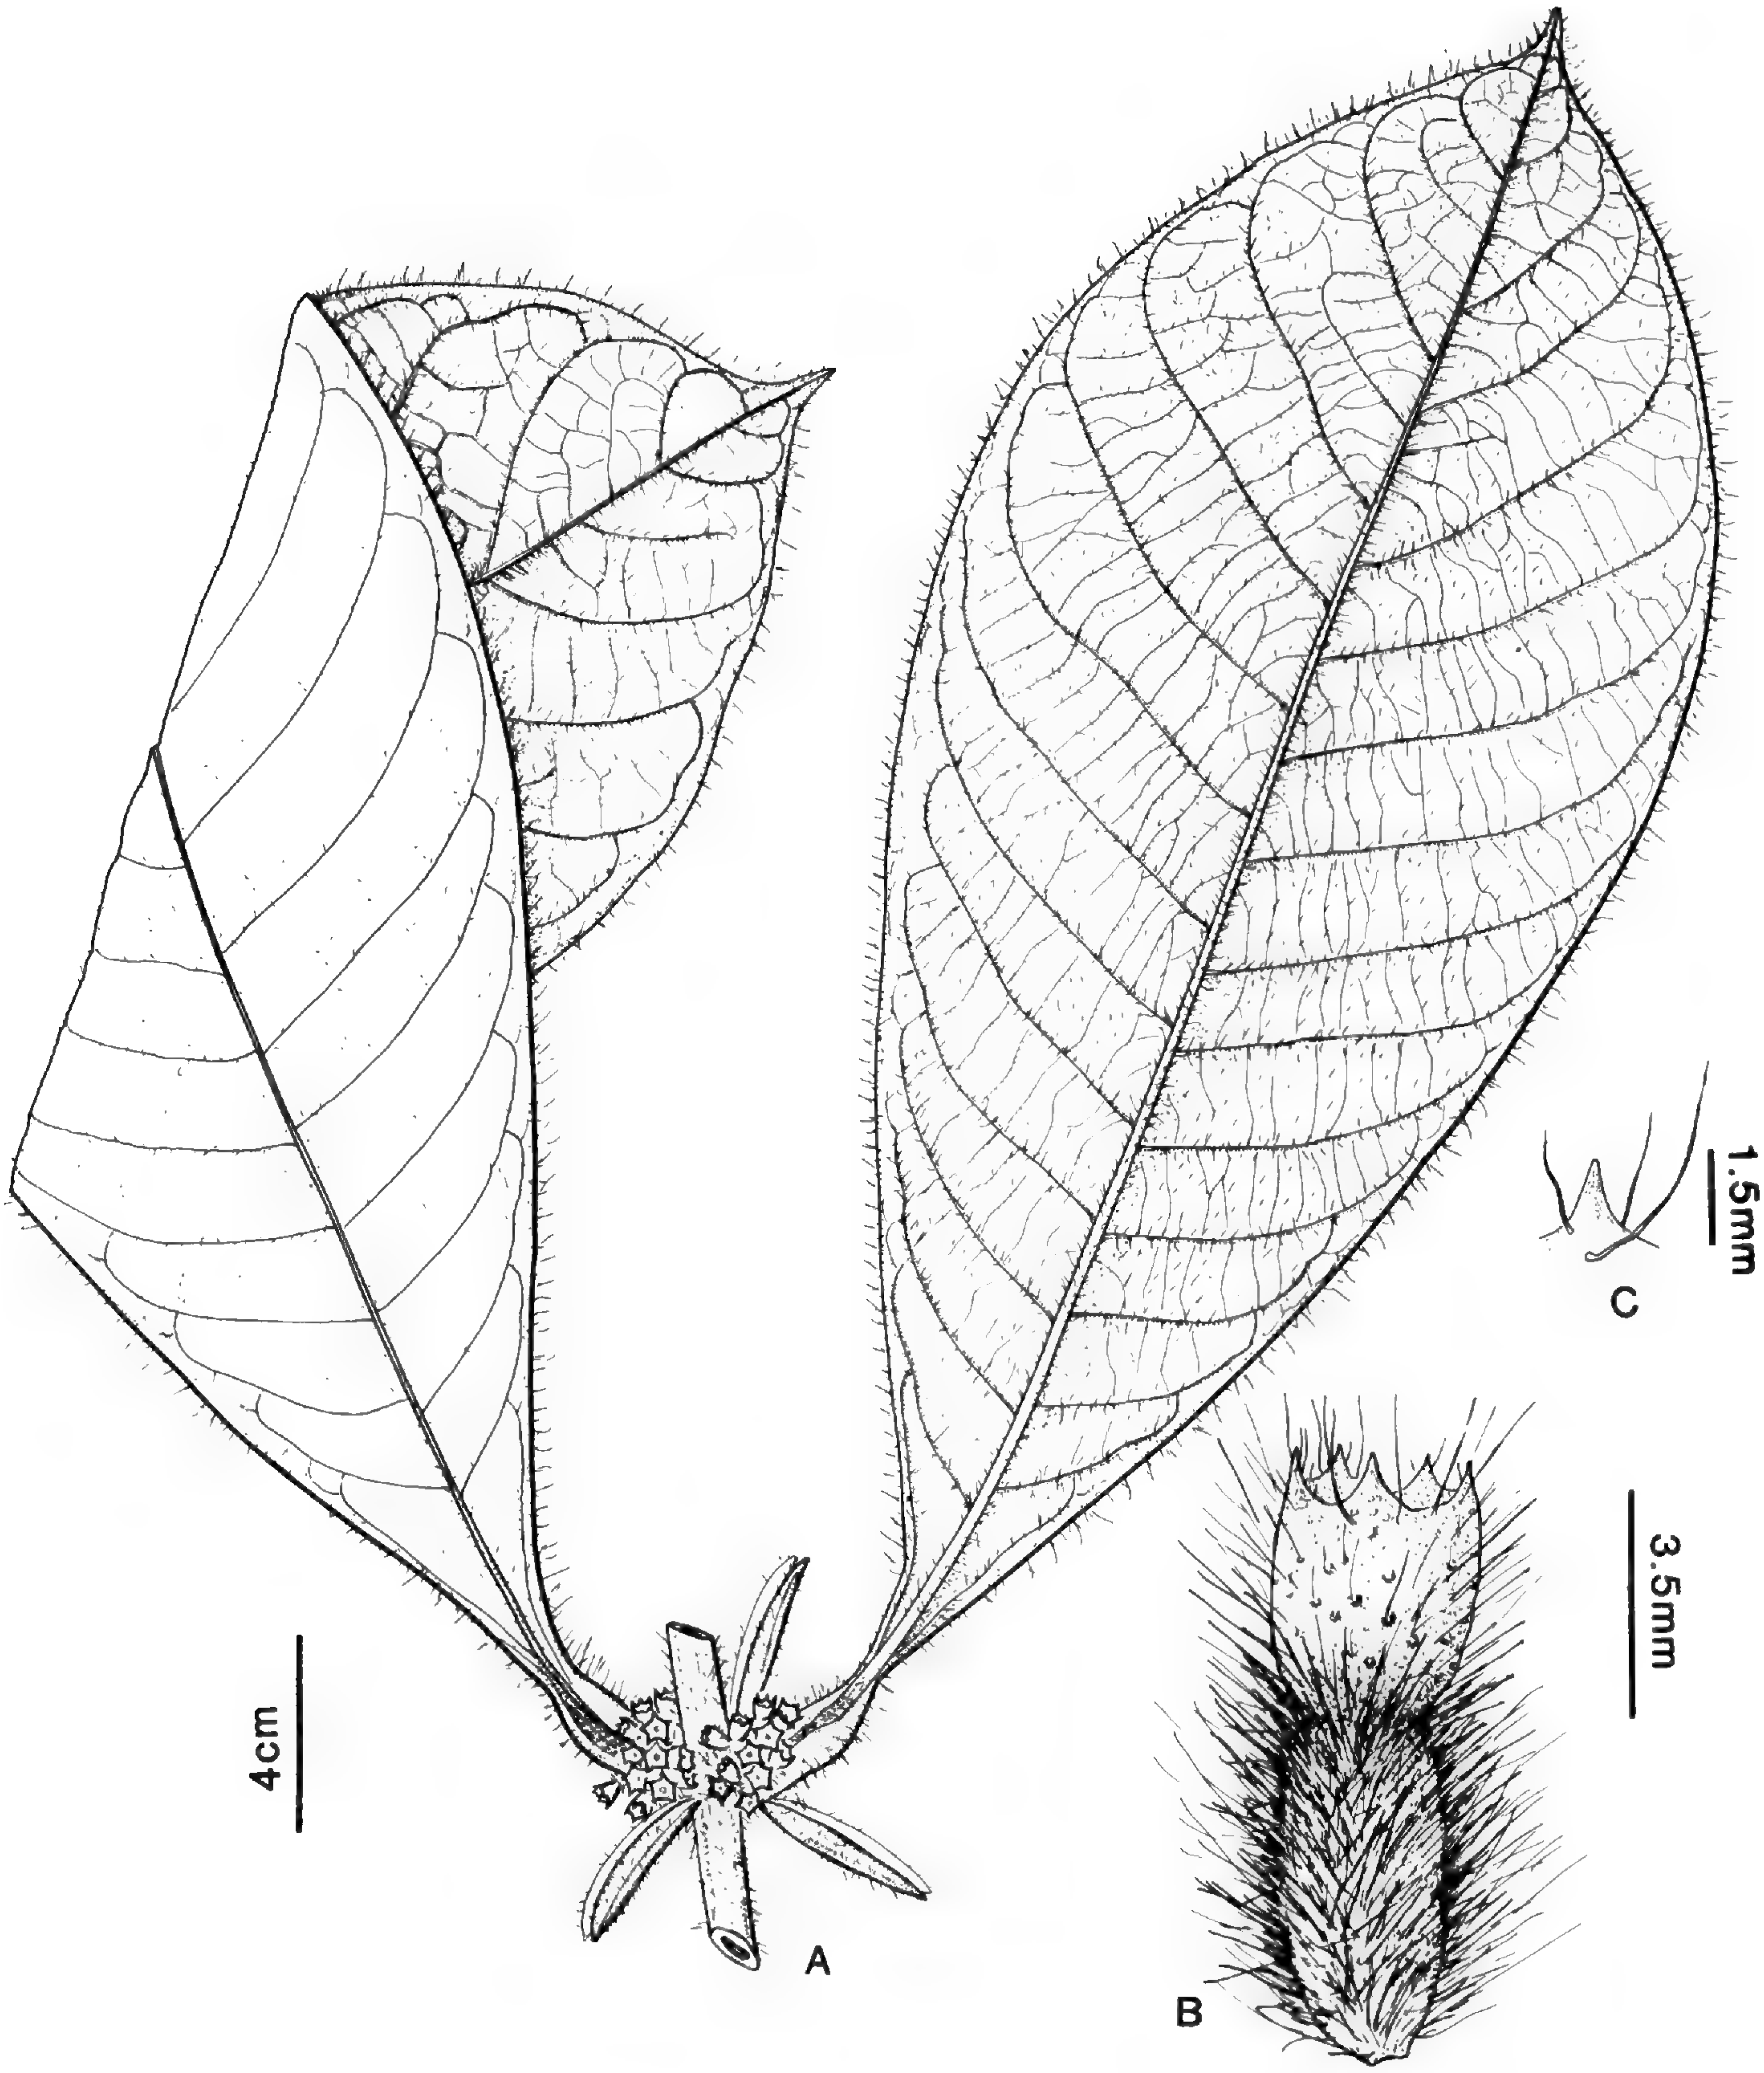

FIGURE 9. Remijia sessilis.—*A. Portion of stem with infructescence.—B. Calyx and hypanthium in post-anthesis.—C. Calyx lobe.*

long, 1.5–2 cm broad; flowers sessile, 12–15 in each cluster between the stem and base of petiole. Calyx tube campanulate, 3.5–5 mm long, 3.5–5 mm wide, brown hirsute with spreading hairs; lobes 5, broadly triangular, attenuate, 1–1.2 mm long, hirsute-ciliate. Hypanthium obconic, 5 mm long, 2–2.5 mm wide, densely brown hirsute. Capsules loculicidally dehiscent, the valves linear-oblong, 3.2–3.8 cm long, 5–11 mm wide, short-hirsute without, glabrous within.

This species is unique in the genus in having a congested, sessile inflorescence. It strongly simulates *Remija physophora* Benth. ex Schum. of the Río Vaupes, Colombia, in the conspicuous, long, brown-hirsute pubescence of the stem, petiolar leaf blades, and calyx, as well as shape of leaves and bladderiform, inflated petioles, but that taxon has conspicuously long-pedunculate, shortly cymosely branched inflorescences with scattered flowers. The calyx lobes of *R. sessilis* are also relatively shorter and more broadly deltoid. Except for the differences in the inflorescence, the two taxa are strikingly similar.

SIMIRA

Simira ignicola Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Dist. Cedeño: shaded canyon on igneous cerro, 1 km S of Quebrada La Flore, affluent of Río Ore, affluent of Río Parguaza, 6°17'N, 67°5'W, 85 m, 9 Sep. 1985, *Steyermark, Holst & Manara 131659* (holotype, MO; isotype, VEN).

Arbor 15-metralis, foliis ovato-ellipticis apice acuminatis base cordatis 17–19 cm longis 11 cm latis subtus dense tomentosis, nervis lateralibus utroque latere 15–16; petiolis 12–16 mm longis dense tomentosis; inflorescentia trichotome cymosa, pedunculo 2–2.3 mm longo sparsim pubescenti; calyce hypanthioque in alabastro 2.5–3 mm longo; lobis calycinis 4 suborbicularibus; corolla in alabastro 3–3.2 mm longa 4-lobata extus minute hirtella.

Tree 15 m tall, the wood dull rose when cut. Leaves subcoriaceous, rugose above, dull green below with elevated nerves. ovate-elliptic, acuminate at apex, cordate at base, 17–19 cm long, 11 cm wide, glabrous above, soft tomentose below, densely so on midrib and lateral nerves; lateral nerves 15–16 each side, slightly ascending at an angle of 25–45°, terminating near the margins without forming any common anastomosing nerve; tertiary veins subsulcate above. Inflorescence terminal, cymosely trichotomous with 3 main axes, 5–5.5 cm long, 5–6.5 cm broad; peduncle 2–2.3 cm long, 3–3.5 mm wide, sparsely pubescent; lower main axes 2.5–3 cm long, densely brown tomentose, the upper main axes 1.5 cm long, densely brown tomentose; ultimate axes 3–6-flowered. Calyx and hypanthium 2.5–3 mm long in bud; calyx 4-lobed, the lobes suborbicular, rounded, ciliate. Hypanthium 2 mm long, 1–1.2 mm wide, subclavate, minutely hirtellous without. Corolla urceolate, 3–3.2 mm long in bud, 4-lobed, minutely hirtellous without. Stamens 4; anthers oblong. Style 2 mm long in bud, glabrous.

The small flowers and the leaf shape resemble *Simira cordifolia*, but the leaf blades and petioles are densely pubescent. From *S. rubescens* the new taxon differs in the pubescence of leaves and floral parts.

REVISED SYNOPSIS OF PANAMANIAN EUPHORBIACEAE[1]

Grady L. Webster[2] *and Michael J. Huft*[3]

ABSTRACT

Collections made in the last two decades have added 9 genera and 42 species to the 35 genera and 100 species included in the Flora of Panama *treatment of the Euphorbiaceae published in 1968. The new taxa and combinations proposed in this paper are* Richeria dressleri *Webster,* Phyllanthus gentryi *Webster,* Tragia correae *Huft,* Dalechampia canescens *Kunth subsp.* friedrichsthalii *(Muell. Arg.) Webster & Huft,* Tetrorchidium costaricense *Huft,* Tetrorchidium microphyllum *Huft,* Croton pachypodus *Webster,* Croton speciosus *Muell. Arg. subsp.* tacarcunensis *Webster,* Croton draco *Cham. & Schldl. subsp.* panamensis *(Klotzsch) Webster,* Croton billbergianus *Muell. Arg. subsp.* pyramidalis *(J. D. Smith) Webster,* Croton santaritensis *Huft,* Sebastiania panamensis *Webster,* Gymnanthes dressleri *Webster, and* Gymnanthes farinosa *(Griseb.) Webster. In addition, new or updated keys are provided where appropriate, as well as descriptions and specimen citations.*

When the treatment of the Euphorbiaceae for the *Flora of Panama* was originally published (Webster & Burch, 1968), it was anticipated that it would prove to be incomplete, but collections made during the past 20 years show that it was even more provisional than we had thought. Not only has *Pausandra* been found as predicted, but no fewer than nine other genera new to Panama: *Adenophaedra, Astrocasia, Croizatia, Drypetes, Gymnanthes, Maprounea, Richeria,* and *Senefeldera,* and an unpublished genus from Cerro Tacarcuna in Darién; this brings the number of native genera to 45. In addition, species new to Panama have been found in a number of genera, including *Acalypha, Alchornea, Cleidion, Croton, Dalechampia, Euphorbia, Hyeronima, Mabea, Manihot, Sapium, Sebastiania, Tetrorchidium,* and *Tragia.* The arrangement of genera within the family has become obsolete since the publication of a new classification (Webster, 1975); there are now five subfamilies recognized, of which four occur in Panama. This new treatment, with the order of the genera now following the revised classification, includes the taxa new to Panama as well as references to recent publications on these taxa.

In order to incorporate all of these additions and changes, the generic key has been revised, and new keys to species have been made for several genera. Citations of specimens are not given for species already included in the original treatment unless they represent new records for provinces or considerable range extensions. Descriptions are provided for most species new to Panama, but in a few cases, if the Panamanian material is not adequate for description or if the species has been recently described elsewhere, a literature reference is given in lieu of a description.

The preparation of this paper has involved us in the study of much extra-Panamanian material and has led to the resolution of a number of ancillary taxonomic and distributional problems. We have not hesitated to discuss these additional items where appropriate. The central position of Panama in the Neotropics certainly renders this account of Panamanian Euphorbiaceae of value to an understanding of the family throughout Central America and northern South America. It seems appropriate, therefore, to include peripheral items that, while not concerning Panamanian species directly, are definitely of relevance.

---

[1] *We thank the curators of the several herbaria for the loan of specimens. Part of the work of the senior author was supported by grants from the National Science Foundation and from the Graduate Division, University of California, Davis; considerable assistance was provided by the staff of the Missouri Botanical Garden, particularly Dr. Gordon McPherson, who supplied material of some critical taxa. Drawings were provided by Wan-Ling Peng, Clara Richardson, and Steve Wilson.*

ANN. MISSOURI BOT. GARD. 75: 1087–1144. 1988.

KEY TO THE GENERA OF EUPHORBIACEAE IN PANAMA

1a. Ovules paired in each cell of the ovary; seeds ecarunculate; milky latex absent; leaves unlobed, entire or obscurely toothed, usually without embedded laminar glands; indumentum simple or lepidote. [Subfamily Phyllanthoideae.]

2a. Petals present.

3a. Petals equalling or longer than the sepals; filaments connate; seeds with copious endosperm ... 1. *Astrocasia*

3b. Petals much shorter than sepals; filaments free or connate; seeds with endosperm scanty or absent.

4a. Monoecious; stipules intrapetiolar; petals glabrous; styles dilated, bifid; columella tapering from base, not apically winged ... 2. *Amanoa*

4b. Dioecious; stipules not projecting between petiole and stem; petals pubescent; styles twice bifid; columella distally expanded into 3 papery wings ... 3. *Croizatia*

2b. Petals absent.

5a. Dioecious; staminate flowers in spikes or racemes, with prominent pistillode.

6a. Indumentum simple; calyx deeply lobed, nearly chorisepalous; anther sacs not pendulous; carpels 2 or 3; fruits capsular; seeds fleshy ... 4. *Richeria*

6b. Indumentum mainly lepidote; calyx distinctly gamosepalous; anther sacs pendulous; carpels 2; fruits drupaceous ... 5. *Hyeronima*

5b. Monoecious or dioecious; staminate flowers in axillary clusters (or if racemose, then branchlets deciduous), lacking a prominent pistillode.

7a. Staminate flowers with a central (intrastaminal) disk; carpels 1 or 2; styles obsolete, the stigmas dilated; fruits drupaceous; seeds solitary in each locule ... 6. *Drypetes*

7b. Staminate flowers without a central disk; carpels 3–5 or more; styles distinctly bifid, the stigmas slender to dilated; fruits mostly dehiscent; seeds 2 per locule.

8a. Carpels 4 or 5 (rarely 3 or 6), irregularly dehiscent; seeds with fleshy bluish outer coat and bony inner coat; staminate flower with annular disk and 4 free stamens; dioecious tree ... 7. *Margaritaria*

8b. Carpels 3 (rarely 2), dehiscent into valves (except in *P. elsiae*); seeds neither fleshy nor bony; stamens 2 or 3 (or if 4, then disk absent); monoecious or dioecious, the habit various ... 8. *Phyllanthus*

1b. Ovules solitary in each cell of the ovary; seeds carunculate or ecarunculate; sap often colored or milky; leaves often dentate and/or palmately veined or lobed, often with laminar or petiolar glands; indumentum various.

9a. Floral bracts not glandular at base (except in *Tetrorchidium*); sepals imbricate to valvate, usually completely covering the anthers in bud; petals present or absent; disk often present; indumentum various; leaves simple to palmately lobed or compound.

10a. Petals absent, or if present then leaves pinnately veined; stalked petiolar glands absent (embedded laminar glands often present); pollen grains mostly 3-colporate; seeds mostly ecarunculate (carunculate only in *Ricinus* and *Pera*); indumentum simple or malpighiaceous (lepidote in *Pera*); flowers in axillary clusters, racemes, or spikes (these sometimes aggregated into panicles). [Subfamily Acalyphoideae.]

11a. Petals present; flowers in racemes; stamens 10; seeds more or less foveolate.

12a. Leaves finely serrate, the lateral veins distinctly parallel; hairs simple or glandular; staminate flowers with pistillode ... 9. *Caperonia*

12b. Leaves entire, the lateral veins not distinctly parallel; hairs malpighiaceous (at least in part); staminate flowers without pistillode ... 10. *Argythamnia*

11b. Petals absent.

13a. Flowers neither sessile nor enclosed in a stalked involucre; seeds not carunculate, black, or shiny.

14a. Flowers not enclosed in a bilabiate involucre formed by 2 palmately veined bracts.

15a. Stamens fasciculate-ramified, anthers numerous; leaves peltate, palmately lobed; inflorescences terminal, paniculate, the pistillate flowers distal; seeds carunculate ... 18. *Ricinus*

15b. Stamens not branched; leaves neither peltate nor palmately lobed; inflorescences otherwise; seeds ecarunculate or the caruncle very small.

16a. Staminate sepals valvate; stamens mostly 3 or more (if 2, connectives not enlarged); latex not distinctly reddish or purplish; fruit less than 8 cm across.

17a. Stinging hairs absent.

18a. Styles free or basally connate; inflorescences unisexual; carpels 2 or 3, not prominently carinate; trees or shrubs, not climbing.

19a. Anthers not vermiform; pistillate bracts not strikingly larger or differently shaped from staminate bracts; styles various, often bifid or unlobed (but not slender and lacerate except in *Adelia*).

20a. Carpels 3; styles bifid (or if unlobed, then seeds fleshy).

21a. Stamens fewer than 10; stipules absent or caducous; dioecious.

22a. Pistillode present in staminate flowers; inflorescences axillary; seed coat fleshy; leaves triplinerved .... 11. *Alchorneopsis*

22b. Pistillode absent; inflorescences terminal (at least in part); seed coat not fleshy; leaves pinnately veined.

23a. Leaves with laminar glands; staminate disk massive, pulviniform; stamens 4–7; styles elongate; seeds over 1 cm long .... 12. *Caryodendron*

23b. Leaves eglandular; staminate disk absent; stamens 3; styles broadly dilated, stigmatiform; seeds less than 1 cm long .... 13. *Adenophaedra*

21b. Stamens more than 10; stipules sometimes persistent.

24a. Stamens less than 30; anther connective not enlarged; pistillate disk present; stipules thin.

25a. Styles 1 or 2 times bifid; pistillate flowers sessile or with short pedicels (less than 5 mm long); leaves with conspicuous foliar glands near base .... 14. *Bernardia*

25b. Styles laciniate; pistillate flowers with long pedicels (at least 20 mm); leaves eglandular .... 15. *Adelia*

24b. Stamens more than 50; anther connective enlarged; pistillate disk absent; stipules indurate .... 17. *Cleidion*

20b. Carpels 2; styles elongate, free, entire; stamens usually 8; seeds tuberculate, ecarunculate, dry; indumentum minutely stellate (at least in part) .... 16. *Alchornea*

19b. Anthers vermiform; styles laciniate; inflorescences spicate; pistillate bracts much larger than the staminate bracts, or else the ovary densely verrucose .... 19. *Acalypha*

18b. Styles connate into a long column; inflorescences bisexual, axillary; carpels 4, prominently carinate; leaves biglandular at base; lianas .... 20. *Plukenetia*

17b. Stinging hairs present; styles unlobed, connate below; disk absent; seeds smooth, ecarunculate.

26a. Anthers with apical tuft of stinging hairs; dioecious shrubs or trees; leaves cuneate at base, glabrescent .... 21. *Acidoton*

26b. Anthers not apically tufted; monoecious twining vines; leaves cordate at base, copiously pubescent with stinging hairs .... 22. *Tragia*

16b. Staminate sepals 4, imbricate (in 2 whorls); stamens 2, the anther connectives greatly enlarged and fleshy; latex purplish or reddish; fruit pomiform, 8–12 cm across .... 24. *Omphalea*

14b. Inflorescences pseudanthial, bisexual; flowers subtended by a bilabiate involucre of 2 palmately veined (or lobed) bracts; styles connate to the stigmas; ovary and fruit armed with irritating hairs; twining or clambering vines with palmately veined, lobed, or dissected leaves .... 23. *Dalechampia*

13b. Flowers sessile in a stalked globose 2-valved involucre; seeds smooth, black, and shiny, carunculate; dioecious trees, indumentum lepidote .... 25. *Pera*

10b. Petals present, at least in staminate flowers, or else calyx petaloid (except in *Tetrorchidium*, with raised foliar glands, and in *Croton punctatus*); leaves often palmately veined or lobed; petioles or leaf bases often with raised or stalked glands; pollen grains with clavate exine, porate or inapurturate (3-colporate in *Tetrorchidium*); seeds carunculate or fleshy (except in *Garcia*); indumentum simple, malpighiaceous, stellate, or lepidote; latex clear, colored, or milky. [Subfamily Crotonoideae.]

27a. Petals absent; stamens 3, the anthers peltate and appearing 4-locellate; pollen grains 3-colporate; seeds fleshy; dioecious shrubs or trees; leaves with stalked petiolar glands and malpighiaceous hairs .... 26. *Tetrorchidium*

27b. Petals present (or else calyx petaloid or indumentum lepidote); stamens 8 or more, the anthers not appearing 4-locellate; pollen grains porate or inaperturate; seeds carunculate (except in *Garcia*), not fleshy.

28a. Petals absent; calyx petaloid; leaves palmately lobed; indumentum simple; latex milky; pollen grains porate; monoecious, the inflorescences terminal, dichasial or paniculate.

29a. Stinging hairs absent; calyx yellowish or greenish to purplish; stamens free; disk central and intrastaminal .... 27. *Manihot*

29b. Stinging hairs present (sometimes very sparse); calyx whitish; stamens connate; disk extrastaminal .... 28. *Cnidoscolus*

28b. Petals present (or else indumentum lepidote); latex not distinctly milky; pollen grains inaperturate.

30a. Anthers more or less erect in bud; indumentum neither stellate nor lepidote.

31a. Calyx of imbricate sepals; stamens not more than 12; staminate petals normally 5; seeds carunculate.

32a. Leaves palmately veined or lobed; stamens mostly 8–12, the filaments connate; monoecious, the inflorescences terminal, dichasial; indumentum simple or of more or less branched glandular setae .... 29. *Jatropha*

32b. Leaves pinnately veined; stamens 3–7, the filaments free; dioecious, the inflorescences axillary, spiciform; indumentum malpighiaceous .... 30. *Pausandra*

31b. Calyx rupturing into valvate segments; stamens 30–100 or more; staminate petals 6–13; seeds ecarunculate; monoecious shrubs or trees; indumentum simple .... 31. *Garcia*

30b. Anthers inflexed in the bud, the stamens 8–50 or more, free; indumentum (at least in part) stellate or lepidote; monoecious (in Panamanian taxa), the inflorescences mostly bisexual, racemose or spicate; seeds carunculate .... 32. *Croton*

9b. Floral bracts biglandular at base; sepals imbricate or reduced; anthers mostly not covered in the bud; petals absent; calyx not petaloid; disk reduced or absent; leaves unlobed; indumentum simple or absent (dendritic in *Mabea*); pollen grains tricolporate, tectate; styles unlobed (or else inflorescence a pseudanthium). [Subfamily Euphorbioideae.]

33a. Inflorescences spicate, racemose, or paniculate, not pseudanthial with a gamophyllous involucre; styles unlobed.

34a. Inflorescences thyrsoid or paniculate; stamens subsessile on an elevated receptacle.

35a. Indumentum dendritic; stylar column elongated; staminate flowers long-pedicellate, 2 or more per node; stamens (in ours) 10 or more .... 33. *Mabea*

35b. Indumentum absent; styles nearly free; staminate flowers subsessile, solitary at each node; stamens (in ours) 5 .... 34. *Senefeldera*

34b. Inflorescences spicate or racemose; stamens with filaments mostly well developed.

36a. Stylar column less than 2.5 cm long, diverging into slender tips; staminate flowers in glomerules, not rupturing bracts at anthesis.

37a. Ovary (2–)3-locular; fruits capsular.

38a. Seeds carunculate, the seed coat dry; petioles eglandular; pistillate sepals free.

39a. Columella without persistent 3-pronged gynobase; milky latex scanty (or perhaps sometimes absent); leaves without raised or stalked glands.

40a. Staminate part of inflorescence elongated; seeds with small caruncle.

41a. Spikes terminal or opposite the leaves; staminate calyx 3-lobed; ovary 6-cornute; fruiting pedicels less than 5 mm long .... 35. *Sebastiania*

41b. Spikes axillary; staminate calyx of 1 segment or absent; ovary smooth; fruiting pedicels more than 10 mm long .... 36. *Gymnanthes*

40b. Staminate part of inflorescence contracted, subglobose; stamens and styles distinctly connate; seeds foveolate, with large calyptrate caruncle .... 37. *Maprounea*

39b. Columella with persistent 3-pronged gynobase; milky latex usually copious; leaves with paired basal cyathiform glands; seeds (in ours) with small caruncle .... 38. *Stillingia*

38b. Seeds ecarunculate, the coat fleshy; petioles usually with a pair of projecting or stipitate glands; calyces distinctly gamophyllous; stamens 2 .... 39. *Sapium*

37b. Ovary 6–9-locular; fruits drupaceous; seeds ecarunculate; pistillate calyx 3-parted .... 40. *Hippomane*

36b. Stylar column at least 2.5 cm long, terminating in a lobed, fleshy disk 2–3 cm wide; staminate flowers aggregated into a fleshy cone; carpels more than 5 .... 41. *Hura*

33b. Inflorescences pseudanthial, i.e., the 5 involucral bracts fused into a cupular cyathium; pistillate flower solitary, terminal, the staminate flowers each with a single stamen, in 5 lateral cymes; styles usually bifid; milky latex copious; seeds (in Panamanian taxa) ecarunculate or minutely carunculate.
  42a. Cyathia more or less radially symmetrical, with glands alternating with bract tips (lobes) around rim; styles free or nearly so.
    43a. Leaves alternate, opposite, or whorled (but if opposite then not inequilateral at base); stipules (in Panamanian taxa) obsolete or glanduliform; veins not chlorenchyma-sheathed; main axis not precociously aborting .... 42. *Euphorbia*
    43b. Leaves opposite, stipulate, inequilateral at base, the veins with chlorenchyma sheaths; main axis aborting just above the cotyledons .... 43. *Chamaesyce*
  42b. Cyathia reddish, bilaterally symmetrical, the involucral glands hidden within the nectar spur; styles connate into a long column .... 44. *Pedilanthus*

ENUMERATION OF TAXA

Subfamily I. PHYLLANTHOIDEAE Asch.

1. *Astrocasia*

Astrocasia Robinson & Millsp., Bot. Jahrb. Syst. 36, Beibl. 80: 19. 1905. TYPE: *Astrocasia phyllanthoides* Robinson & Millsp. = *Astrocasia tremula* (Griseb.) Webster.

Dioecious, glabrous *trees* or shrubs. *Leaves* alternate, petiolate; stipules ribbed, deciduous; blades entire, pinnately veined. *Inflorescences* axillary; flowers in clusters. *Staminate flowers* pedicellate; sepals 5, sometimes unequal; petals 5, longer than the sepals; disk annular; stamens 3 or 5, the filaments connate into a column, anthers extrorse in bud, dehiscing horizontally; pollen grains tricolporate, reticulate; pistillode dilated at tip into a peltate disk capping the staminal column. *Pistillate flowers* long-pedicellate; sepals 5, articulated, deciduous; petals 5, longer than sepals; disk cupuliform, surrounding the ovary; ovary of 3 or 5 carpels; ovules 2 per locule, anatropous; styles free, bifid. *Fruits* capsular; columella slender, persistent; seeds 1 or 2 per locule, ecarunculate; seed coat dry, thin, smooth; raphe conspicuous; endosperm copious; embryo straight; cotyledons thin, flat, much longer and broader than the radicle.

This neotropical genus of four species was not reported from Panama in the original treatment. *Astrocasia* is one of the more primitive genera of Euphorbiaceae and has its closest relatives in Africa and Madagascar (*Heywoodia* Sim, *Wielandia* Baillon).

1.1. Astrocasia tremula (Griseb.) Webster, J. Arnold Arbor. 39: 208. 1958. *Phyllanthus tremulus* Griseb., Fl. Brit. W.I. 34. 1859. TYPE: Jamaica: *Purdie, Wullschlaegel* (syntypes, K).

Astrocasia phyllanthoides Robinson & Millsp., Bot. Jahrb. Syst. 36, Beibl. 80: 19. 1095. TYPE: Mexico. Yucatán: Mérida, *Seler 3943* (holotype, F).

Shrub or tree 2–10 m high; branches terete or obscurely angled, pale; foliage deciduous. *Leaves* with slender petioles 2–6 cm long; stipules lanceolate, chartaceous, 4–6 mm long; blades chartaceous, ovate, acute or obtuse at tip, broadly cuneate at base, 5–12 cm long, 3–7.5 cm broad; major veins 5–8 on a side, ascending, brochidodromous; veinlets prominulous beneath; margins narrowly revolute. *Flower clusters* axillary, staminate and pistillate on separate plants (or on separate branches of the same plant). *Staminate flow-*

ers with pedicels 8–15 mm long; sepals broadly elliptic to obovate, entire, 1.2–1.5 mm long, 1.2–1.8 mm broad; petals elliptic-lanceolate, 2.4–2.7 mm long, 0.8–1.1 mm broad; disk cupuliform, fluted, 0.4–0.5 mm high, 0.9–1 mm broad; androecium 0.7–0.9 mm across; stamens 5; anthers 0.4 mm across; pistillode head circular, 0.5–0.6 mm across. *Pistillate flowers* with slender pedicels becoming 2.5–5.5 cm long; sepals suborbicular to elliptic, 2–2.2 mm long, 1.8–2 mm broad; disk cupuliform, its margin undulate, ca. 1 mm high and 2 mm broad; styles thickened, 0.6 mm long, bifid, the tips clavate. *Fruits* oblate, 3-angled, reticulate-venose, cocci ribbed on back; columella cylindric, 3.2–3.5 mm long; seeds plano-convex, smooth, yellowish, 4.4–5 mm long, 3.8–4 mm broad.

The recent discovery of *Astrocasia* in Panama is one of the most surprising additions to the flora, particularly since it was found near Madden Dam in what is surely one of the most heavily botanized locations in the country. *Astrocasia tremula* has a broad but greatly disjunct distribution from Mexico and Jamaica to Colombia, Venezuela, and Brazil. The Madden Dam locality, however, is the only known station in Central America south of Belize and Guatemala.

Specimens examined. PANAMA. COLÓN: forests along shores of Madden Lake, near Madden Dam, 50 m, *Knapp 1299* (DAV, F, MO), *Witherspoon 8805* (DAV, MO); 6 km N of Chilibre, along Madden Lake, *Knapp 2715* (MO).

2. *Amanoa*

Amanoa Aublet, Hist. Pl. Guiane 256. 1775. TYPE: *Amanoa guianensis* Aublet.

2.1. Amanoa guianensis Aublet, Hist. Pl. Guiane 256. 1775. TYPE: French Guiana: *Aublet* (possibly at BM, not seen).

Additional specimens examined. PANAMA. COLÓN: along Río Chagres and associated tidal channels off side road 9 km from Fort Lorenzo turnoff, 9°40′N, 80°03′W, sea level, *Knapp 1329* (F, MO). SAN BLAS: along Río Armilo, W of Puerto Obaldía, ca. 8°40′N, 77°25′W, sea level, *McPherson 6944* (F, MO).

3. *Croizatia*

Croizatia Steyerm., Fieldiana, Bot. 28: 308, fig. 57. 1952. TYPE: *Croizatia neotropica* Steyerm.

Dioecious *trees* or shrubs; indumentum simple. *Leaves* alternate, petiolate; stipules persistent or deciduous; blades entire, pinnately veined, without embedded glands. *Flowers* in axillary clusters. *Staminate flowers* pedicellate; sepals 5, imbricate; petals 5, much shorter than sepals, pubescent; disk annular; stamens 5, free or connate, the anthers ± introrse; pollen grains 3-colporate, the sexine echinate; pistillode 3-fid. *Pistillate flowers* pedicellate; sepals 5, imbricate; petals 5, much shorter than sepals, pubescent; disk annular; ovary pubescent; styles free, twice bifid; ovules paired in each locule, hemitropous. *Fruits* capsular; columella distally expanded into 3 broad papery wings; seeds paired or solitary in each locule, smooth, not fleshy, ecarunculate; endosperm absent; cotyledons greenish, contortuplicate, much broader than and about as long as the radicle.

LITERATURE

WEBSTER, G. L., L. GILLESPIE & J. STEYERMARK. 1987. Systematics of *Croizatia* (Euphorbiaceae). Syst. Bot. 12: 1–8.

The affinities of this small neotropical genus of three species have remained questionable because of fragmentary material. The recent discovery of staminate flowers of *Croizatia naiguatensis* Steyerm. (Webster et al., 1987) has not made it possible to determine the affinities of the genus more closely. In the protologue to the original description of *Croizatia*, Steyermark proposed a relationship to the Old World genus *Actephila* Blume on the basis of a suggestion by Dr. Leon Croizat. That suggestion seems very perceptive, as there is a clear resemblance to that genus in details of habit, flower, and fruit. On the basis of gross morphology, *Croizatia* can be maintained as a genus distinct from *Actephila*, especially by virtue of its pubescent petals and ovary and its twice-bifid styles. In this latter character it is similar to the African *Pentabrachium* Muell. Arg.; however, in the African genus the seeds have abundant endosperm and the embryo is not contorted as in *Croizatia*. The echinate pollen grains of *Croizatia* are very different from those of *Actephila* or *Pentabrachium* and indicate a possible closer affinity to genera in subfamily Oldfieldioideae.

3.1. Croizatia panamensis Webster, Syst. Bot. 12: 7. 1987. TYPE: Panama. Panamá: primary forest along road from El Llano to Cartí-Tupile, 300–500 m, 30 Mar. 1973, *Liesner 1279* (holotype, MO; isotype, DAV).

Shrub or small tree 1–6 m high, usually with a single main stem. *Leaves* with petioles 0.5–1 cm long, 3–4 mm thick; stipules ± persistent, oblong-lanceolate, acuminate, ribbed, sericeous, 10–20 mm long, 6–7 mm broad; blades chartaceous, glabrous or sparsely strigose-hispidulous beneath, obovate, abruptly short-acuminate, basally attenuate, 22–47 cm long, 5–15 cm broad, with ca. 15 arcuate-ascending lateral nerves connected by intramarginal loops, the veins and (to some extent) veinlets prominulous beneath. *Staminate flowers* with sparsely pubescent pedicels 3–4 mm long; sepals (4–)5, elliptic, entire, 1.7–2.5 mm long, 1–1.5 mm broad; stamens 5, the filaments 2–4 mm long, connate at the base for 0.5–1.5 mm, the column long-pubescent; anthers 0.6–0.8 mm long; pistillode 1.5–2.5 mm long. *Pistillate flowers* with pubescent pedicels ca. 1.5 cm long, becoming 2.5–3.5 cm long in fruit; sepals 5, elliptic-lanceolate, ± acute, 8–12 mm long, 3–4 mm broad, hispidulous without, persistent and becoming reflexed in fruit; ovary 3.5–5 mm diam., densely hirsutulous; styles 3, 3–4 mm long, connate basally into a column ca. 1 mm high, three times bifid. *Fruit* capsular, 10–15 mm broad; columella ca. 8–9 mm high, 10–11 mm broad; seeds trigonous, smooth, brownish, 7.2–10 mm long, 5.3–6.5 mm broad.

Rainforests, Panama and Colombia.

This more complete species description of *Croizatia panamensis* has been made possible by recently collected flowering specimens and data provided by Dr. Gordon McPherson. It is now apparent that *C. panamensis* is clearly different from *C. naiguatensis* in floral characters: staminate flowers with stamens connate in *C. panamensis* (free in *C. naiguatensis*), staminate petals more long-ciliate and styles more divided in *C. panamensis*. Since flowering material of *C. neotropica* is still unknown, it remains difficult to assess its relationships with *C. panamensis*.

Additional specimens examined. PANAMA. SAN BLAS: near road from El Llano to Cartí, beyond Nusagandí, along divide trail to east, 9°15′N, 79°00′W, ca. 300 m (fr), *McPherson 11037* (DAV, MO), (fl, pistillate), *11040* (DAV, MO), (fl, staminate), *11041* (DAV, MO).

4. *Richeria*

Richeria Vahl, Eclog. Amer. 1: 30, tab. 4. 1797. TYPE: *Richeria grandis* Vahl.

Trees or shrubs; dioecious; indumentum simple or absent. *Leaves* alternate, petiolate; stipules deciduous; blades entire or distantly crenulate, pinnately veined, sometimes with basal laminar glands. *Inflorescences* axillary, racemose or spicate; staminate flowers several per bract in sessile or pedunculate glomerules; pistillate bracts subtending solitary flowers; flowers apetalous. *Staminate flowers* sessile; calyx 3–5-lobed, the lobes imbricate; disk segments 3–5; stamens 3–6, free; filaments exserted from calyx; anthers introrse, ± versatile, dehiscing longitudinally; connective not enlarged; pollen grains prolate, 3-colporate, semitectate, reticulate; pistillode present. *Pistillate flowers* pedicellate; calyx 3–5-lobed, the lobes imbricate; disk cupulate; ovary 3-locular, glabrous or pubescent; styles short, bifid; ovules 2 per locule, anatropous. *Fruits* capsular (somewhat fleshy and tardily dehiscent); columella slender, upwardly dilated, with papery wings; seeds solitary in each locule, ecarunculate, the outer testa fleshy; endosperm present; cotyledons broad, plane, basally cordate.

A neotropical genus of five closely related species, previously unreported from mainland North America. *Richeria* appears to be most closely related to the African genus *Maesobotrya* Benth. and to *Aporusa* Blume of southeastern Asia and Malaysia. The circumscription of the genus adopted here differs from that of Mueller (1866) and Jablonski (1967), since section *Podocalyx* (Klotzsch) Muell. Arg. (based on *Richeria loranthoides* (Klotzsch) Muell. Arg.) should be segregated as the monotypic genus *Podocalyx* Klotzsch, which, in fact (as indicated by the spinose pollen), belongs in the subfamily Oldfieldioideae rather than the Phyllanthoideae.

There are two species of *Richeria* in Panama, neither previously reported.

KEY TO THE SPECIES OF *RICHERIA* IN PANAMA

1a. Carpels 3; capsules glabrous; styles suppressed (stigmas sessile); leaves obtuse or rounded at tip, glabrous or nearly so; stipules less than 1 cm long, lanceolate .... 1. *R. obovata*
1b. Carpels 2; capsules distinctly puberulent; styles ca. 1.5 mm long; leaves acuminate at tip, pubescent abaxially; stipules over 1 cm long, foliaceous .... 2. *R. dressleri*

4.1. Richeria obovata (Muell. Arg.) Pax & K. Hoffm., Pflanzenreich IV. 147. XV(Heft 81): 29. 1922; Jablonski, Mem. New York Bot. Gard. 17(1): 126. 1967. *Richeria grandis β obovata* Muell. Arg. in DC., Prodr. 15(2): 468. 1866; Fl. Bras. 11(2): 16. 1873. TYPE: "Brazil," Rio Casiquiari, *Spruce 3526* (not seen).

A species description is not offered here, since the Panamanian specimens are incomplete, and it is not possible to expand the description of Pax & Hoffmann. In the absence of flowers, it is not entirely certain that the Panamanian specimens belong with those cited by Jablonski from montane rain forests in the states of Bolívar and Amazonas, Venezuela.

Specimens examined. PANAMA. PANAMÁ: ca. 5–6 mi. N of El Llano, 1,300 ft., *Gentry 5796* (GH, MO, SCZ). VERAGUAS: cloud forest, Cerro Tute, NW of Santa Fe, *Mori & Kallunki 5264* (DAV, MO).

4.2. Richeria dressleri Webster, sp. nov. TYPE: Panama. Panamá: Santa Rita Ridge, road to Estación Calibrar el Agua Clara, 9°22′N, 79°42–45′W, 1,000–1,500 ft., 26 June 1971, *Webster & Dressler 16744* (holotype, DAV; isotype, MO).

Species haec ab congeneribus differt stylis elongatis, capsulis 2-locularis; foliis acuminatis eglandulosis, integris, subtus puberulis; ovario sericeo-hispido.

Tree to 15 m high, 3.5 dm thick; twigs terete, mostly densely appressed-hirtellous when young, eventually glabrate; foliage evergreen. *Leaves* with hirtellous petioles 1.5–5 cm long; stipules lanceolate, 1–1.5 cm long, densely sericeous, caducous; blades chartaceous, obovate, mostly abruptly acuminate, at base narrowly cuneate and decurrent on the petiole, 10–30 cm long, 4–14 cm broad; major veins mostly 10–12 on a side, straight, brochidodromous, the midrib saliently raised beneath; secondaries archingly and irregularly scalariform; ultimate veinlets fine, scarcely prominulous; surface of blade above glabrous and flecked or pitted with minute colored spots, beneath bronze-colored and densely to sparsely hirtellous (becoming glabrate in age except along midrib and larger veins); margins entire, plane or recurved. *Inflorescences* spiciform; staminate spikes 1.5–5.5 cm long, pistillate spikes 1.5–7 cm long; axes densely hirsutulous without. *Staminate flowers* sessile; calyx deeply 4–5-lobed, densely hirsutulous without; calyx lobes oblong to obovate or suborbicular, unequal, the larger ones 1.4–1.8 mm long, 1.2–1.5 mm broad, the smaller ones 1.2–1.5 mm long, ca. 1 mm broad; disk segments 5, erect, cylindric-prismatic, apically hirtellous, 0.2–0.3 mm high; stamens 5(–6); filaments free, 2–3 mm long; anthers ellipsoid, ca. 0.4 mm long; pistillode cylindrical, densely hirtellous, 1–1.2 mm high, 0.6–0.9 mm broad. *Pistillate flowers* subsessile; sepals mostly 4(–5), elliptic, tomentulose outside, sericeous within, 1.5–2 mm long, 0.8–1.3 mm broad; disk entire, adnate, ciliate-margined, ca. 1.5 mm across; ovary of 2 carpels, sericeous; styles stout, 2- or 3-fid, 1.5–1.7 mm long. *Capsules* ellipsoid, reddish, smoothish (not venose), ca. 10–13 mm long, 6–9 mm broad; columella flattened, papery-winged, 11–12 mm long; seeds somewhat asymmetrically ovoid-ellipsoid, tapering to an obtuse beak, with reddish, fleshy ribbed-striate exotesta, 8.3–9 mm long, 4.8–5.3 mm broad.

This species is sharply characterized within *Richeria* by its 2-carpellate densely sericeous gynoecium with distinct styles; the staminate flowers are similar to those of *Richeria grandis* but differ in the more slender cylindrical pistillode. The acuminate leaves often copiously hirtellous beneath and the large foliaceous stipules also appear distinctive. The collections from Costa Rica are morphologically divergent but may tentatively be grouped with the Panamanian plants. It seems appropriate to name this species in honor of the co-collector of the type specimen, Dr. Robert Dressler, formerly of the Smithsonian Tropical Research Institute, since he has made a significant contribution to our knowledge of Mesoamerican Euphorbiaceae through his many collections and his monographs of *Pedilanthus* (Dressler, 1957) and *Euphorbia* subgenus *Poinsettia* (Dressler, 1961).

Additional specimens examined. COSTA RICA. HEREDIA: Finca La Selva, the OTS Field Station on the Río Puerto Viejo just E of its junction with the Río Sarapiquí, 100–450 m, *Grayum & Perry 1447* (F), *Hammel 8689, 8833* (F), *Jacobs 2179* (F). PUNTARENAS: on road to radio and telecommunications tower 6 km N of Golfito, 300–400 m, *Utley & Utley 4902* (F). PANAMA. COCLÉ: near El Valle de Antón, ca. 8°37′N, 80°07′W, ca. 550 m, *McPherson 7616* (F). COLÓN: Santa Rita lumber road, 15 km E of Colón, *Dressler & Williams 3968* (MO). PANAMÁ: rainforest along El Llano–Cartí road, 4.6–8.2 mi. N of Panamerican Highway, 350–450 m, *D'Arcy 11496* (MO, dupl. at SCZ seen by M. Huft), *Gentry 5076* (MO), *Hammel 7350* (MO), *Knapp 5929* (DAV, F, MO), *McPherson 9959* (F, MO), *Mori & Kallunki 5607* (DAV, MO). SAN BLAS: Cerro Brewster, 9°18′N, 79°16′W, 850 m, *de Nevers et al. 5414* (F).

5. *Hyeronima*

Hyeronima Allemão, Pl. Novas Brasil 1. 1848. TYPE: *Hyeronima alchorneoides* Allemão.

A number of collections made in cloud forests in Panama indicate that there is at least one additional taxon of *Hyeronima* besides the lowland *H. laxiflora*. However, as often happens, these additional specimens have increased the difficulties taxonomically; the following revised treatment is highly tentative pending revisionary studies of this poorly understood genus.

KEY TO THE SPECIES OF *HYERONIMA* IN PANAMA

1a. Stamens 4; pistillode slender, bifid, 0.7–0.8 mm high; leaves sparsely lepidote; blades mostly 10–30 cm long with petioles of 3–9 cm; stipules

5–15 mm long; ovary densely lepidote; endocarp of fruit not over 3.5 mm long .... 1. *H. laxiflora*

1b. Stamens 5; pistillode stout, not bifid, to 0.5 mm high; leaves sparsely to densely lepidote beneath; blades mostly 5–10 cm long with petioles of 1–2 cm; stipules apparently obsolete; ovary glabrous to lepidote; endocarp of fruit at least 4 mm long .... 2. *H. oblonga*

5.1 Hyeronima laxiflora (Tul.) Muell. Arg., Linnaea 34: 67. 1865. *Stilaginella laxiflora* Tul., Ann. Sci. Nat. Bot. III, 15: 244. 1851. TYPE: Guyana: "British Guiana," *Schomburgk 879, Hostmann 391* (syntypes, P).

The specimens originally cited under this name were correctly referred to *H. laxiflora*, which is apparently widespread in lowland rain forests in northern South America. All of the lowland populations of *Hyeronima* in Panama belong to this species.

5.2 Hyeronima oblonga (Tul.) Muell. Arg., Linnaea 34: 66. 1865; in DC., Prodr. 15(2): 271. 1866. *Stilaginella oblonga* Tul., Ann. Sci. Nat. Bot. III, 15: 248. 1851. TYPE: Guyana: "British Guyana," *Schomburgk 805* (P, not seen).

Stilaginella benthamii Tul., Ann. Sci. Nat. Bot. III, 15: 247. 1851. *H. oblonga* (Tul.) Muell. Arg. var. *benthamii* (Tul.) Muell. Arg., Linnaea 34: 66. 1865. SYNTYPES: Mexico. Oaxaca: *Hartweg 513* (P), *Galeotti 7240* (P).

Hieronyma guatemalensis J. D. Smith, Bot. Gaz. (Crawfordsville) 54: 241. 1912. TYPE: Guatemala. Alta Verapaz: *Tuerckheim 423, II 2228* (not seen).

Tree to 10 m high; young twigs angled, densely lepidote (scales ca. 0.15–0.25 mm across). *Leaves* with petioles mostly 10–15 mm long; stipules apparently absent; blades mostly obovate, abruptly cuspidate or short-acuminate, cuneate at base, generally 4–8 cm long, 2.5–5 cm broad; major veins ca. 5–7 on a side, divergent, straight, brochidodromous; midrib and veins raised beneath and ± hirsutulous, the veins and veinlets distinctly prominulous above (upper surface scabrous to the touch); lepidote scales on upper surface scattered to absent, ca. 0.1–0.2 mm across, with reddish center, beneath sparse to dense and overlapping, ca. 0.2–0.25 mm across, with pale center (lower leaf surface much paler than upper). *Panicles* densely lepidote with whitish scales; lateral axes mostly 2–4, the staminate ones 5–10 cm long, the pistillate ones ca. 1.5–2.5 cm long; bracts densely lepidote, acute, ca. 0.7–1 mm long. *Staminate flowers* with rigid stout pedicels ca. 0.4–1.2 mm long; calyx cupulate, shallowly 5-lobed, 1–1.4 mm high, densely lepidote; disk massive, 0.6–0.8 mm high, densely lepidote on top. *Pistillate flowers* subsessile (pedicels equaling or shorter than the bracts); calyx cupulate, shallowly 5-lobed, densely lepidote, 1–1.3 mm high; disk cupulate, subentire, glabrous, ca. 0.4–0.5 mm high; ovary ovoid, ca. 1.5 mm high, glabrous or nearly so; stigmas punctiform. *Fruits* ellipsoid, acute at both ends, coarsely bullate-rugose, 5–6 mm long (endocarp 4–5.5 mm long).

Montane rainforests, Guatemala to Panama and South America.

With some reluctance we are referring all of the high-elevation (cloud forest) populations of *Hyeronima* in Panama to a single species. There is a striking amount of variation in pubescence, and the literature might lead one to recognize two, three, or even more species. Plants with densely lepidote leaves, pale inflorescence axes, and the ovary glabrous or nearly so could be referred to *H. scabrida* (Tul.) Muell. Arg., and plants with sparsely lepidote leaves and densely lepidote ovary to *H. oblonga* s. str. However, specimens from Darién in particular have the pale inflorescence axes of *H. scabrida* combined with the sparsely lepidote leaves of *H. oblonga*. Both "species" occur in the vicinity of El Valle. Plants from the vicinity of Cerro Campana, divergent in having densely lepidote leaves (with prominulous venation above) and larger flowers, appear to match the descriptions of *H. oblonga* var. *benthamii* (Tul.) Muell. Arg. However, it is not clear whether that variety can be satisfactorily delimited from other populations. Only critical field studies can establish whether the broad delimitation of *H. oblonga* adopted here is correct.

Representative specimens examined. PANAMA. BOCAS DEL TORO: between Criollo and Quebrada Higuerón on Chiriquí Trail, *Kirkbride & Duke 783* (MO). CHIRIQUÍ: Cerro Hornitos, ca. 40 km NW of Gualaca, 2,238 m, *Mori & Bolten 7505, 7514* (DAV, MO); Cerro Pate Macho, 4 km NE of Boquete, *Sytsma et al. 4868* (MO). COCLÉ: La Mesa, 2.5 km N of El Valle, 850 m, *Mori et al. 6610* (DAV, MO); hill 3 km E of El Valle, 2,500 ft., *Hammel 4776* (MO); swampy area 5 mi. from El Valle, *Gentry & Dwyer 3622* (DAV, MO); foothills of Cerro Pilón, *Duke & Correa 14675* (MO). DARIÉN: Cerro Mali, 1,400 m, *Gentry & Mori 13629* (DAV, MO); Cerro Tacarcuna, 1,800–1,850 m, *Gentry & Mori 13989, 14025* (DAV, MO). PANAMÁ: Cerro Campana, *Webster & Breckon 16490* (DAV). VERAGUAS: 3–4 km W of Santa Fe, 2,500 ft., *Nee 11315* (DAV, MO); summit of Cerro Arizona, N of Santa Fe, 4,700 ft., *Hammel 4741* (MO); Cerro Tute, just W of Santa Fe, *Knapp & Dressler 5390* (MO).

6. *Drypetes*

Drypetes Vahl, Eclog. Amer. 3: 49. 1807. TYPE: *Drypetes glauca* Vahl.

Trees or shrubs, dioecious; indumentum absent or of simple hairs. *Leaves* alternate, short-petiolate, stipulate; the blades often coriaceous, entire to serrate. *Inflorescences* axillary; flowers in axillary clusters, sometimes cauliflorous. *Flowers* apetalous; sepals usually 4 or 5, imbricate, deciduous. *Staminate flowers* sessile to pedicellate, with intrastaminal disk; stamens mostly 4–5(–50), filaments free; anthers basifixed, extrorse to introrse; pollen grains tricolporate, reticulate; pistillode present or absent. *Pistillate flowers* pedicellate; disk cupuliform; ovary of 1 or 2 (rarely 3 or 4) carpels; styles obsolete or nearly so, dilated stigmas capping the ovary; ovules 2 in each locule, anatropous. *Fruits* indehiscent, ± drupaceous, the exocarp fleshy or leathery, the endocarp crustaceous or bony; seeds usually solitary in each locule, ecarunculate, the testa smooth; endosperm copious; embryo straight, the cotyledons broad and flat.

A large circumtropical genus of about 150 species, best represented in the Old World; about 20 neotropical species have been described. The single Panamanian species was discovered on Barro Colorado Island shortly after the publication of our original treatment.

LITERATURE

WEBSTER, G. L. 1977. A new species of *Drypetes* (Euphorbiaceae) from Panama. Madroño 24: 65–68.

6.1. **Drypetes standleyi** Webster, Madroño 24: 65, fig. 1. 1977; Croat, Fl. Barro Colorado I. 529, fig. 321. 1978. TYPE: Panama. Canal Zone: Barro Colorado I., Armour Trail, *Foster & Croat 2307* (holotype, DAV; isotypes, DUKE, F, F neg. 62358, MO).

Recent collections indicate that *Drypetes standleyi* may occur over a broad area in Panama. A barren collection from the Burica Peninsula, Chiriquí Province (*Busey 602*, MO) may possibly represent *D. standleyi*, although it differs from the other collections in its stiffer leaves with a more prominent veinlet reticulum. The species may also occur in Costa Rica; a specimen from La Selva (*Hartshorn 1009*, DAV) resembles *D. standleyi*, although it is divergent in having more slender pistillate pedicels.

Additional specimens examined. PANAMA. PANAMÁ: Barro Colorado I., Armour Trail, *Foster & Croat 2308* (DAV); vicinity of Armour Trail, *Croat 14843, 14849, 16516* (DAV, MO); S of Zetek 11, *Foster 1122* (DAV, DUKE, MO). COLÓN: Santa Rita lumber road, 9.4 km from Transisthmian Highway, *Dressler 3810* (MO). VERAGUAS: Alto Piedra Santa Fe, *Lao & Maasola 480* (MO); Cerro Tute, *Mori et al. 7541* (MO).

7. *Margaritaria*

Margaritaria L. f., Suppl. Pl. 66. 1782. TYPE: *Margaritaria nobilis* L. f.

RECENT LITERATURE

WEBSTER, G. L. 1979. A revision of *Margaritaria* (Euphorbiaceae). J. Arnold Arbor. 60: 403–444.

8. *Phyllanthus*

Phyllanthus L., Sp. Pl. 981. 1753. LECTOTYPE: *Phyllanthus niruri* L. (chosen by Small in Britton & Brown, Ill. Fl. N. U.S. edition 2, 2: 453. 1913).

RECENT LITERATURE

BANCILHON, L. 1971. Contribution à l'étude taxonomique du genre *Phyllanthus* (Euphorbiacées). Boissiera 18: 1–81.

8.11. **Phyllanthus anisolobus** Muell. Arg. in DC., Prodr. 15(2): 382. 1866. TYPE: Peru: *Pavón* (holotype, G).

The collection from La Palma, Darién (*Pittier 6600*, US) mentioned with doubt in 1968 now appears to represent *Phyllanthus anisolobus* on the basis of its resemblance to the Darién specimens cited below.

Additional specimens examined. PANAMA. BOCAS DEL TORO: Río Teribe, below Puerto Palenque, *Kirkbride & Duke 553* (MO). DARIÉN: Manené, *Kirkbride & Bristan 1592* (MO); Río Balsa, between Manené and Guayabo, *Duke & Nickerson 14958* (MO); Río Pucuro, between Cerro Mali and Cerro Tacarcuna, *Gentry & Mori 13861* (MO). VERAGUAS: 2–5 km NW of Santa Fe on road to Río Calovébora, 500–700 m, *Hernández et al. 744* (F).

8.12. **Phyllanthus gentryi** Webster, sp. nov. TYPE: Panama. Darién: lower slopes of Cerro Pirre, 200–500 m, *Gentry & Clewell 7017* (holotype, F, F neg. 62354; isotypes, DAV, MO). Figure 1.

Species haec aff. *P. juglandifolio* sed ab subsp. *juglandifolio* differt foliis seminibus grandioribus, ab subsp. *cornifolio* differt staminibus 3, stipulis longioribus, ab ambibus differt disco non rugoso, columna stylari breviore.

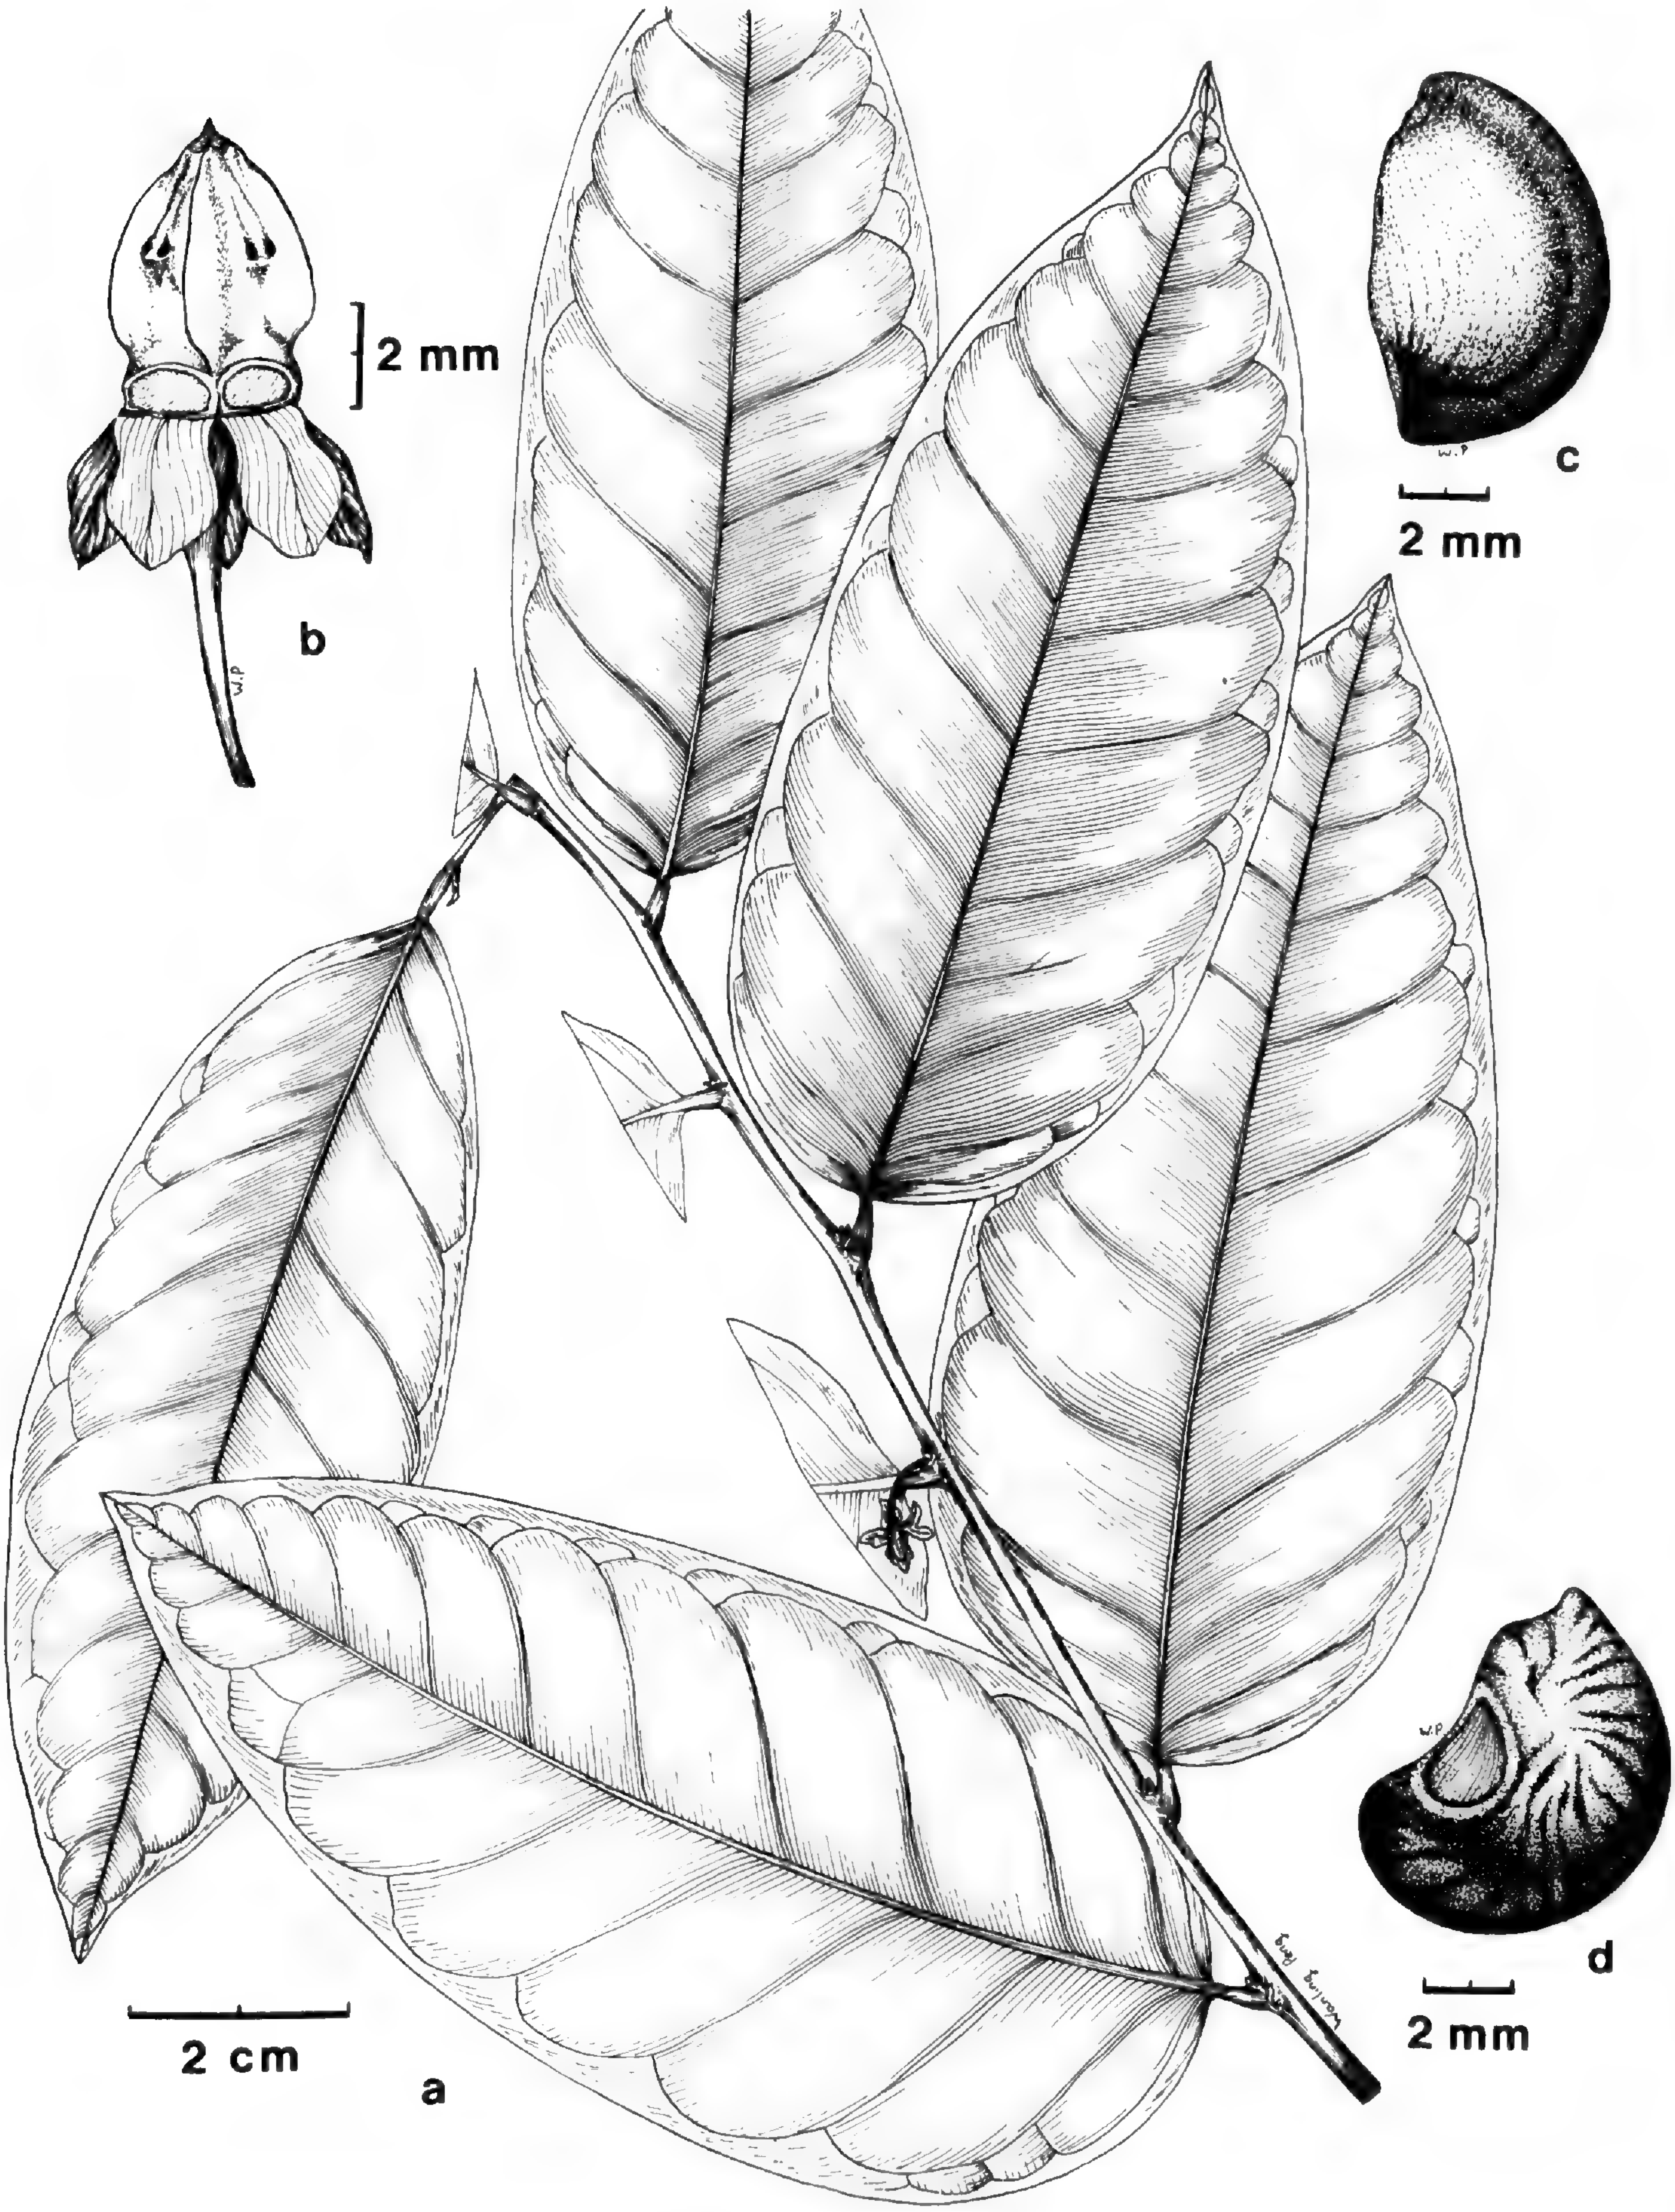

FIGURE 1. Phyllanthus gentryi. —*a. Habit.*—*b. Columella of fruit, showing seed scars and persistent calyx.*—*c. Seed, dorsal view.*—*d. Seed, ventral view. Based on* Gentry 4589. *Illustration by Wan-Ling Peng.*

Shrub or small tree to 5 m high; monoecious; deciduous branchlets pinnatiform, at least 5 dm long, obtusely angled, brownish, minutely scabridulous. *Leaves* with petioles 5–8 mm long; stipules cordate, acuminate, brownish, scarious, ca. 3.5 mm long; blades chartaceous, elliptic-lanceolate, 12–28 cm long, 6–7.5 cm broad, acuminate, rounded to cuneate at base, glabrous on both faces. *Cymules* each of 1 pistillate and several staminate flowers. *Staminate flowers* with pedicels 15–20 mm long; sepals 5, broadly elliptic or oblong; 2.5–3 mm long, 2.2–2.7 mm broad; disk entire, angled, not pitted, 1.8–2.2 mm across; stamens 3, the filaments connate into a column 0.7–0.8 mm high and ca. 0.5 mm broad; anthers suborbicular, flattened, dehiscing horizontally, 0.8–0.9 mm long and broad. *Pistillate flowers* with pedicels 8–13 mm long; sepals 5, elliptic-oblong, blunt, mostly 3–4 mm long, 2.5–3 mm broad; disk massive, angled, not pitted, 2.2–2.5 mm across; ovary smooth, of 3 carpels; styles nearly free, dilated, 1–1.2 mm long, 0.7–1 mm across. *Capsules* reddish, valves 12.5–13 mm long; columella massive, 4.5–5 mm long, 4.2–4.5 mm broad; seeds trigonous-umbonate, 6.5–7.1 mm long, 5.2–5.3 mm broad, smooth, with irregular wavy horizontal dark brown bands on a light brown background, the apex sometimes with a small whitish caruncular outgrowth (ca. 0.5 mm across); hilum triangular, broad, ca. 3 mm long and broad.

Additional specimens examined. PANAMA. DARIÉN: trail up Cerro Pirre, *Gentry 4589* (MO); razorback ridge on Cerro Pirre, *Duke 6556* (MO); Serranía de Pirre, trail from Q. Perecingo to Cerro Pirre, ca. 10 km airline SSE of El Real, in subtropical moist-to-wet forest, 300–750 m, *Reveal & Duke 4919* (MARY, MO); around Rancho Frío, halfway up slope of Cerro Pirre from Piji Vasal, *Folsom 6245* (F, MO); S of El Real on trail up Cerro Pirre, ca. 8°00′N, 77°45′W, 550–1,030 m, *McPherson 7051* (F, MO).

Phyllanthus gentryi is the first representative of subgenus *Xylophylla* (L.) Pers. discovered in Panama. It clearly belongs in section *Asterandra* (Klotzsch) Muell. Arg. by virtue of its confluent staminate disk and dilated styles, and it resembles *P. juglandifolius* Willd. in general aspect. Although it could be interpreted as a subspecies of *P. juglandifolius*, it is distinctive in its large seeds, smooth (nonpitted) disk, and nearly free styles.

In order to accommodate this species in the *Flora of Panama* treatment, the key on p. 221 must be revised as follows:

e. Branchlets pinnatiform.
  e′. Plants (in Panama) herbaceous; leaves less than 3 cm long; seeds less than 3 mm long; pollen grains prolate, 3–4-colporate (subg. *Phyllanthus*).
  ee′. Plants woody; leaves more than 3 cm long; seeds over 3 mm long; pollen grains globose, areolate (subg. *Xyllophylla*) .... 12. *P. gentryi*

Subfamily II. ACALYPHOIDEAE Asch.

9. *Caperonia*

Caperonia A. St. Hil., Hist. Pl. Remarq. Bresil 244. 1826. LECTOTYPE: *Caperonia castaneifolia* (L.) A. St. Hil. (*Croton castaneifolius* L.) (chosen by Britton & Wilson, Bot. Porto Rico 6: 486. 1925).

No additional Panamanian species have been discovered. However, examination of additional specimens indicates that we may not have gone far enough in reducing the taxa proposed under *C. paludosa* Klotzsch. It is extremely difficult to separate that species from *C. castaneifolia* (L.) A. St. Hil., and we now believe that our Panamanian specimens of *C. paludosa* probably represent only forms of that more wide-ranging species. However, the narrower leaves of plants referred to *C. paludosa* are distinctive, and further study in the field is required to establish whether that species concept can be upheld.

10. *Argythamnia*

Argythamnia P. Browne, Civ. Nat. Hist. Jamaica 338. 1756. TYPE: *Argythamnia candicans* Sw.

11. *Alchorneopsis*

Alchorneopsis Muell. Arg., Linnaea 34: 156. 1865: TYPE: *Alchorneopsis floribunda* (Benth.) Muell. Arg. (*Alchornea glandulosa* var. ?*floribunda* Benth.).

11.1 Alchorneopsis floribunda (Benth.) Muell. Arg., Linnaea 34: 156. 1865; in DC., Prodr. 15(2): 765. 1866. *Alchornea glandulosa* Poeppig var. *floribunda* Benth., Hooker's J. Bot. Kew Gard. Misc. 6: 331. 1854. TYPE: Brazil. Amazonas: *Spruce 2681* (holotype, K, not seen).

The single collection of this species cited in the original treatment, from Darién, was the only Central American record known at the time and was likewise a range extension of over 800 miles. The specimens cited below extend the range to western Panama as well as to Costa Rica.

Additional specimens examined. COSTA RICA. CARTAGO: 24 km NE of Turrialba on hwy. to Limón, then E at Tres Equis on jeep road 1.5 km, 9°58'N, 83°34'W, 450–525 m, *Liesner et al. 15354* (MO). HEREDIA: Finca La Selva, the OTS Field Station on the Río Puerto Viejo just E of its junction with the Río Sarapiquí, ca. 100 m, *Hammel 9425, 11083* (F, MO); Istarú Farm, Tirimbina, Sarapiquí, 220 m, *Lent 2320* (F, MO). LIMÓN: S end of Lomas de Sierpe, NE of terminus of road from Villa Franca, 10°19'N, 83'34'W, *Grayum et al. 3520* (F, MO). SAN JOSÉ: 2 km N of Dominical along CR 223, 40–100 m, *Utley & Utley 4938* (F). PANAMA. BOCAS DEL TORO: Cerro Pila de Arroz, along road to Chiriquí Grande, 10 road-mi from Continental Divide and 2 mi. along pipeline access road E of highway, ca. 8°55'N, 82°08'W, 350–500 m, *McPherson 8750* (F).

12. *Caryodendron*

Caryodendron Karsten, Fl. Columb. 1: 91, tab. 45. 1860. TYPE: *Caryodendron orinocense* Karsten.

12.1. Caryodendron angustifolium Standley, Publ. Field Columbian Mus., Bot. Ser. 4: 217. 1929. TYPE: Panama. Chiriquí: Progreso, *Cooper & Slater 192* (holotype, F, F neg. 59913).

The collection cited from Darién under this name in the original collection is now known to be *Senefeldera testiculata* Pittier (q.v.). No additional collections of *Caryodendron angustifolium* are known from Panama or elsewhere.

13. *Adenophaedra*

Adenophaedra (Muell. Arg.) Muell. Arg. in Mart., Fl. Bras. 11(2): 385. 1874. *Bernardia* sect. *Adenophaedra* Muell. Arg., Linnaea 34: 172. 1865; in DC., Prodr. 15(2): 918. 1866. TYPE: *Bernardia ?megalophylla* Muell. Arg. = *Adenophaedra megalophylla* (Muell. Arg.) Muell. Arg.

Dioecious *trees* and shrubs; indumentum of simple trichomes. *Leaves* alternate, petiolate, stipulate; blades pinnately veined, without embedded laminar glands, dentate. *Inflorescences* axillary or terminal, spiciform, the staminate often compound; bracts eglandular, subtending 1 pistillate or several staminate flowers. *Staminate flowers* pedicellate; calyx splitting into 3 valvate lobes at anthesis; petals and disk absent; stamens 2(–3); filaments short; anthers with enlarged connectives, dehiscing introrsely and longitudinally; pistillode absent. *Pistillate flowers* pedicellate; calyx lobes 6, biseriate, imbricate; petals absent; disk 3-lobed; ovary of 3 carpels; ovules 1 per locule; styles contracted into sessile stigmas. *Fruits* capsular, 3-lobed; seeds 1 per locule, smooth, ecarunculate.

LITERATURE

CROIZAT, L. 1946. Nomenclatural transfers and corrections in the Euphorbiaceae. Trop. Woods 88: 30–32.

This poorly known genus, hitherto considered to be South American, includes only three species. Croizat (1946) reported *Adenophaedra* from Panama on the basis of *Adenophaedra woodsoniana*; but in the original treatment (Webster & Burch, 1968: 278) it was pointed out that his original generic disposition (J. Arnold Arbor. 24: 167. 1943) of this plant as *Cleidion woodsonianum* was correct, although that species is now known to be synonymous with *C. membranaceum* Pax & K. Hoffm. (q.v.). Several recent collections of *A. grandifolia* from Panama and Costa Rica, however, firmly establish the presence of *Adenophaedra* in southern Central America. In addition, it now appears that the plant called *Bernardia denticulata* in the original treatment is actually *A. grandifolia.*

13.1. Adenophaedra grandifolia (Klotzsch) Muell. Arg. in Mart., Fl. Bras. 11(2): 386. 1874. *Tragia grandifolia* Klotzsch, London J. Bot. 2: 46. 1843. TYPE: Guyana: "British Guiana," *Schomburgk 948* (presumably K, not seen). *Bernardia ?grandifolia* (Klotzsch) Muell. Arg., Linnaea 34: 173. 1865; in DC., Prodr. 15(2): 918. 1866.

Cleidion denticulatum Standley, Publ. Field Columbian Mus., Bot. Ser. 4: 218. 1929. *Bernardia denticulata* (Standley) Webster, Ann. Missouri Bot. Gard. 54: 200. 1967. TYPE: Panama. Bocas del Toro: Chiriquí Trail, Buena Vista Camp, 1,250 ft., *Cooper 606* (holotype, F, F neg. 52608; isotypes, NY, Y).

Shrub or small tree to 8 m; twigs smooth, reddish, thinly puberulent, tardily glabrate. *Leaves* with petiole 3–6 mm long; stipules lanceolate, ca. 1 mm long, ca. 1 mm broad, caducous; blades chartaceous, oblanceolate, acuminate at the tip, attenuate at the base, 12–35 cm long, 3–12 cm wide, 2.5–4.5 times as long as broad, glabrous, or sometimes thinly villous below on the principal veins, the secondary veins 7–9 per side, arcuate, prominent below, the tertiaries reticulate, prominulous; margins remotely denticulate. *Inflorescences* axillary, densely villous, the bracts deltate, 1–2 mm long, densely villous; staminate spikes slender, flexuous, to 15 cm long, the glomerules widely spaced, to 25; pistillate spikes thicker, not flexuous, 5–12 cm long, with 4–7 solitary flowers. *Staminate flowers* to 12 per glomerule, early dehiscent, leaving persistent pedicels ca. 1 mm long; calyx lobes membranous, deltate, spreading at anthesis, ca. 0.5 mm long. *Pistillate flowers* not seen; pedicels at maturity ca. 4 mm long, reflexed, sericeous. *Capsules* depressed-globose, deeply 3-lobed, 6–8 mm high, 12–18 mm diam., sericeous, glabrate at maturity, the persistent calyx lobes ca. 2 mm long, deltate, sericeous; seeds subglobose to ovoid, ca. 1 mm long, ca. 0.7 mm diam., yellowish, mottled.

Additional specimens examined. COSTA RICA. LIMÓN: 7 km SW of Bribrí, 100–150 m, *Gómez et al. 20422* (F); camino entre la finca de don Calixto Kiamble y el antiguo camino a Katsi, subiendo hasta el Cerro Kikírchabata, *Gómez et al. 23800* (F); camino de Fila Dimat (casa de Hermógenes Pereira) hasta Soki pasando por la quebrada Sha, *Gómez et al. 23859* (F). PANAMA. BOCAS DEL TORO: along road from Fortuna Dam to Chiriquí Grande, ca. 8°45′N, 82°15′W, ca. 700 m, *McPherson 8430* (F); Cerro Pila de Arroz along road to Chiriquí Grande, 10 road-miles from Continental Divide and 2 mi. along pipeline access road E of highway, ca. 8°55′N, 82°08′W, 350–500 m, *McPherson 8752* (F), *8775* (F, distributed as *Cleidion woodsonianum*). VERAGUAS: 5 mi. NW of Santa Fe, 700–1,200 m, *Liesner 976* (GH, MO).

14. *Bernardia*

Bernardia Miller, Gard. Dict. abr. ed. 4, 28. 1754. LECTOTYPE: *Bernardia carpinifolia* Griseb. (see Buchheim, 1962).

Following the reduction of *Bernardia denticulata* to the synonymy of *Adenophaedra grandifolia* (q.v.), this genus is now represented in Panama by a single species.

LITERATURE

BUCHHEIM, G. 1960. Nomenklatorische und systematische Bemerkungen über die Gattung *Bernardia* (Euphorbiaceae). Willdenowia 2: 291–318.

———. 1962. Über die Typusart der Gattung *Bernardia* (Euphorbiaceae). Willdenowia 3: 217–220.

14.1. Bernardia macrophylla Standley, J. Wash. Acad. Sci. 15: 103. 1925. TYPE: Panamá: Río Tocumen, near sea level, 3 Jan. 1924, *Standley 29389* (holotype, US).

No Panamanian specimens of this species have been found in addition to those cited in the original treatment. The recent collection cited below extends the range to Costa Rica. That specimen has somewhat more acuminate leaf apices than the Panamanian collections and was taken at a considerably higher altitude but seems otherwise identical. As indicated in the original treatment, the closest relative of *Bernardia macrophylla* seems to be *B. jacquiniana* Muell. Arg. of Venezuela, but the latter differs in having retrorse rather than ascending pubescence on the stems, more prominent venation on the undersurface of the leaves, and 9–12 vs. 14 stamens.

Additional specimen examined. COSTA RICA. PUNTARENAS: foothills of the Cordillera de Talamanca, around Tres Colinas, 9°07′N, 83°04′W, 1,800–1,850 m, *Davidse et al. 25611* (F).

15. *Adelia*

Adelia L., Syst. Nat. ed. 10, 1298. 1759, nom. cons. TYPE: *Adelia ricinella* L. (typ. cons.).

16. *Alchornea*

Alchornea Sw., Prodr. 98. 1788; Fl. Ind. Occ. 2: 1153. 1800. TYPE: *Alchornea latifolia* Sw.

Several recent collections of *Alchornea* indicate that there are some additional taxa in Panama, but the material is still inadequate for a satisfactory treatment. The taxa that appear to be present may be treated as follows.

LITERATURE

PAX, F. & K. HOFFMANN. 1914. Euphorbiaceae—Acalypheae—Mercurialinae. *In:* A. Engler, Das Pflanzenreich IV. 147. VII(Heft 63): 1–473 (*Alchornea*, pp. 220–253).

KEY TO THE SPECIES OF *ALCHORNEA* IN PANAMA

1a. Pistillate spikes less than 25 cm long; leaves less than 25 cm long (or else copiously stellate-pubescent beneath), with 2 or more basal laminar glands; seeds (where known) not over 7 mm long.
  2a. Leaves (except on sprout shoots) not over ca. 20 cm long, glabrate, the veinlet reticulum only moderately prominulous beneath.
    3a. Leaves chartaceous, abruptly cuspidate-acuminate; vein axils not barbate beneath; basal foliar glands usually 2; staminate spikes unbranched, mostly axillary .... 1. *A. costaricensis*
    3b. Leaves not abruptly cuspidate (or else coriaceous); vein axils often barbate beneath.
      4a. Styles 5–20 mm long, relatively slender.
        5a. Leaves coriaceous, usually with 2–4 basal glands; spikes mostly cauliflorous.
          6a. Leaves mostly 8–20 cm long, acuminate, with mostly 5–8 main lateral veins, entire or crenate-dentate; foliar glands mostly 2(–4); pistillate sepals 2–2.8 mm long .... 2. *A. latifolia*

6b. Leaves mostly 2–7 cm long, acute, with mostly 3 or 4 main lateral veins; foliar glands 2–4; pistillate sepals shorter than 2 mm long .... 3. *A. triplinervia*
5b. Leaves chartaceous, usually with 5–10 basal glands, with 5–8 main lateral veins; spikes mostly axillary; pistillate sepals 1–1.5 mm long .... 4. *A. glandulosa*
4b. Styles 3–7 mm long, thick; leaves coriaceous, acuminate, with 5–7 main lateral veins; foliar glands 2–4; spikes axillary .... 5. *A. grandiflora*
2b. Leaves over 20 cm long, copiously stellate-pubescent beneath, with veinlet reticulum corrugate-impressed above and distinctly raised beneath; spikes cauliflorous .... 6. *A. grandis*
1b. Pistillate spikes mostly 25 cm long or longer, cauliflorous; leaves coriaceous, oblanceolate, ca. 25–40 cm long, glabrescent beneath; basal foliar glands obscure or absent; seeds 9–11 mm long .... 7. *A. megalophylla*

16.1. Alchornea costaricensis Pax & K. Hoffm., Pflanzenreich IV. 147. VII(Heft 63): 235. 1914. TYPE: Costa Rica: Palmar, *Tonduz 6757* (not seen).

Recent collections show that *Alchornea costaricensis* is not confined to western Panama; it extends into South America, where there is at least one record from Colombia (Chocó: *Ordóñez et al. 58*, MO). The plant described from Colombia by Croizat (Caldasia 2: 357. 1944) as *A. umboensis* may prove to be a form of *A. costaricensis.*

Additional specimens examined. PANAMA. CHIRIQUÍ: vicinity of San Bartolo Limite, 11 mi. W of Puerto Armuelles, *Croat 21973a* (MO). COCLÉ: along Río San Juan below its junction with Río Tife, *Hammel 3405* (MO). COLÓN: Río Boquerón near juncture with Río Escandaloso, *Hammel 2743* (MO, determination somewhat dubious); along Río Guanche toward Cerro Bruja, *Huft & Knapp 1789* (MO); 3 mi. from Portobelo, *Correa & Dressler 1749* (GH, MO). DARIÉN: Río Ucurgantí, *Bristan 1137* (MO); Río Tuqueza, below Quebrada Venado, *Bristan 1065* (DAV, MO). LOS SANTOS: Loma Prieta, Cerro Grande, *Duke 11859, Lewis et al. 2208* (MO). PANAMÁ: Chiltepe, *Holdridge 6471* (MO). SAN BLAS: Canagangí, forest upstream of village, 9°24′N, 79°24′W, 100 m, *de Nevers et al. 5720* (F).

16.2. Alchornea latifolia Sw., Prodr. 98. 1788. TYPE: Jamaica: *Swartz* (not seen).

Southern Mexico to Venezuela and Peru.

Further botanical exploration has shown that *Alchornea latifolia* is widely distributed in Panama, including Barro Colorado Island, whence it was correctly recorded by Croat (1978). On several peaks and ridges in central Panama occur montane forms that appear very different from typical *A. latifolia* of lowland Central America and the West Indies. For example, plants with entire leaves and unusually short petioles are found on Cerro Jefe and Santa Rita Ridge (e.g., *Gentry & Dwyer 5536, Croat 15309*). These specimens somewhat suggest the South American *A. pearcei* Britton, but their relatively long petioles and short spikes bring them closer to *A. latifolia.* Specimens with very unusual narrowly obovate leaves have been collected on Santa Rita Ridge (e.g., *Croat 13844, Duke 15264*); however, since plants with this leaf form occur in the same area as plants with more typical leaves, it seems probable that they are merely local variants. At present, it seems best to include all of these variants within *A. latifolia*, but it must be admitted that the species so conceived has an extraordinary amplitude of foliar variation; until critical studies in the field are made, the situation will remain unsatisfactory.

Additional specimens examined. PANAMA. CHIRIQUÍ: San Félix, *Croat 33416* (MO). PANAMÁ: Cerro Campana, *Croat 14673, Duke 10742, Sullivan 434* (MO), *Méndez 19, 49* (F); Cerro Jefe, *Dwyer et al. 5048, 5049, Gentry 4938* (MO), *Gentry & Dwyer 5536* (GH, MO), *Webster & Dressler 16454* (DAV); between Cerro Jefe and Cerro Azul, *Tyson et al. 4325, Mori et al. 6543* (MO); Cerro Azul, *Dwyer 5042* (MO), *Lao & Holdridge 33* (DAV, MO), *Stimson et al. 5158* (GH, MO), *Tyson & Blum 4081* (MO); N of El Llano, *Gentry 5105* (MO); El Llano–Cartí road, 7.8–8.6 mi. from Pan-American Hwy., *Folsom 3572, Mori & Kallunki 6405* (MO).

16.3. Alchornea triplinervia (Sprengel) Muell. Arg. in DC., Prodr. 15(2): 909. 1866; Pax & K. Hoffm., Pflanzenreich IV. 147. VII (Heft 63): 227. 1914. *Antidesma triplinervium* Sprengel, Neue Entdeck. 2: 116. 1821. TYPE: Brazil. Rio de Janeiro: Serra do Mar, *Gardner 617* (neotype, G; chosen here).

This species is tentatively added to the Panamanian flora on the basis of two recent collections from a single locality. The collection of Knapp has only staminate flowers, but the small coriaceous leaves with only three or four main veins and the cauliflorous spikes match those of *Alchornea triplinervia* better than those of any of the species of *Alchornea* previously known from Panama. Another collection that may represent *A. triplinervia* is *Hammel 7252* (MO) from Cerro Sapo, Darién; this has much larger leaves and somewhat resembles some of the aberrant forms here treated as *A. latifolia*; for the present, its assignment must be regarded as dubious.

The collections from Coclé do not fit any of the varieties recognized by Pax & Hoffmann (1914: 228–230), but the variation within *A. triplinervia* has not yet been critically studied, and it would certainly be premature to assign the Panamanian material to a new variety. The typification of *Alchornea triplinervia* requires some comment, since Sprengel apparently left no type specimen. Mueller (1866: 909) designated what may be regarded as the typical element of the species as *Alchornea triplinervia* var. *genuina* forma *psilorhachis*. Since there is a good microfiche image (G, Prodromus Herb.) of *Gardner 617*, probably from the general area of the collection that was available to Sprengel, it seems appropriate to designate that as neotype.

Specimens examined. PANAMA. COCLÉ: hills N of El Valle, E slope of Cerro Gaital, 900–1,000 m, *Knapp 5351* (MO), *McPherson 11242, 11260* (MO).

16.4. Alchornea glandulosa Poeppig var. **pittieri** (Pax) Pax, Pflanzenreich IV. 147. VII(Heft 63): 235. 1914. *Alchornea pittieri* Pax, Bot. Jahrb. Syst. 33: 291. 1903. TYPE: Costa Rica: Cañas Gordas, *Pittier 11101* (isotype, US).

Since the Darién collection of Terry & Terry was reported in our original treatment, a number of additional specimens have accumulated; these confirm the widespread occurrence of *Alchornea glandulosa* in montane forests of Panama. Examination of this expanded suite of specimens now shows that the Panamanian plants represent var. *pittieri*, originally described from Costa Rica. This variety is very similar to var. *glandulosa* of the upper Amazon but differs in the smaller glandular spots at the base of the leaf (mostly 0.5 mm long or less in var. *pittieri*, reaching 1–1.5 mm long in var. *glandulosa*). At present, var. *pittieri* is known only from Costa Rica, Panama, and adjacent Colombia (Chocó).

Additional specimens examined. PANAMA. BOCAS DEL TORO: headwaters of Río Mali, between Q. Gutiérrez and La Zorra, *Kirkbride & Duke 726* (MO); along pipeline road in area of Fortuna Dam, near end of road, ca. 8°48'N, 82°15'W, 900–950 m, *McPherson 8691, 8699* (F). DARIÉN: Cana-Cuasí Trail, *Terry & Terry 1575* (MO); Cerro Pirre, *Bristan 620* (MO); Alto de Nique, Cerro Pirre massif, 1,300–1,520 m, *Gentry et al. 28647* (DAV, MO); Cerro Tacarcuna, lower montane wet forest, 1,500 m, *Gentry & Mori 13793* (DAV, F, MO, PMA). VERAGUAS: lower montane wet forest, 7 km W of Santa Fe, ca. 900 m, *Nee 11183* (MO, US); NW of Santa Fe, 2.8 km from Escuela Agrícola, Alto de Piedra, *Mori & Kallunki 6219* (MO).

16.5. Alchornea grandiflora Muell. Arg., Linnaea 34: 170. 1865; in DC., Prodr. 15(2): 907. 1866. SYNTYPES: Venezuela: *Fendler 1272* (G), *Moritz 1497a* (G). Costa Rica: *Hoffman 530* (G, not seen).

Although it has been confused with *A. glandulosa*, the relatively short thick styles and stiff glandular leaves distinguish *A. grandiflora* from *A. glandulosa* and from *A. latifolia*. Mueller (loc. cit.) reported *A. grandiflora* from Costa Rica and Venezuela, so its occurrence in Panama is not surprising.

Specimens examined. PANAMA. CHIRIQUÍ: Cerro Colorado, 1,690 m, *Croat 37195* (MO). DARIÉN: Cerro Tacarcuna, elfin forest, 1,800–1,850 m, *Gentry & Mori 13995* (DAV, F, MO).

16.6. Alchornea grandis Benth., Bot. Voy. Sulphur 164. 1844. TYPE: Colombia. Nariño: Tumaco, *Barclay & Hinds* (K, not seen).

The specimens cited below, and several collections from Chocó Province, Colombia (*Fernández 206, Killip & Cuatrecasas 39076*, both UC) furnish previously unknown characters for the staminate plant: staminate spikes mostly compound, 4–12 cm long, with 1–6 lateral axes; staminate calyx glabrous, sepals ca. 1.2 mm long; stamens 8, anthers 0.7–0.8 mm long, blunt.

Specimens examined. PANAMA. VERAGUAS: Isla de Coiba, road from Campamento Juncal to Colonia Penal, *Antonio 2417* (MO); Playa Hermosa, *Antonio 2342* (MO).

16.7. Alchornea megalophylla Muell. Arg., Flora 47: 343. 1864; in DC., Prodr. 15(2): 911. 1866. TYPE: Colombia. Antioquia: *Purdie* (K, not seen).

Tree to ca. 10 m high; trunk 1.5 dm diam.; twigs subterete, smooth, glabrous. *Leaves* with stout petioles 0.5–1.5 cm long, glabrous, plicate; stipules inconspicuous, ca. 1.5 mm long or shorter, dark, triangular, pubescent; blades becoming subcoriaceous or coriaceous, elliptic to obovate, abruptly short acuminate at apex (the acumen ca. 1–2 cm long), ca. 25–40 cm long, 7–15 cm broad, glabrous or glabrescent (minute scattered stellate hairs on underside of lamina or confined to midrib); basal foliar glands obscure or absent; major lateral veins ca. 10–15 on a side, straight, ascending, raised beneath, connected by ladderlike prominulous veinlets, contracted to an obtuse base; margins distantly crenulate-dentate (ca. 10–15 glandular teeth on a side), apex abruptly short-acuminate (acumen ca. 1–2 cm long). *Spikes* cauliflorous, pendulous, stellate-pubescent; staminate spikes not seen; pistillate spikes ca. 50–75 cm long, with ca. 20–30 flowers. *Staminate flowers* not seen. *Pistillate flowers* subsessile; calyx ca. 3.5 cm broad, 4-lobed, pubescent; ovary copiously pubescent with minute stellate hairs; styles slender, unlobed, ca. 20–25 mm long, basally connate for 2–4 mm, basally stellate, apically smooth and long-attenuate. *Capsules* reddish brown, stellate-pubescent, not seen entire; seeds elliptic, plump, pale brown, coarsely tuberculate, 9–11 mm long.

Rainforests, Panama and Colombia.

This striking species stands out from all other Panamanian taxa by virtue of its long, pendulous, cauliflorous inflorescences and its large, coriaceous, more or less oblanceolate leaves. It resembles *A. grandis* in a number of respects but differs in leaf shape and sparseness of the laminar pubescence.

Specimens examined. PANAMA. DARIÉN: La Laguna, ridge between Pucuro and Tapalisa rivers, 820–840 m, *Gentry & Mori 13560* (DAV, MO); top of Cerro Mali, 1,400 m, *Gentry & Mori 13693* (DAV, MO); Cerro Tacarcuna, *Gentry & Mori 13938* (MO); Alturas de Nique, S of El Real, 900–1,250 m, *McPherson 11614* (MO).

17. *Cleidion*

Cleidion Blume, Bijdr. Fl. Ned. Ind. 612. 1826. TYPE: *Cleidion javanicum* Blume.

Recent collections in Panama and further study of the South American species have greatly altered the picture of *Cleidion* in Panama. Largely as a result of problems encountered in the preparation of this account, the junior author has undertaken a revisionary study of the neotropical species of *Cleidion*, and until its completion, some of the conclusions expressed here must remain tentative.

In addition to the two species treated here, a recent collection in Darién by Dr. Gordon McPherson may belong to *Cleidion prealtum* Croizat (J. Arnold Arbor. 24: 167. 1943), a species otherwise known only from material collected in the basin of the upper Rio Madeira in Amazonian Brazil. The poorly known *Polyandra bracteosa* Leal (Arch. Jard. Bot. Rio de Janeiro 11: 64. 1951), described from staminate material, also from the Rio Madeira, now appears to be synonymous with *C. prealtum.*

LITERATURE

VAN DER WERFF, H. & A. R. SMITH. 1980. Pteridophytes of the State of Falcon, Venezuela. Opera Bot. 56: 1–34.

KEY TO THE SPECIES OF *CLEIDION* IN PANAMA

1a. Fruiting spikes slender, (5–)8–18 cm long; capsules 3–6, remote, 5–8 mm in diameter; leaves up to 13 cm long; leaf vein axils barbate beneath; veins 7 or 8 on a side; staminate thyrses ca. 1 cm long .... 1. *C. membranaceum*

1b. Fruiting spikes thick, 2–3 cm long; capsules 1–3, 13–15 mm in diameter; leaves over 15 cm long; leaf vein axils not barbate beneath; veins 8–10 on a side; staminate thyrses 5–9 cm long .... 2. *C. castaneifolium*

17.1. **Cleidion membranaceum** Pax & K. Hoffm. in Engler, Pflanzenreich IV. 147. XIV(Heft 68): 23. 1919. TYPE: Venezuela. Lara: around Palmosola, in forest along Río Aroa, near sea level, 26–28 June 1913, *Pittier 6375* (US, photo F neg. 44609).

Cleidion woodsonianum Croizat, J. Arnold Arbor. 24: 167. 1943. TYPE: Panama. Panamá: vicinity of Salamanca Hydrographic Station, Río Pequení, ca. 80 m, *Woodson et al. 1587* (holotype, A; isotypes, F, F neg. 62417, MO, F neg. 62356, NY).

There appear to be no differences between the Panamanian plants and the Venezuelan collections of *Cleidion membranaceum.* The three known Venezuelan collections are all from a restricted area near the junction of the provinces of Falcón, Yaracuy, and Lara. No substrate is indicated on the labels of these collections, but it is known that much of this area is underlain by limestone (van der Werff & Smith, 1980), which is also true of the Panamanian collections. The recent disjunct collection from Peru strengthens the probability that this species is restricted to limestone, and that this accounts for the peculiar disjunctions in its range.

Further study may show that *Cleidion membranaceum* is synonymous with *C. tricoccum* (Casar.) Baillon, of eastern Brazil from Bahia to São Paulo, which has leaves similar in shape and size to those of the Panamanian plant, similar long, nearly filiform pistillate inflorescences, and similar capsules.

Additional specimens examined. PANAMA. PANAMÁ: Majé, second growth on limestone hillsides, along Chocó Indian trail, ca. 5 mi. up from village of Majé, *Foster & Kennedy 2021* (MICH, MO, PMA). PERU. HUÁNUCO. LEONCIO PRADO: Distrito Rupa Rupa, Tingo María, ca. 9°18′S, 75°59′W, limestone hills opposite airport, *Plowman et al. 11246* (DAV, F, K). VENEZUELA. FALCÓN: Parque Nacional Quebrada de la Cueva El Toro, steep wet valley along river, 10°50′N, 69°07′W, *Liesner et al. 7722* (F, MO). YARACUY-FALCÓN: Reserva Forestal "Rio Tocuyo," a 4 km del Campto. "Canelon," via Tucacas, *Blanco 895* (MO).

17.2. **Cleidion castaneifolium** Muell. Arg., Linnaea 34: 184. 1865. TYPE: Peru: *Pavon* (holotype, G, F neg. 7159).

Alchornea oblongifolia Standley, Carnegie Inst. Wash. Publ. 461(Botany of the Maya Area 4): 66. 1935. *Cleidion oblongifolium* (Standley) Croizat, J. Arnold Arbor. 24: 166. 1943. TYPE: Guatemala. Petén:

Camp 35, boundary with Belize, 750 m, *Schipp S-279* (holotype, F, F neg. 52594).

Trees to 10 m high; dioecious; twigs glabrous. *Leaves* with petioles 1.5–4 cm long, glabrous or sparsely pubescent with short, white, appressed hairs, swollen toward apex; stipules not evident; blades membranous or thinly chartaceous, elliptic, abruptly caudate-acuminate at tip, acute or cuneate at the somewhat inequilateral base, 15–26 cm long, 6.5–9.5 cm broad, minutely pustulate, glabrous, the veins 8–10 on a side; margins shallowly dentate, the teeth callose, 15–28 on a side. *Inflorescences* unisexual, axillary; pistillate racemes to 16 cm long, widely divergent from the stem, the rachis glabrous, or puberulent toward the apex, with ca. 3 flowers occurring singly (3 fruits on only complete pistillate raceme seen); staminate thyrses 5–9 cm long, with 7–12 flowers crowded at each of the 20–50 nodes, the rachis densely puberulent. *Staminate flowers* on pedicels to 1 mm long; calyx lobes cucullate, reflexed, 1.5–2 mm long, glabrous, ovate, the apex acute or acuminate; stamens ca. 60–80. *Pistillate flowers* not seen; bracts narrowly lanceolate, rigid, divergent, ca. 2 mm long, puberulent; fruiting pedicels 10–12 mm long, slightly clavate, puberulous, jointed; calyx lobes (in fruit) 3–5, somewhat reflexed, deltate, 2–3 mm long, acute, canescent below, ciliate on the margins; styles (persistent on mature fruits) 7–12 mm long, deeply bifid, densely strigose. *Capsules* 3-locular (of which often only 2 fully developed), deeply lobed, dorsally carinate, ca. 1 cm high, 14–18 mm diam., densely puberulent, drying black; columella 6–8 mm long, trigonous, narrowly winged, the seed scars elongate, conspicuous; seeds globose, smooth, not beaked, ca. 9 mm long, mottled light and dark brown.

Rainforests, southern Mexico to Panama, Ecuador.

The Panamanian collections of *Cleidion castaneifolium* match perfectly the type photograph as well as the original description except for the curious statement in the latter that the capsule is six-lobed. Since all other species of *Cleidion* have three-lobed capsules (as do the Panamanian collections), and since the one capsule on the type photo appears crushed and misshapen (and thus made to appear six-lobed), it seems that Mueller was merely careless in his description. Since these collections are in perfect agreement with all other distinguishing characteristics of this species (large elliptic-ovate leaves, petioles 3–5 cm long and glabrous except for the subpuberulous tips, long undivided pistillate racemes, and large capsules with dorsally carinate lobes), their identification seems certain. The only other Panamanian species of the genus, *C. membranaceum*, and the Peruvian *C. amazonicum* Pax both differ from *C. castaneifolium* in their smaller leaves, much shorter petioles (2–5 mm long), and smaller capsules. *Cleidion prealtum* Croizat of Amazonian Brazil differs from all of these in its obovate and coriaceous leaves.

Cleidion castaneifolium was described from "Peru," but a possible isotype sheet at F (*Ruiz & Pavón s.n.*) is labeled as having been collected at Guayaquil, Ecuador (another Ruiz & Pavón specimen at F has no locality data). The species is not definitely known from Peru, but there are two modern collections from between Santo Domingo and Quinindé in Esmeraldas Province, Ecuador (*Acosta Solís 13649, Little 6196*, both at F, both distributed as *Alchornea*).

There appear to be no salient differences separating *Cleidion castaneifolium* from Panama and South America from the Mexican and Central American populations that have long been referred to *C. oblongifolium*. In addition to the common characters given in the key, these populations all frequently exhibit a characteristic purplish cast to the leaves.

Specimens examined. PANAMA. DARIÉN: Serranía de Pirre, on the NW slope of the mountain range dominated by Cerro Pirre, along Q. Perecingo (Parasénico), a tributary to Río Pirre, ca. 10 air km S of El Real, 8°03'N, 77°43'W, *Reveal & Duke 4875* (MARY, MO); 2–3 mi. SE of Pijibasal on Río Perasénico, ca. 9–10 mi. S of El Real, *Hartman 12038* (F, MO).

18. *Ricinus*

Ricinus L., Sp. Pl. 1007. 1753. TYPE: *Ricinus communis* L.

19. *Acalypha*

Acalypha L., Sp. Pl. 1003. 1753. LECTOTYPE: *Acalypha virginica* L. (chosen by Small in Britton & Brown, Ill. Fl. N. U.S. ed. 2, 2: 457. 1913).

19.10. Acalypha cuneata Poeppig in Poeppig & Endl., Nov. Gen. Sp. Pl. 3: 22. 1841. TYPE: Peru. Maynas: Yurimaguas, *Poeppig* (not seen).

Acalypha obovata Benth. in Seemann, Bot. Voy. Sulphur 163. 1844. TYPE: Ecuador. Esmeraldas: Atacames, *Hinds* (BM, not seen). *A. cuneata* Poeppig var. *obovata* (Benth.) Muell. Arg. in DC., Prodr. 15(2): 816. 1866.

Shrub or small tree 2–5(–8) m high; monoecious; stems nearly glabrous. *Leaves* with petioles 1–7 cm long, glabrous; stipules lanceolate, 4–7 mm long, strongly keeled, caducous; blades obovate or obovate-oblong, cuspidate-acuminate at the tip (the acumen 1.5–3 cm long), acute at the base, 15–30 cm long, 5–13 cm broad, 2–3.2 times as long as broad, glabrous, pinnately veined, the secondary veins 11–15 per side, arcuate, prominent above and below, connected by a prominulous reticulum; margins shallowly crenate-denticulate. *Inflorescences* axillary, spicate, unisexual; staminate spikes to 15 cm long, densely flowered, densely puberulent, solitary and pedunculate or 2–4 and sessile on a slender rachis; pistillate spikes 7–15 cm long, 4–7 mm thick, loosely flowered with 15–50 bracts, the rachis glabrous to densely puberulent. *Pistillate flowers* solitary; bracts ± reniform, 3–4 mm long, 6–7 mm wide, inconspicuously 8–10-lobed, each lobe with a short tuft of bristles, the bracts otherwise glabrous or lightly short-strigose; calyx lobes obscure; ovary densely hispid, the styles free, lightly strigose, pinnatifid along entire length into 8–12 narrow segments. *Capsules* 4–5 mm diam., hispid, verrucose; seeds obovoid-ellipsoid, 3–3.5 mm long, ca. 2.5 mm diam., smooth, brown, the caruncle nearly obsolete.

This is a widespread species of lowland rainforests in northern South America, and its discovery in eastern Panama is not surprising. It is easily recognized by the long-petiolate obovate leaves with pinnate venation and axillary pistillate inflorescences. In order to accommodate this species in the *Flora of Panama* treatment, the key on p. 300 must be revised as follows:

ee. Leaves pinnately veined; pistillate bracts subentire or shallowly dentate.
  e′. Spikes mostly bisexual, 3–8 cm long, with 1 or 2 pistillate bracts at base, these subtending 2 or 3 flowers .... *A. diversifolia*
  ee′. Spikes unisexual, to 15 cm long, the pistillate ones toward the apex of the branch, the staminate below; pistillate bracts subtending a single flower .... *A. cuneata*

Specimen examined. PANAMA. DARIÉN: S of El Real on trail to Cerro Pirre, disturbed forest along Cerro Perrecénega, ca. 8°00′N, 77°45′W, ca. 50 m, *McPherson 6977* (F).

20. *Plukenetia*

Plukenetia L., Sp. Pl. 1192. 1753. TYPE: *Plukenetia volubilis* L.

The discovery of a second species of *Plukenetia* in Panama makes it necessary to provide the following key.

KEY TO THE SPECIES OF *PLUKENETIA* IN PANAMA

1a. Leaves palmately veined; stylar column cylindrical, slender, 10–25 mm long; capsules to 3.5 mm broad .... 1. *P. volubilis*
1b. Leaves pinnately veined; stylar column obovoid, to 2 mm long; capsules to 1.5 mm broad .... 2. *P. penninervia*

20.1. Plukenetia volubilis L., Sp. Pl. 1192. 1753. TYPE: West Indies, *Plumier* (perhaps at BM).

This species is more widespread in eastern Panama than was indicated by the single collection cited in the original treatment. These new collections also confirm the identity of the Panamanian species with *Plukenetia volubilis* of the Antilles and South America. Recent collections have also extended the range to Costa Rica (*Gómez et al. 19184*, F), Nicaragua (*White 5323*, F), and Veracruz, Mexico (*Calzada 1034*, F).

Additional specimens examined. PANAMA. COLÓN: upstream from bridge over Río Guanche, 0–100 m, *Antonio 3351* (F, MO); near Portobelo, *Croat 12969* (MO); Portobelo, along stream running into Río Buena Ventura, S of Portobelo, 0–10 m, *Foster 2060* (F, MO); along Río Guanche, 6 km S of Portobelo, 0–10 m, *Nee & Gentry 8686* (MO). DARIÉN: Cerro Pirre, valley between Pirre and next most southerly peak, *Folsom 4426* (F, MO). PANAMÁ: 4–5 hours walk upriver from Tortí Arriba, 200–300 m, *Folsom et al. 6845* (F, MO).

20.2. Plukenetia penninervia Muell. Arg., Linnaea 34: 158. 1864; in DC., Prodr. 15(2): 770. 1866. TYPE: Venezuela, near Biscaina, *Fendler 2412* (holotype, G, not seen; photo F neg. no. 7110).

Plukenetia angustifolia Standley, Publ. Field Columbian Mus., Bot. Ser. 4: 314. 1929. TYPE: Honduras. Atlántida: Lancetilla Valley, 8 Mar. 1928, *Standley 56708* (holotype, F, F neg. 52742).

Liana; twigs spreading-puberulent, glabrescent. *Leaves* with petioles ca. 1 cm long, puberulent; stipules brownish, glabrous, rigid, deltate-lanceolate, 1–1.7 mm long; blades chartaceous-oblong, oblong-elliptic, or oblong-lanceolate, acute to acuminate at tip, abruptly acuminate-truncate at base, 5–10 cm long, 2–4.5 cm broad, glabrous and shining above, glabrate or with a few hairs along the nerves and paler below, with 2 prominent glands above at the base, often with 1–3 pairs of smaller ones in a row above them, pinnately veined, the midrib and secondary veins (6–11 on a side) prominent below; margins shallowly crenate-denticulate. *Inflorescences* axillary, bisexual or staminate, 0.5–3 cm long; pistillate flowers solitary at lower nodes of bisexual inflorescences, the staminate flowers few at the distal nodes. *Staminate flowers* with pedicels short-pilose, 4–7 mm long; calyx segments generally 3, obovate, acute, 1.2–1.6 mm long; receptacle cylindrical, 1.6–1.8 mm high; disk obsolete; stamens ca. 18–25, inserted spirally on the receptacle, the filaments ca. 0.1 mm long, the anthers 0.1–0.2 mm long. *Pistillate flowers* with pedicels becoming 12–20 mm long, these narrowly clavate, strigose when young, glabrate to sparsely short-pubescent at maturity; calyx lobes lanceolate, 1–1.2 mm long, ca. 0.5 mm broad, strigose in a band along the center; ovary of 4 carinate carpels, strigose on the keels, otherwise glabrous, the stylar column to 2 mm long, obovoid, the stigmas thick, unlobed. *Capsules* deeply 4-lobed, oblate, to ca. 1 cm high, 1.5 cm broad, the cocci thick and rigid; seeds subglobose, only slightly compressed laterally, reticulate-venose, brownish mottled, ca. 5 mm long, 3–4 mm thick.

Lowland evergreen rainforests, Mexico (Oaxaca, Yucatán Peninsula) to Colombia and Northern Brazil (Pará); here reported from Panama for the first time.

The discovery of *Plukenetia penninervia* in Panama is not surprising, although it is still unknown in Costa Rica, and the reason for its apparent scarcity in southern Central America is not clear. The populations from northern Central America, where the species is much better known, were described by Standley as *P. angustifolia*, but no salient differences between these plants and those of South America are apparent.

Specimens examined. PANAMA. COLÓN: Santa Rita Ridge, in ravine bottom near Agua Clara rainfall station, 400–500 m, *Foster & Morton 2222* (F); Santa Rita Ridge, ca. 9°20′N, 79°45′W, ca. 500 m, *McPherson 8461* (F). PANAMÁ: 1–2 mi. S of Pan American Highway, 3.0 mi. E of Cañazas checkpoint, foothills of Serranía de Cañazas, 8°52′N, 78°15′W, 0–50 m, *Knapp 3887* (F, MO).

21. *Acidoton*

Acidoton Sw., Prodr. 84. 1788. TYPE: *Acidoton urens* Sw.

21.1 Acidoton nicaraguensis (Hemsley) Webster, Ann. Missouri Bot. Gard. 54: 191. 1967. *Cleidion ?nicaraguensis* Hemsley, Biol. Cent.-Amer., Bot. 3: 130. 1883. TYPE: Nicaragua. Chontales: *Tate 352, 455* (syntypes, presumably K, not seen).

Additional specimens examined. PANAMA. COLÓN: Santa Rita, *Correa & Dressler 607* (MO); Santa Rita Ridge Rd., 20 km from Transisthmian Hwy., 9°24′N, 79°39′W, *Sytsma 1117* (F, MO). PANAMÁ: along the El Llano–Cartí rd., ca. 10 mi. N of Pan Am Hwy., 500 m, *Gentry et al. 8878* (MO). SAN BLAS: El Llano–Cartí road, km 26.5, 9°19′N, 78°55′W, 300–400 m, *de Nevers et al. 5292* (F); Nusagandí, along trail to Quebrada de Nusagandí, *van der Werff 7029* (F).

22. *Tragia*

Tragia L., Sp. Pl. 980. 1753. LECTOTYPE: *Tragia volubilis* L. (chosen by Small in Britton & Brown, Ill. Fl. N. U.S. ed. 2, 2: 458. 1913).

The discovery of three additional species in Panama makes it necessary to provide a key to the Panamanian species.

LITERATURE

PAX, F. & K. HOFFMANN. 1919. Euphorbiaceae—Acalypheae—Plukenetiinae. *In:* A. Engler, Das Pflanzenreich IV. 147. IX (Heft 68): 1–108 (*Tragia*, pp. 32–101).

KEY TO THE SPECIES OF *TRAGIA* IN PANAMA

1a. Leaf blades 12–25 cm long, 11–18 cm broad, often 3-lobed; stamens ca. 40 .... 1. *T. bailloniana*
1b. Leaf blades 6–16 cm long, less than 10 cm broad, unlobed; stamens 2–12.
    2a. Inflorescence bifurcate, the pistillate flowers 5–10 on lower branch; stamens 8–12 .... 2. *T. fendleri*
    2b. Inflorescence racemose, not bifurcate; pistillate flowers solitary at basal node; stamens 2 or 3.
        3a. Pistillate flower long-pedicellate; styles connate .... 3. *T. volubilis*
        3b. Pistillate flower subsessile; styles free .... 4. *T. correae*

22.1. Tragia bailloniana Muell. Arg., Linnaea 34: 178. 1865; in DC., Prodr. 15(2): 927. 1866. TYPE: Mexico. Tabasco: Teapa, *Linden* (P, not seen). *Zuckertia cordata* Baill., Etud. Euphorb. 496, pl. 4, 1858, not *Tragia cordata* Michx., 1803.

Twining vine; stamens and foliage ± densely covered with stinging hairs. *Leaves* with petioles 8–14 cm long; stipules ovate-lanceolate, acuminate, greenish, 7–10 mm long; blades membranous, broadly ovate, unlobed, with a single lateral lobe, or shallowly 3-lobed, acuminate or caudate at tip, deeply cordate at base, 12–25 cm long, 11–18 cm wide, sparsely beset above and below with stinging hairs, usually 7-veined at the base, the margins remotely denticulate. *Inflorescences* opposite the leaves, bifurcate; peduncle 3–10 cm long; staminate branch to 20 cm long, many-flowered; pistillate branch 15–25 cm long, 7–15-flowered. *Staminate flowers* 1–3 per bract; bracts foliaceous, ovate-lanceolate, acuminate, 3–5 mm long, reflexed; pedicels 8–10 mm long, divergent, glabrate; sepals 5, linear-lanceolate, acuminate, ca. 6 mm long; stamens ca. 40; buds pyriform, acute. *Pistillate flowers* solitary in the axil of each bract; bracts similar to those of the staminate flowers; pedicels 1–4 mm long, hirsute; sepals deltate to lanceolate, acute to acuminate, 4–5 mm long; margins ciliate with long, stiff hairs; ovary densely hirsute with stiff hairs ca. 1 mm long; styles black, 6–8 mm long, fused ca. ⅔ their length, the style branches slightly spreading. *Capsules* deeply 3-lobed (one lobe sometimes abortive), ca. 15 mm diam., ca. 8 mm high, densely hirsute with stiff hairs; columella 6–7 mm long, with 3 prominent, narrow wings at tip; seeds nearly globose, ca. 6 mm diam., smooth, with 8 or 9 light longitudinal striations.

Forests, southern Mexico to western Panama.

This distinctive species is the only member of *Tragia* section *Zuckertia* (Baill.) Muell. Arg., distinguished from all other American species of the genus by its numerous stamens (ca. 40 vs. 2 or 3 or rarely up to 20) and its large, usually lobed leaves. The Panamanian collection represents a considerable range extension, for the species had previously been known only from southern Mexico (Veracruz, Chiapas, Yucatán Peninsula) to Honduras. Earlier reports of *Tragia bailloniana* from Costa Rica (Standley, 1937: 622) are erroneously based on collections of *Dalechampia shankii* (see discussion in Huft, 1984); however, several recent collections establish the presence of the former there.

Specimens examined. COSTA RICA. ALAJUELA: along upper Río Sarapiquí, near Cariblanco and along the road to Colonia Virgen del Socorro, 10°18'N, 84°10'W, ca. 800 m, *Burger et al. 11850* (F); lower NE slope of Arenal Volcano, 10°29'N, 84°42'W, 500 m, *Lent 2947* (F). LIMÓN: hills 2 airline km SSE of Islas Buena Vista in the Río Colorado, 14 airline km SW of Barro del Colorado; 83°40'W, 10°40'N, 10–120 m, *Davidse & Herrera 31023* (F, MO); southwesternmost ridge of Cerro Coronel, NW-facing slope, just S of the Río Colorado, 10°40'30"N, 83°39'30"W, 10–80 m, *Davidse & Herrera 31388* (F, MO); Cerro Coronel, E of Laguna Danto; 10°41'N, 83°38'W, 20–170 m, *Stevens 24383* (F, MO). PANAMA. CHIRIQUÍ: Fortuna Dam site, 1,400–1,600 m, *Folsom et al. 5612* (MO).

22.2. Tragia fendleri Muell. Arg., Linnaea 34: 178. 1865; in DC., Prodr. 15(2): 928. 1866. TYPE: Venezuela: Biscaina, *Fendler 1208* (G).

Twining vine; stems and petioles hirsutulous or strigose with mostly nonstinging hairs. *Leaves* with petioles 4–11 cm long; stipules lanceolate, 5 mm long or more; blades thinly chartaceous, oblong- or elliptic-obovate, rather abruptly short-acuminate at tip, distinctly cordate at base with open to closed sinus, mostly 8–16 cm long, 4–7 cm broad, sparsely hispidulous on both faces with stinging and nonstinging hairs, mostly 5-nerved at base; the margins bluntly and coarsely crenate (teeth 15–25 on a side). *Inflorescences* opposite the leaves, becoming ca. 10–15 cm long, distinctly bifurcate and protogynous, the lower pistillate branch with 5–10 flowers; pistillate bracts entire, 3–4 mm long, the staminate ones entire, 1.5–2 mm long. *Staminate flowers* with minutely hispidulous pedicels ca. 1.5–2 mm long, articulate near the base (stumps remaining after dehiscence of flower much shorter than subtending bract); sepals 3 or 4, obovate, acute, strigose without, 1.5–3 mm long, 1.8–2.2 mm broad; disk glands 5, erect, cylindric, thicker than filaments, 0.5–0.8 mm high; stamens 8–12; filaments free; anthers 1–1.2 mm long. *Pistillate flowers* with hispidulous pedicels up to 2.5 mm long in fruit; sepals 6, lanceolate, asymmetric, green, reflexed in fruit, becoming 3.5–6 mm long, 1–1.5 mm broad; ovary densely hispidulous with stinging hairs; styles basally connate or nearly free, 2–2.5 mm long, distinctly papillate. *Capsules* copiously hispid with stinging hairs, cocci ca. 8 mm long; columella 2.4–2.7 mm long; seeds globose, mottled brownish and gray, 3.6–3.7 mm across.

The single specimen of this species, previously unrecorded from Panama, is in poor condition and without flowers, so there is some doubt regarding its assignment. The Bristan collection matches a photograph of the type specimen from Venezuela, although the basal leaf sinus is not as open in the Panamanian plant. There is also some resemblance to *T. japurensis* Muell. Arg., described from Amazonian Brazil. However, it seems probable that the Brazilian species is synonymous with the one from Venezuela; at least, no convincing differences are given by Pax & Hoffmann (1919: 36).

Specimen examined. PANAMA. DARIÉN: Río Uruceca, *Bristan 1444* (MO).

22.4. Tragia correae Huft, sp. nov. TYPE: Panama. Panamá: Picada da Estrada Panamá–San Blas entre 320–420 m, 9.1.1973, *Sucre, Braga, Dressler & Correa 9832* (holotype, RB-165572, F neg. 62359).

Caulis volubilis lignosus; ramunculi rubelli dense pilosi. Folia alterna elliptica-oblonga 6–12 cm longa septemnervia, infra dense pilosa supra sparsia, basi cordata, margine remote denticulata. Inflorescentia racemosa unico flore femineo infime, ceteris floribus (20–25) masculis; flores masculi calyce trilobo, staminibus 3, filamentis crassis, antheris extrorsis; flores feminei calyce 5-lobo, ovario dense hispiduloso, stylis papillatis.

Twining woody vine; twigs reddish, densely pilose, tardily glabrate, the older twigs with loose, exfoliating bark. *Leaves* with petioles 0.5–4 cm long, densely pilose; stipules deltate-lanceolate, acute, 6–10 mm long, pilose below, glabrous above; blades membranous, elliptic-oblong, acuminate at tip, cordate at base, 6–12 cm long, 3–4.5 cm broad, 2.2–2.7 times as long as broad, sparsely pilose above, more densely so below, usually 7-nerved at base; margins remotely denticulate (teeth 18–22 on a side). *Inflorescences* opposite the leaves, racemose, ca. 3 cm long (immature), with a single basal pistillate flower, the remaining nodes (ca. 20–25) with staminate flowers; bracts trifid; bracts entire. *Staminate flowers* on short, hispidulous pedicels; calyx lobes 3, obovate, acute, ca. 1.3 mm long, ca. 1.2 mm broad, hispidulous without, cucullate; stamens 3, the filaments thick and fleshy, free, ca. 0.8 mm long; anthers elliptic, 0.2–0.3 mm long, extrorse. *Pistillate flowers* with pilose pedicels ca. 2 mm long; calyx lobes 5, lanceolate, acute, ca. 3 mm long; ovary densely hispidulous with stinging hairs, the styles free to the base, spreading, papillate, ca. 2 mm long. *Mature capsules* not seen.

In aspect *Tragia correae* resembles the species that Pax & Hoffmann (1919) placed in section *Bia*, particularly such species as *T. fendleri*, *T. japurensis* Muell. Arg., and *T. fallax* Muell. Arg. The new species is excluded from that affinity, however, by its racemose rather than bifurcate inflorescences and staminate flowers with three (vs. 8–20) stamens. The entire sepals and extrorse anthers dictate its placement in section *Tragia* (section *Eutragia* Muell. Arg. of Pax & Hoffmann, 1919). This species bears some similarity to *T. volubilis* but differs by a much woodier habit, densely pilose leaves, and persistently sessile pistillate flowers.

It is a pleasure to name this distinctive new species for Profesora Mireya Correa of the University of Panama. *Tragia correae* is known only from the type collection. Dra. Correa has kindly searched for a duplicate at the herbarium of the University of Panama (PMA), but so far, unfortunately, none has been found.

23. *Dalechampia*

Dalechampia L., Sp. Pl. 1054. 1753. TYPE: *Dalechampia scandens* L.

LITERATURE

ARMBRUSTER, W. S. 1984. Two new species of *Dalechampia* (Euphorbiaceae) from Mesoamerica. Syst. Bot. 9: 272–278.

——— & A. HERZIG. 1984. Partitioning and sharing of pollinators by four sympatric species of *Dalechampia* (Euphorbiaceae) in Panama. Ann. Missouri Bot. Gard. 71: 1–16.

HUFT, M. J. 1984. A new combination in *Dalechampia* (Euphorbiaceae). Ann. Missouri Bot. Gard. 71: 341.

PAX, F. & K. HOFFMANN. 1919. Euphorbiaceae—Dalechampieae. *In:* A. Engler (editor), Das Pflanzenreich IV. 147. XII (Heft 68): 1–59.

WEBSTER, G. L. & B. WEBSTER. 1972. The morphology and relationships of *Dalechampia scandens* (Euphorbiaceae). Amer. J. Bot. 59: 573–586.

As a result of additional collecting in Panama, the species of *Dalechampia* are now considerably better understood, and the number of species has increased from five to seven, necessitating a new key. The order of species has been modified to reflect better their systematic relationships (Webster & Armbruster, unpubl. synopsis).

KEY TO THE SPECIES OF *DALECHAMPIA* IN PANAMA

1a. Leaves lobed or unlobed, never compound.

  2a. Stem tips and inflorescences densely golden-hirsute; leaves unlobed to 3-lobed, mostly 15–30 cm long, with broad, open sinus at base; stamens 60–70 (involucral bracts narrowly spathulate and apically trifid, dull yellowish; bracts of staminate involucel free) .... 1. *D. shankii*

  2b. Stem tips and inflorescences with appressed to spreading hairs, these never golden; leaves mostly smaller, variously shaped; stamens 15–45.

    3a. Bracts of staminate involucel free and disarticulating separately; bractlets within staminate involucel apically lacerate; leaves unlobed (occasionally with 1 or 2 small lateral teeth); involucral bracts creamy or pinkish, marginally lacerate; seeds more or less rugulose.

      4a. Stigma asymmetric, slightly dilated, not over 1.2 mm across; involucral bracts creamy or white with greenish veins; hairs of stem spreading at least in part; leaves persistently pubescent beneath, attenuate-acuminate, basal sinus narrow or lobes overlapping .... 2. *D. canescens* subsp. *friedrichsthalii*

      4b. Stigma peltate, 1–3.5 mm across; involucral bracts pink or purple to white with pink veins (rarely white with greenish veins); hairs of stem appressed; leaves glabrate beneath, cuspidate, with broad open sinus .... 3. *D. dioscoreifolia*

    3b. Bracts of staminate involucel more or less connate into a cup, not disarticulating separately; leaves lobed, at least in part; involucral bracts creamy or white, with entire denticulate margins; seeds smooth.

5a. Unlobed leaves often present with lobed leaves; involucral bracts merely 3-dentate at apex, 7–9-nerved, 3–6.5 cm long; bractlets within staminate involucel apically lacerate .... 5. *D. tiliifolia*

5b. Unlobed leaves rare or absent, the leaves all 3- or 5-lobed; involucral bracts 3-lobed at least to the middle, 5-nerved, 1.5–3 cm long; bractlets within staminate involucel entire, laminar .... 7. *D. scandens*

1b. Leaves compound, 3-foliolate (rarely 5-foliolate).

6a. Young stems and lower leaf surfaces spreading-hirsute; leaflet tips cuspidate-acuminate; involucral bracts white; staminate involucel of 4 separate bracts, staminate bractlets lacerate; central fruiting pedicel ca. 3 cm long .... 4. *D. websteri*

6b. Young stems retrorsely pubescent; leaf blades glabrate; leaflet tips acute to evenly acuminate; involucral bracts green; staminate involucel 2-lipped (bracts confluent); staminate bractlets truncate, laminar; central fruiting pedicel ca. 1 cm long .... 6. *D. cissifolia* subsp. *panamensis*

23.1. Dalechampia shankii (A. Molina) Huft, Ann. Missouri Bot. Gard. 71: 341. 1984. *Tragia shankii* A. Molina, Ceiba 11: 68. 1965. TYPE: Costa Rica. Limón: Río Reventazón, 15 m, 23 Oct. 1951, *Shank & Molina 4427* (holotype, F).

This species, originally described from Costa Rica, has now been recorded from Nicaragua to Colombia. It may easily be distinguished from our other Panamanian species by its large and distinctive golden hairs, as well as yellowish, narrowly spathulate, trifid involucral bracts. The free bracts of the staminate involucel and the lacerate staminate bractlets indicate that the species belongs to section *Dioscoreifoliae* in the emended sense (Webster & Armbruster, ined.), along with the two following Panamanian taxa. The collections of Barry Hammel show that *D. shankii* is polymorphic in leaf shape, since leaf blades from the single locality vary from unlobed to having one lateral lobe to three-lobed. Additional collections from Costa Rica, Panama, and Colombia are cited by Huft (1984).

Specimens examined. PANAMA. COCLÉ: near sawmill, 16.7 km N of turnoff to Coclesito from Llano Grande, 700 ft., *Hammel 1811, 1812, 1813* (MO); 12 mi. from Llano Grande, 200 m, *Churchill et al. 4148* (F, MO).

23.2. Dalechampia canescens Kunth subsp. **friedrichsthalii** (Muell. Arg.) Webster & Huft, stat. nov. *Dalechampia friedrichsthalii* Muell. Arg., Flora 55: 45. 1872. TYPE: Nicaragua. Río San Juan: *Friedrichsthal 683* (not seen; locality erroneously cited by Mueller as Guatemala).

Several additional collections of this plant have now been made in Panama.

Specimens examined. PANAMA. COLÓN: along Río Mendosa, 8 km NW of Gamboa *Nee & Smith 11370* (MO); Río Fato, *Pittier 3866* (GH, NY, US); Río Boquerón, 6–8 km upstream from Peluca Hydro Station, *Siri 1005* (DAV). SAN BLAS: Puerto Obaldía, sea level, *Knapp & Mallet 4627* (DAV, MO).

It now appears that *Dalechampia friedrichsthalii* is excessively close morphologically to *D. canescens* Kunth (Nov. Gen. Sp. 2: 98. 1817). The collection from San Blas in particular seems somewhat intermediate, and it makes more sense biologically to treat the two taxa as allopatrically replacing subspecies of a single species. The two subspecies may be keyed out as follows:

1a. Leaf blades mostly attenuate-acuminate, sparsely to moderately pubescent beneath (hairs mostly 0.1–0.2 mm long, not overlapping in sinuses between veinlets) .... subsp. *friedrichsthalii*

1b. Leaf blades mostly abruptly cuspidate, softly pubescent beneath (many hairs over 0.2 mm long, overlapping in sinuses between veinlets) .... subsp. *canescens*

The Colombian taxon, subsp. *canescens*, was described from Tolima Province (Mariquita) and cited from Nariño by Pax & Hoffmann (1919: 52). The additional collections cited below indicate that subsp. *canescens* is widely distributed in the lowlands and foothills of the western Andean region in Colombia.

Specimens examined. COLOMBIA. CALDAS: Quebrada Yeguas, 20 km N of Honda, 300 m, *Gentry et al. 18167* (DAV, MO). CAUCA: Río Patía, 590 m, *Plowman & Vaughan 5354* (DAV). SANTANDER: 29 km W of San Vicente de Chucurí, 200 m, *Gentry & Aguirre 15429* (MO).

23.3. Dalechampia dioscoreifolia Poeppig in Poeppig & Endl., Nov. Gen. Sp. Pl. 3: 20. 1841. TYPE: Peru. Maynas: *Poeppig 2163* (W).

One additional locality merits noting: PANAMA. DARIÉN: near Río Canglón, *Duke & Bristan 378* (MO).

An unusual specimen from Playón Chico, San

Blas (*Gentry 6365*, MO) appears to be intermediate between *D. dioscoreifolia* and *D. canescens* subsp. *friedrichsthalii*, having the broad stigma of the former and the pubescent attenuate-acuminate leaves of the latter.

23.4. Dalechampia websteri Armbruster, Syst. Bot. 9: 272. 1984. TYPE: Costa Rica. Heredia: La Selva, 3 km SE of Puerto Viejo, *Armbruster & Herzig 79-207* (DAV).

This species, recently described from Costa Rica, has been identified from Panama on the basis of the single record that was attributed (with doubt) to *D. cissifolia* in our treatment of 1968.

Specimen examined. PANAMA. BOCAS DEL TORO: Chiriquicito, *Lewis et al. 2123* (MO).

23.5. Dalechampia cissifolia Poeppig subsp. **panamensis** (Pax & K. Hoffm.) Webster, Ann. Missouri Bot. Gard. 54: 193. 1967. *D. panamensis* Pax & K. Hoffm., Pflanzenreich IV. 147. XII (Heft 68): 19. 1919. SYNTYPES: Costa Rica: *Tonduz 8089*, Guatemala: Cubilgüitz, *Tuerckheim II. 244*, *7978*, Mexico. Chiapas: Escuintla, *Donnell Smith 2079*. Panama: *Oersted; Pittier 2311*, *3775*.

This species still requires additional study. A variant with simple, unlobed leaves mixed with the compound ones, to which the name *Dalechampia heteromorpha* Pax & K. Hoffm. has been applied, occurs in Panama and throughout Central America but does not appear to be specifically distinct from the South American subsp. *cissifolia*.

There is one new provincial record for *D. cissifolia* subsp. *panamensis*.

Additional specimen examined. PANAMA. BOCAS DEL TORO: 10 mi. NW of Almirante, *D'Arcy 11204A* (MO).

24. *Omphalea*

Omphalea L., Syst. Nat. ed. 10. 1264. 1759. Nomen conserv. TYPE: *Omphalea triandra* L. (typ. conserv.).

24.1. Omphalea diandra L., Sp. Pl. ed. 2. 1377. 1763. TYPE: Jamaica, *Browne* (presumably BM, not seen).

Additional specimen examined. PANAMA. CHIRIQUÍ: Burica Peninsula, 2–4 mi. SW of Puerto Armuelles, *Croat 22045*, *Liesner 409* (MO).

25. *Pera*

Pera Mutis, Kongl. Vetensk. Akad. Nya. Handl. 5: 299, tab. 8. 1784. TYPE: *Pera arborea* Mutis.

Subfamily III. CROTONOIDEAE Pax

26. *Tetrorchidium*

Tetrorchidium Poeppig in Poeppig & Endl., Gen. Nov. Sp. Pl. 3: 23, tab. 227. 1841. TYPE: *Tetrorchidium rubrivenium* Poeppig.

The discovery of two distinctive new species in western Panama makes it necessary to provide a revised key. New province records are also recorded.

KEY TO THE SPECIES OF *TETRORCHIDIUM* IN PANAMA

1a. Stems knobby, the apex densely hirsute or strigose.
  2a. Stems with persistent swollen stipules; leaves less than 7 cm long, the paired glands toward the apex of the petiole .... 1. *T. microphyllum*
  2b. Stems with raised leaf scars, the stipules persistent or not, rarely swollen; leaves usually over 10 cm long, the paired glands near the middle of the petiole .... 2. *T. costaricense*
1b. Stems smooth, the apex appressed-pubescent or glabrescent; leaves mostly more than 7 cm long; staminate inflorescence usually more than 4 cm long.
  3a. Basal foliar glands ca. 0.5–0.6 mm thick, definitely attached on laminar tissue; leaves mostly 15 cm long or more, with 6 or 7 prominent lateral veins; pistillate flowers sessile .... 3. *T. euryphyllum*
  3b. Basal foliar glands ca. 0.15–0.3 mm thick, attached at junction of lamina and petiole or well down on petiole; leaves 7–12 cm long, mostly with only 4 or 5 prominent lateral veins; pistillate flowers with distinct pedicels mostly 1.5–2 mm long .... 4. *T. gorgonae*

26.1. Tetrorchidium microphyllum Huft, sp. nov. TYPE: Panama. Chiriquí: 3.5 mi. NE of Boquete, end of road along Río Alto, 6,200 ft., 18 Nov. 1978, *Hammel 5721* (holotype, MO; isotype, F, F neg. 62357). Figure 2.

Arbor mediocris, gracilis, dioecia; ramulis junioribus fragilibus, praeter apicem dense hirsutum, glabris; foliis oblanceolatis, 2.5–7 cm longis, sparsim pubescentibus utrinque pilis malpighiaceis vel glabratis, margine integris, apice acuminatis; petiolis brevibus, dense appressis pubescentibus pilis malpighiaceis; stipulis glanduliformibus, tumidis, persistentibus; floribus masculis in thyrsis axillaribus ad 3 cm longis; floribus femineis et capsulis ignotis.

Dioecious *tree* to 10 m; branches brittle, glabrous except at tips where densely hirsute, appearing warty by the presence of persistent, swollen

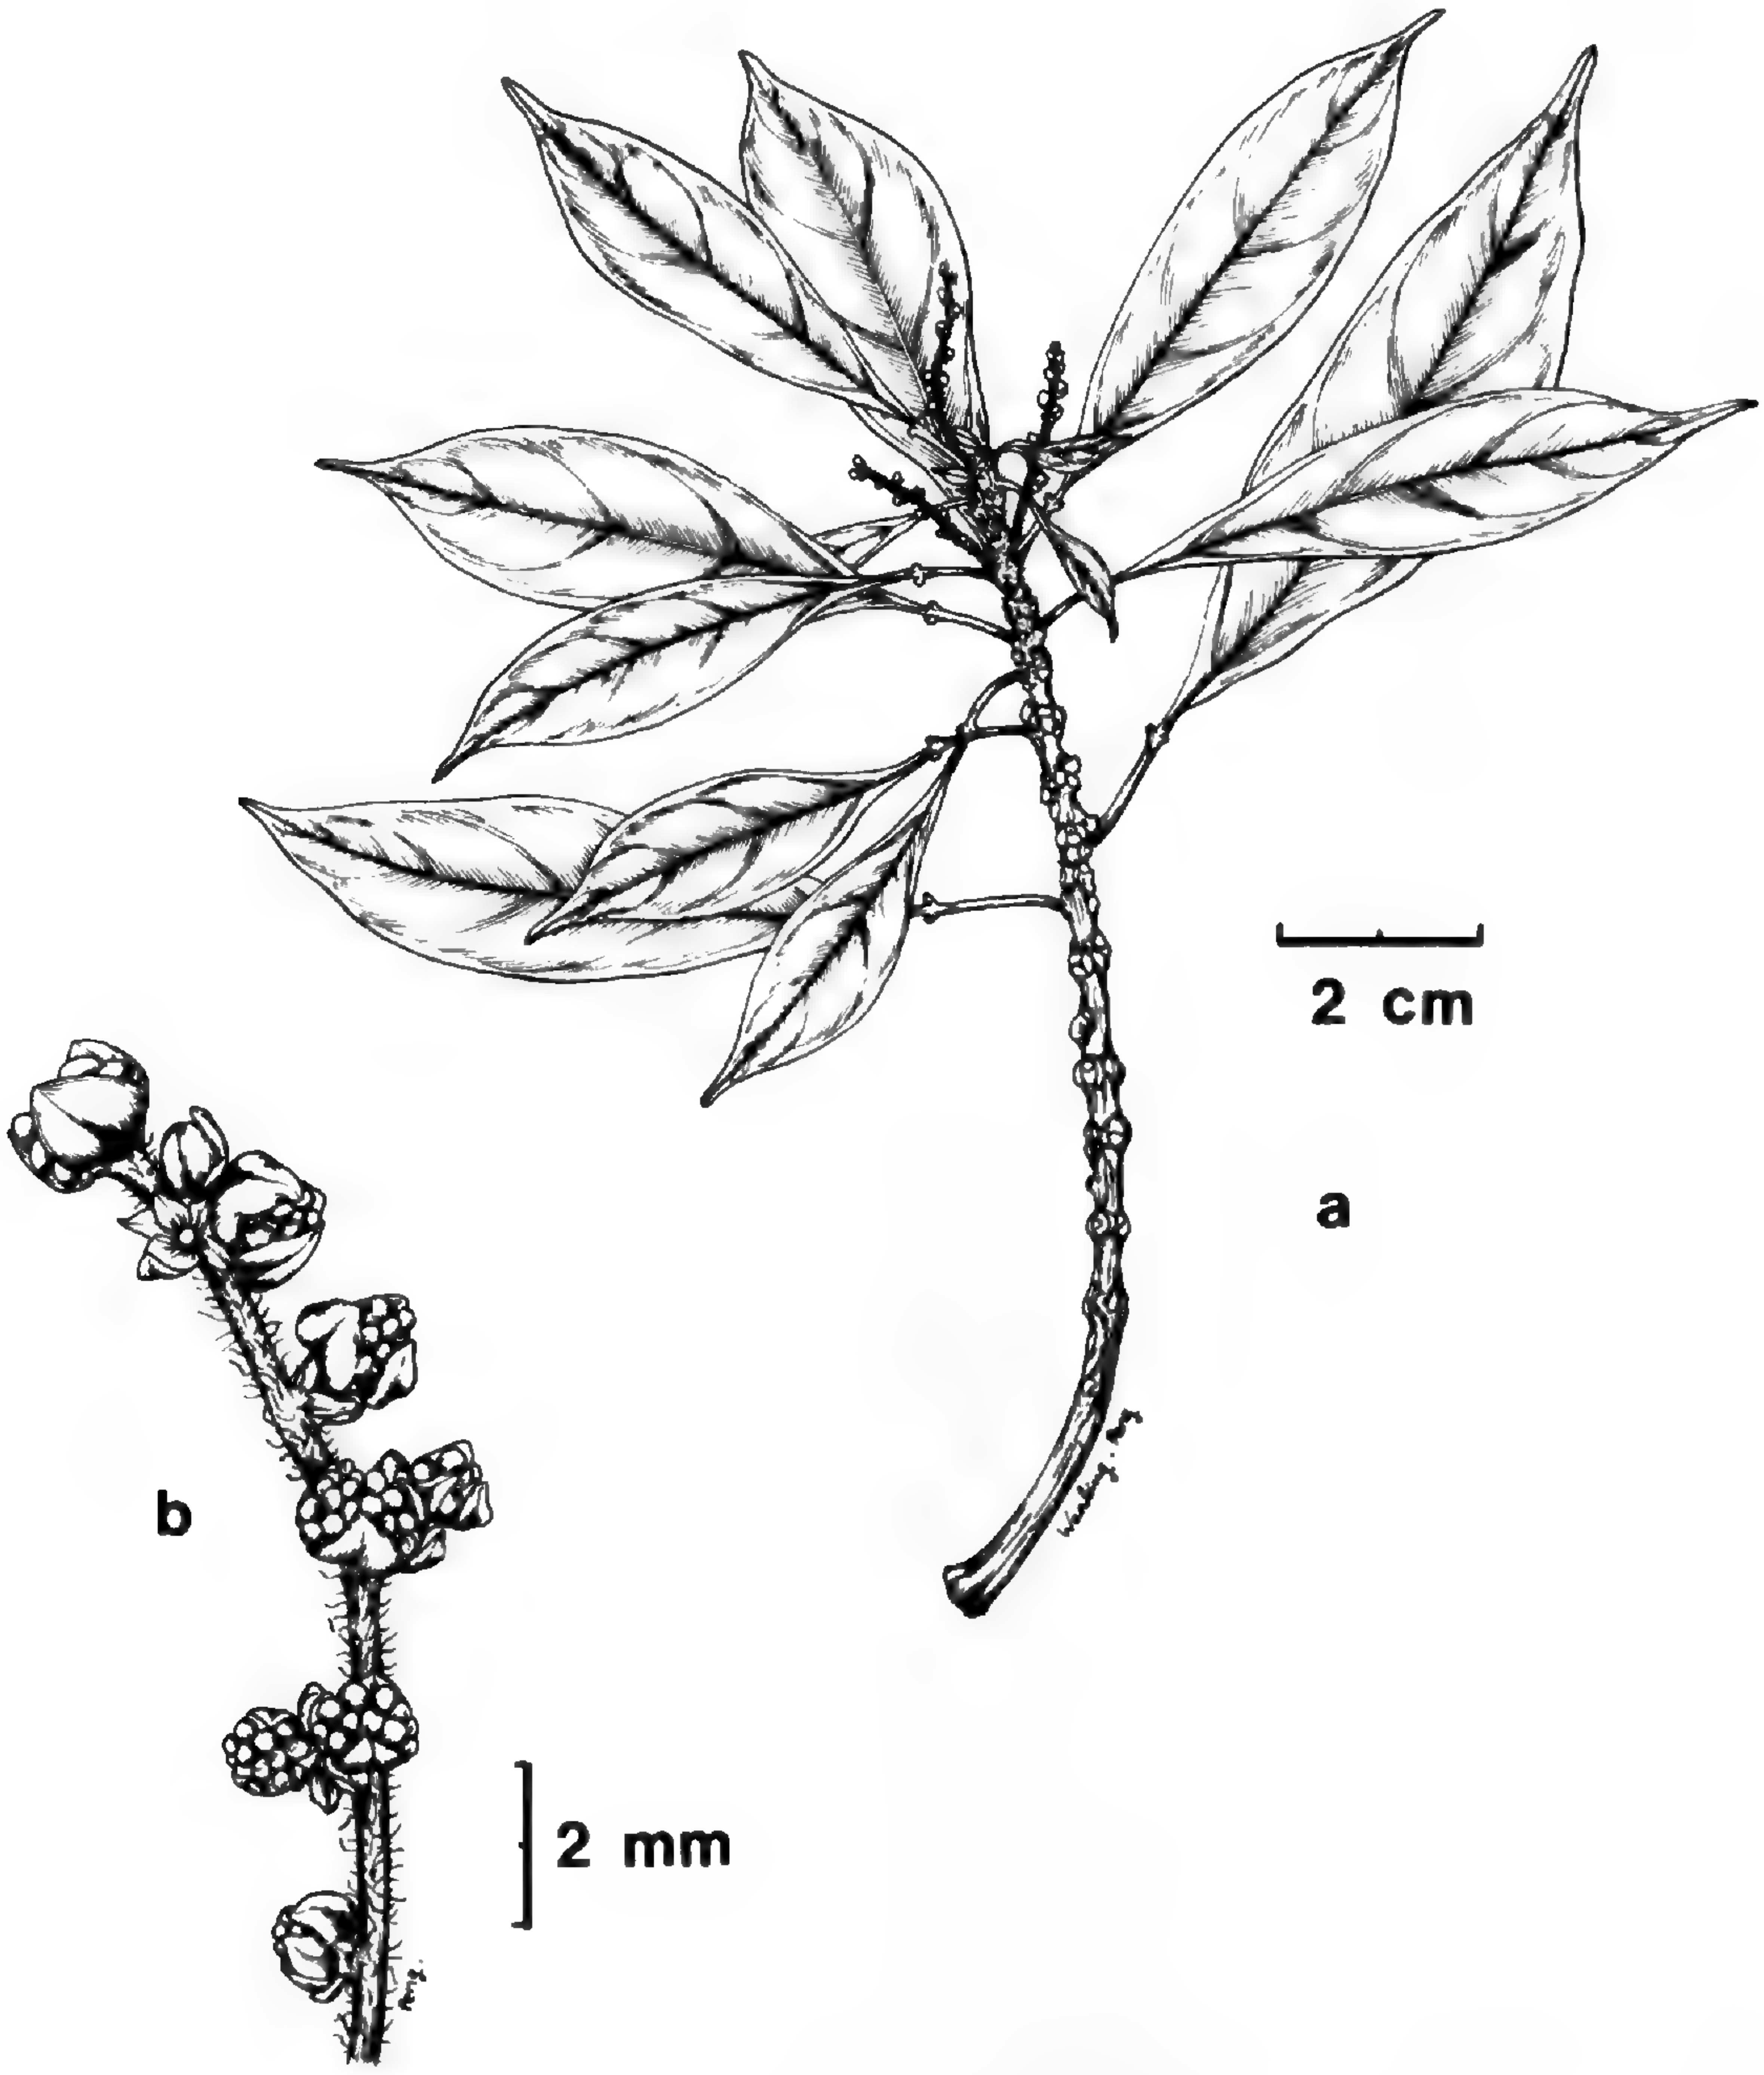

FIGURE 2. Tetrorchidium microphyllum.—*a. Habit.—b. Detail of staminate inflorescence. Based on* Hammel 6039. *Illustration by Wan-Ling Peng.*

stipules. *Leaves* short-petiolate, crowded near ends of branches; petioles 0.5–1.2(–1.5) cm long, densely appressed-pubescent with malpighiaceous hairs to glabrate, with massive, paired, thick-stalked, opposite or subopposite glands near the tip, these 0.6–0.8 mm long, 0.8–1 mm thick, stipules glanduliform, tumid, broadly triangular, 1.5–2 mm long, densely pubescent, persistent, glabrate soon after leaf-fall; blades chartaceous, oblanceolate, acuminate at tip, cuneate at base, (2.5–)4–5.5(–7) cm long, (0.9–1)1.2–2 cm broad, sparsely pubescent with malpighiaceous hairs to glabrate on both sides, the midrib and primary veins (3–4 on a side) prominently raised below, the veinlets forming a prominent reticulum; margins entire. *Inflorescences* axillary; staminate thyrses unbranched, 1.5–3 cm long, the rachis densely strigose; pistillate inflorescences unknown. *Staminate flowers* subsessile; calyx lobes 3, triangular, glabrous, ca. 1–1.2 mm long; petals lacking; anthers subsessile, 0.8–0.9 mm long. *Pistillate flowers* unknown. *Fruits* unknown.

Cloud forests, western Panama.

This distinctive new species of *Tetrorchidium* appears to be most closely related to *T. brevifolium* Standley & Steyerm., described from the province of Alta Verapaz, Guatemala (Publ. Field Mus. Nat. Hist., Bot. Ser. 23: 126. 1944), from which it differs by the smaller leaves (7–12 cm long in *T. brevifolium*), densely pubescent shoot apices and inflorescences (both glabrous in *T. brevifolium*), and shorter inflorescences (4–7 cm long in *T. brevifolium*). The type specimen of the Guatemalan species (Rubelpec, Finca Seamay, *Wilson 188*, F) lacks the persistent tumid stipules that are so characteristic of *T. microphyllum*, but these are present on several collections of the former species made in 1974 and 1975 from Baja Verapaz, Guatemala (*Lundell & Contreras 19173, 19436* (both

F, LL); *Williams et al. 43277*, F). The type specimen consists only of branchlet tips with a few leaves and staminate inflorescences that appear to have been taken from rapidly growing long shoots. *Tetrorchidium molinae* L. Williams, described from cloud forests in the mountains above San Juancito, Honduras (Fieldiana, Bot. 29: 348. 1961, based on *Williams & Molina 17068*, F), is similar in all respects to *T. brevifolium* and should be relegated to the synonymy of that species. A paratype specimen of *T. molinae* from the same area, *Williams & Molina 13980* (F), has long shoots without stipules attached to a normal shoot with persistent stipules. This matches the pattern of the type collection of *T. brevifolium*, thus confirming the suspicion voiced above concerning the nature of that collection.

Additional specimen examined. PANAMA. CHIRIQUÍ: end of road past Palo Alto NE of Boquete in forest along ridge, 6,200–6,800 ft., *Hammel 6039* (F, MO).

26.2. Tetrorchidium costaricense Huft, sp. nov. TYPE: Costa Rica. Puntarenas: Cordillera de Tilarán, Monteverde Reserve, near Continental Divide on Pacific side, 1,520–1,580 m, *Dryer 1403* (holotype, CR, F neg. 62351; isotypes, F, F neg. 62350, MO, F neg. 62349).

Arbor ad 16 m alta, dioecia; ramulis junioribus dense strigosis; foliis anguste oblongis, 8–16 cm longis, apice abrupte cuspidatis; petiolis longis, prope medium glandibus binatis; floribus masculis sessilibus, in thyrsis axillaribus 4–9 cm longis; floribus femineis subsessilibus, ad fructus maturitatem brevipedicellatis, segmentis disci discretis ligulatis; ovariis 2-locularibus; seminum ovoideis, grosse reticulatis.

Dioecious *tree* to 16 m; branches densely strigose toward tip, appearing knobby from the raised leaf scars and occasionally from persistent, indurate stipules. *Leaves* long-petiolate, not crowded toward ends of branches; petioles 2.5–6 cm long, glabrous or minutely strigose, with paired, subopposite, sessile, patelliform glands near the middle, these ca. 1 mm (rarely to 2.2 mm) diam.; stipules oblong, 1.5–2.5 mm long, 1–1.5 mm broad, densely strigose, persistent, sometimes indurate after leaf-fall; blades membranous, narrowly oblong, 8–16 cm long, 3–7 cm broad, 2.2–3.3 times as long as broad, abruptly cuspidate at tip with an acumen 5–10 mm long, acute to attenuate at base, minutely puberulent below with scattered short malpighiaceous hairs, glabrous or nearly so above, the midrib prominent below, the secondary veins 6–8 on a side, arcuate, prominent below, obscure above; margin entire, eglandular. *Inflorescences* axillary, the axes densely strigose with short malpighiaceous hairs; staminate thyrses 4–9 cm long, freely branched, the lateral branches to 3.5 cm long; pistillate racemes to 5 cm long. *Staminate flowers* in glomerules of 2–5, sessile; sepals 3, obovate, cucullate, glabrous without, pilose within; anthers subsessile, 1.3–1.5 mm broad. *Pistillate flowers* subsessile, the pedicels becoming 0.5–3 mm long in fruit; sepals broadly ovate, obtuse, 3–3.5 mm long, glabrous or sparingly short-strigose without, densely hispid toward base within; disk segments free, narrowly ligulate, ca. 2 mm long; ovary smooth, 2-locular, glabrous above, densely long-strigose below; style cap at maturity 0.5–0.8 mm high, 1.5–1.8 mm diam. *Capsule* 3–5 mm high, 5–6 mm diam., glabrous, oblate to globose; seeds ovoid-lenticular, 5–6 mm long, prominently and coarsely reticulate, the caruncle an irregular yellow papery keel running halfway from the hilum to the apex.

Known only from Costa Rica and extreme western Panama, this distinctive species is easily distinguished by the large, dark green, lanceolate leaves that are conspicuously venose, the paired glands near the middle of the rather long petioles, and the densely and minutely strigose branchlet tips, petioles, and leaves.

Tetrorchidium costaricense belongs to the group of species with free ligulate disk segments in the pistillate flower that includes *T. rotundatum* Standley and *T. brevifolium* Standley & Steyerm. in northern Central America. Like *T. costaricense*, *T. rotundifolium* has paired glands near the middle of long petioles, but differs in its completely glabrous stems and leaves, mostly unbranched staminate thyrses that have larger glomerules, densely pubescent pistillate calyces, and distinctly pedicellate fruits. *Tetrorchidium brevifolium* differs in its glabrous stems, leaves, and calyces, short petioles with paired glands near the tip, and unbranched staminate thyrses. The widespread South American species *T. rubrivenium* Poeppig also belongs to this group but has glabrous stems and leaves, crenate or denticulate leaf margins, sometimes long petioles with the paired glands near the tip, densely pubescent pistillate calyces, uniformly puberulent ovary and capsule, and pedicellate fruits.

Additional specimens examined. COSTA RICA. ALAJUELA: Cordillera de Tilarán, Monteverde Reserve, Atlantic side, 1,500–1,580 m, *Dryer 1071* (CR, F). CARTAGO: Reserva de Tapantí, 1,300–1,800 m, *Gómez 18752* (F). PUNTARENAS: Cordillera de Tilarán, Monteverde Reserve, Pacific side, en orilla de Pantano Chomogo, 1,600–1,620 m, *Dryer 659* (CR), *887* (CR, F); Monteverde Reserve, at field station, 1,500 m, *Haber 491* (F); Monteverde Reserve, 1,570 m, *Haber & Bello 1640* (F), 1,500 m, *Haber & Bello 2457* (F). ALAJUELA/PUNTARENAS: on and near the Continental Divide, ca. 2–5 km

E and SE of Monteverde, 10°18′N, 84°46′W, 1,580–1,700 m, *Burger & Gentry 8608* (F); Monteverde, *Dryer 1731* (F). SAN JOSÉ: bajo de La Hondura, *Poveda 862* (CR, USJ). PANAMA. BOCAS DEL TORO: along Continental Divide, trail to headwaters of Río Mali, to W of Oleoducto Road, 8°47′N, 82°13′W, 1,200 m, *Churchill 5276* (F); Fortuna Dam region, along Continental Divide W of highway pass, ca. 8°45′N, 82°15′W, ca. 1,200 m, *McPherson 9695* (F).

26.3. **Tetrorchidium euryphyllum** Standley, Publ. Field Columbian Mus., Bot. Ser. 4: 219. 1929. TYPE: Panama. Bocas del Toro: vicinity of Almirante, 1928, *Cooper 621* (holotype, F).

When the original treatment was written, this species was known only from Costa Rica and extreme western Panama, but recent collections in Panama have now extended its range eastward to Darién.

Additional specimens examined. PANAMA. BOCAS DEL TORO: between Quebrada and Buena Vista, *Kirkbride & Duke 662* (MO). CHIRIQUÍ: Fortuna Dam region, along Quebrada Arena, ca. 8°45′N, 82°15′W, ca. 1,100 m, *McPherson 8394* (F). COCLÉ: slopes of Cerro Pilón near El Valle, 700–900 m, *Duke 12196* (MO, 2 sheets); Cerro Pilón, *Dwyer 8330* (MO); La Mesa, 8.5 mi. from Club Campestre (El Valle), *Dwyer 10515* (MO); Margarita near chicken farm, *Dwyer & Duke 8280* (MO); La Mesa, above El Valle, *Dwyer & Nee 11938* (MO); La Mesa, 4 km N of El Valle, 850–875 m, *Nee & Dwyer 9212* (MO). DARIÉN: Cerro Sapo, ca. 2,500 ft., *Hammel 1240* (MO). SAN BLAS: Cerro Brewster, 9°18′N, 79°16′W, 850 m, *de Nevers et al. 5408* (F). VERAGUAS: Caribbean slope above Río Primero Brazo, 5 mi. NW of Santa Fe, 700–1,200 m, *Croat 23233* (MO); NW of Santa Fe, 4.2 km from Escuela Agrícola Alto de Piedra, *Mori & Kallunki 4831* (MO); ca. 2.7 km from Escuela Agrícola Alto de Piedra, *Mori & Kallunki 5359, 6208* (MO); 7 km W of Santa Fe on road past agricultural school, 2,900 ft., *Nee 11216* (MO).

26.4. **Tetrorchidium gorgonae** Croizat subsp. **robledoanum** (Cuatrec.) Webster, Ann. Missouri Bot. Gard. 54: 199. 1967. *T. robledoanum* Cuatrec., Brittonia 9: 81. 1957. TYPE: Colombia. Antioquia: 23 Jan. 1947, *Gutiérrez 35556* (holotype, CAL, not seen).

This species is still unknown in Central America outside of Central Panama. Several recent collections allow a description of the fruit to be made for the first time. They are on densely strigose pedicels 7–10 mm long and jointed below the middle. The capsule is green, drying to brown, globose, shallowly 3-lobed, rugulose, 4–6 mm high, 4.5–7 mm in diameter, more or less densely strigose with short (0.2–0.6 mm) malpighiaceous hairs. The 3 styles are deeply bifid, 0.6–0.7 mm long, and tumid. The seeds are ovoid, 4–5 mm long, 3–4 mm in diameter, black, coarsely and shallowly pitted, and completely surrounded by bright red, juicy arils.

Additional specimens examined. PANAMA. COLÓN: Santa Rita Ridge Road 1.5 mi. from Transisthmian Hwy., *Dwyer & Gentry 9338* (MO, 2 sheets); Santa Rita Ridge Road 4 mi. from Transisthmian Hwy. to Agua Clara weather station, ca. 500 m, *Gentry et al. 8841* (MO, 2 sheets); in forest along Río Guanche 3–7 km above bridge, 300–700 ft., *Hammel 4894* (MO). PANAMÁ: El Llano–Cartí highway, 17–20 km N of El Llano, *Dressler 4629* (F, MO); 10 km N of Margarita on road to Madroño, then 3 km W on ridgetop road, 1,800 ft., *Hammel 6014* (MO); Cerro Jefe region 2.5 mi. N of turnoff to radio tower along road, 2,400 ft., *Hammel 6300* (MO); El Llano–Cartí road, 9.6–11 km from Inter-American Hwy., 350 m, *Mori & Kallunki 3531* (MO); 5–10 km NE of Altos de Pacora on trail at end of road, 700–800 m, *Mori & Kallunki 6058* (MO); El Llano–Cartí road, 8 km N of Pan Am. Hwy. at El Llano, ca. 450 m, *Nee & Warmbrodt 10391* (MO).

27. *Manihot*

Manihot Miller, Gard. Dict. abr. ed. 4. 1754. TYPE: *Manihot esculenta* Crantz (*Jatropha manihot* L.).

RECENT LITERATURE

ROGERS, D. J. & S. G. APPAN. 1973. *Manihot; Manihotoides.* Fl. Neotropica 13: 1–272.

——— & H. S. FLEMING. 1973. A monograph of *Manihot esculenta*—with an explanation of the taximetric methods used. Econ. Bot. 27: 1–113.

The discovery of an additional *Panamanian* species necessitates a revised key and enumeration.

KEY TO THE SPECIES OF *MANIHOT* IN PANAMA

1a. Leaves glabrous, mostly with 7–9 lobes; calyx glabrous within (12–14 mm long; disk entire; anthers glabrous; ovary not sharply ribbed or winged) .... 1. *M. aesculifolia*
1b. Leaves pubescent or with fewer lobes; calyx pubescent within.
  2a. Leaves pubescent, mostly with 5 or more lobes; ovary distinctly ribbed or winged; staminate calyx 3–4.5 mm long; anthers pubescent; shrubs with erect stems .... 2. *M. esculenta*
  2b. Leaves glabrous, strictly 3-lobed; ovary not ribbed or winged; staminate calyx 10–20 mm long; anthers glabrous; clambering vine .... 3. *M. brachyloba*

27.1. **Manihot aesculifolia** (Kunth) Pohl, Pl. Bras. Icon. Descr. 1: 55. 1827. *Janipha aesculifolia* Kunth, Nov. Gen. Sp. 2: 85, tab. 109. 1817. TYPE: Mexico. Campeche: *Humboldt & Bonpland* (P, not seen).

This plant was called *M. gualanensis* Blake in our original treatment, but that name has been reduced to a synonym of *M. aesculifolia* in the recent monograph of the genus by Rogers & Appan cited above.

27.3. Manihot brachyloba Muell. Arg., Fl. Brasil 11(2): 451. 1874; Rogers & Appan, Fl. Neotrop. 13: 190–192. 1973. TYPE: Brazil. Pará: *Martius* (syntype, G; microfiche seen).

The Bristan specimens have very young inflorescences but vegetatively match the description and illustration given by Rogers & Appan. However, contrary to their description and that of Mueller, the staminate buds in the Panamanian specimens are pubescent externally.

Specimens examined. PANAMA. DARIÉN: headwaters of Río Tuqueza, between Quebrado Venado and Peje Swamp, *Bristan 1001* (DAV, MO); between Manené and Río Coasí, *Hartman 12127* (MO).

28. *Cnidoscolus*[4]

Cnidoscolus Pohl, Pl. Brasil. Icon. Descr. 1: 56. 1827. LECTOTYPE: *Cnidoscolus hamosus* Pohl (chosen by Small in Britton & Brown, Illust. Fl. N. U.S. ed. 2, 2: 462. 1913).

28.1. Cnidoscolus urens (L.) Arthur, Torreya 21: 11. 1921. *Jatropha urens* L., Sp. Pl. 1007. 1753. TYPE: "America calidiori, in Brasilia & c." (not seen, possibly in Hortus Cliffortianus Herbarium, BM).

Since the treatment of 1968, further study of the Panamanian specimens of *C. urens* leads to the conclusion that the two variants discussed there merit taxonomic recognition. Pending a more detailed revision of the *C. urens* complex (Breckon, ined.), the Panamanian plants may be disposed of as follows.

28.1a. Cnidoscolus urens (L.) Arthur subsp. **urens.**

Specimens examined. PANAMA. PANAMÁ: Farfan Beach area, *Correa et al. 1586, Dwyer 3065, Tyson 1803* (MO). COCLÉ: between Aguadulce and San Antón, *Woodson et al. 1226a* (MO); between Antón and Natá, *D'Arcy & Croat 4117* (MO); banks of Río Grande, *Burch et al. 1157* (MO). HERRERA: Chitré to Divisa, *Burch et al. 1357* (MO); Sal Salinas de Chitré, *Croat 9692* (MO). PANAMÁ: San Carlos, *de McPherson 11* (MO).

28.1b. Cnidoscolus urens subsp. **adenophilus** (Pax & K. Hoffm.) Breckon, stat. nov. *Jatropha adenophila* Pax & K. Hoffm., Pflanzenreich IV. 147. VII(Heft 63): 409. 1914. *Cnidoscolus adenophilus* (Pax & K. Hoffm.) Pax & K. Hoffm., Nat. Pflanzenfam. ed. 2, 19c: 166. 1931. TYPE: Panama. Panamá: Chepo, *Pittier 4740* (isotype, US).

Specimens examined. PANAMA. CANAL ZONE: Miraflores Locks, *Stern et al. 81* (MO); Pipeline Road, *Croat 12732* (MO); Curundú, *McDaniel 5180* (MO), *Tyson 1045* (MO); Ft. Amador Islands, *Tyson 5413* (MO). DARIÉN: El Real, *Lazor & Correa 3364* (MO), *Stern et al. 454* (MO). LOS SANTOS: 5 mi. NW of Guararé, *Wilbur et al. 12054* (MO); Monagre Beach, *Lewis et al. 1673* (MO). PANAMÁ: Jenine, Río Cañita, *Duke 3821* (MO); between Las Margaritas and Río Mamoní, *Duke 5867* (MO); Puente de Pacora, *De Hoyos 18* (MO). VERAGUAS: 2–4 mi. E of Santiago, *Duke 12354* (MO); 12 km E of Santiago, *Dwyer & Kirkbride 7450* (MO).

28.2. Cnidoscolus aconitifolius (Miller) I. M. Johnston, Contr. Gray Herb. 68: 86. 1923. subsp. **aconitifolius.** *Jatropha aconitifolius* Miller, Gard. Dict. ed. 8. 1768. TYPE: *Herb. Miller* (presumably at BM, not seen).

In the present interpretation, the Panamanian specimens of *Cnidoscolus aconitifolius* all belong to the nominate subspecies, which is not native to Panama.

29. *Jatropha*

Jatropha L., Sp. Pl. 1006. 1753. LECTOTYPE: *Jatropha gossypiifolia* L. (see McVaugh, 1944: 459).

RECENT LITERATURE

[4] Contributed by Dr. Gary Breckon, University of Puerto Rico, Mayagüez.

nate, simple; petioles swollen distally; blades pinnately veined, biglandular at base, the margins serrate. *Inflorescences* axillary, spiciform; staminate flowers in glomerules; pistillate flowers solitary at each node; bracts inconspicuous, eglandular. *Staminate flowers* subsessile; calyx lobes 5, imbricate; petals 5 or rarely 6, connate (at least below), adaxially villous; disk extrastaminal, urceloate, lobate, glabrous; stamens (3–)5–7; filaments free; anthers dehiscing introrsely and longitudinally, the connective not enlarged; pollen grains globose, inaperturate, clavate; pistillode absent. *Pistillate flowers* subsessile; sepals 5, imbricate; petals 5, free, adaxially villous; disk urceolate, sometimes lobate, glabrous; ovary of 3 carpels; ovules 1 per locule; styles free, bifid. *Fruits* capsular; seeds smooth, carunculate; endosperm copious; embryo straight, cotyledons palmatinerved, much longer than radicle.

This primarily South American genus is here reported from Panama for the first time.

LITERATURE

BAILLON, H. 1873. Nouvelles observations sur les Euphorbiacées. Adansonia 11: 72–138.

LANJOUW, J. 1936. The genus *Pausandra* Radlk. Recueil Trav. Bot. Néerl. 33: 758–769.

30.1. Pausandra trianae Baillon, Adansonia 11: 92. 1873, proposed without reference to *Pogonophora trianae* Muell. Arg. TYPE: Colombia: Bogotá, plains of San Martín, Río Meta, *Triana 2597* (holotype, P, not seen; isotypes, G, not seen, photo F neg. 24574, K, not seen, holotype of *Pogonophora trianae* Muell. Arg.).

Pogonophora trianae Muell. Arg., Flora 47: 434. 1864. TYPE: Colombia. Bogotá: plains of San Martín, Río Meta, *Triana 2597* (holotype, K, not seen, isotypes, G, not seen, photo F neg. 24574, P, not seen, holotype of *Pausandra trianae* Baillon).

Pausandra quadriglandulosa Pax & K. Hoffm., Pflanzenreich IV. 147. XIV(Heft 68): 43. 1919. TYPE: Brazil: Rio Acre, Seringal S. Francisco, *Ule 9538* (holotype, B, not seen, photo F neg. 5406).

Pausandra extorris Standley, Trop. Woods 17: 24. Mar. 1929; Publ. Field Columbian Mus., Bot. Ser. 4: 219. Oct. 1929. TYPE: Nicaragua: Bragman's Bluff, *Englesing 216* (holotype, F, F neg. 52719; wood sample, Y no. 13301).

Clavija septentrionalis L. O. Williams, Fieldiana, Bot. 32: 205. 1970. TYPE: Nicaragua: Cabo Gracias a Dios, Laimos Creek, ca. 15 km SW of Waspam, 7 Mar. 1961, *Bunting & Licht 390* (holotype, F; isotypes, NY, US).

Tree to 30 m; branching pagodiform; sap dark red-brown; twigs and buds ± densely brown-puberulent with malpighiaceous hairs; leaf scars prominent. *Leaves* horizontally aligned; petiole 1.5–3.5 cm long, 2–4 mm thick, terete, strigose with short (to 0.5 mm long) malpighiaceous hairs; glands at apex of petiole (3–)4, cylindrical, 1–1.5 mm long, ca. 1 mm thick; blade chartaceous, obovate to oblanceolate, rounded, obtuse, or abruptly short-cuspidate at tip, long-attenuate at base, 20–50 cm long, 7–18 cm broad, 2.6–4 times as long as broad, glabrous above, glabrate or thinly puberulent with short malpighiaceous hairs below, the secondary veins prominent, 15–23 per side; margin remotely denticulate. *Inflorescences* spicate, arising singly in the upper axils, 10–25 cm long, the rachis densely puberulent. *Staminate flowers* 6–12 per glomerule, these sessile, widely spaced; sepals 5, imbricate, densely puberulent, obovate, ca. 1.5 mm long, ca. 1.5 mm broad, rounded at apex; petals 5, white, narrowly obovate, ca. 6 mm long, glabrous without, densely hirsute toward base within; stamens 6, exserted, the filaments 5–6 mm long; disk cupulate. *Pistillate flowers* not seen. *Capsule* smooth, strigose with short malpighiaceous hairs, apparently subglobose, ca. 1 mm diam. (fragments only seen); columella 7–8 mm long; seeds subglobose, brown with irregular white striations, 8–9 mm long, ca. 6 mm diam.; caruncle a flattened irregular mass near hilum.

Rainforests, Honduras to western Brazil.

The description is based on the Panamanian specimens cited below and supplemented by collections at F from Costa Rica and Nicaragua.

The genus *Pausandra* remains poorly understood. The most recent revision (Lanjouw, 1936) was based upon only 33 collections and resulted in the recognition of nine species, most known from only a single sex. Lanjouw admitted that several of the species might need to be united as more material became available. *Pausandra trianae* does appear, however, to be one of the better-delimited species in the genus and is certainly the most widespread. The Central American plants readily key to that species in Lanjouw's revision, where *P. extorris* and *P. quadriglandulosa* are reduced to synonymy. The identity of *Clavija septentrionalis* as *P. trianae* was first pointed out by R. L. Liesner of the Missouri Botanical Garden (pers. comm.).

The author citation for *Pausandra trianae* has been almost universally given for the last century as *Pausandra trianae* (Muell. Arg.) Baillon, carrying the implication that Baillon had transferred *Pogonophora trianae* Muell. Arg. to its correct place in *Pausandra*. It is clear from Baillon's text, however, that he intended to describe a new species; there is no indication that he was aware of Mueller's name. Baillon's paper (1873) is a series of miscellaneous notes on the Euphorbiaceae. Under *Pausandra* (pp. 92–93), he stated that the genus was described in 1870 and was known by a single species, *P. morisiana*. He then indicated that a collection from Colombia (*Triana 2597*) represented an additional species in the genus, which may be given the name *P. trianae*. ("Ce genre est aussi représenté à la Nouvelle-Grenade, par une plante qui est bien voisin de celle de Brésil, qui n'en est peut-être même qu'une forme; je lui donnerai provisoirement le nom de *P. Trianae*.") No reference whatever was made to Mueller's name, and none would be expected. One would not normally look in *Pogonophora* for species pertaining to *Pausandra*; the genera are too different for that.

The fact that the names of Mueller and of Baillon are both based on the same collection, although on different specimens, is merely a coincidence. That both chose the same epithet is also coincidental, but not very surprising, given the common practice of naming species after the collector of the type.

Thus, although Baillon ideally should have made a transfer of Mueller's name, he was understandably unaware that Mueller had previously described the species at hand, and did not make the transfer. Had the two authors chosen different epithets, then the rules would mandate a transfer of Mueller's epithet to create a new combination in *Pausandra* supplanting Baillon's name. But that solution is closed because it would create a later homonym. Article 63 of the Code (Voss, 1983) might mislead one to reject Baillon's name as superfluous, because it seems to be based on the type of a name whose epithet ought to have been adopted under the rules. A correct reading of the Code, however, makes it clear that a type is a *specimen*, and not a gathering, which usually consists of several duplicate specimens. An isotype has no official standing as long as the holotype exists, although its value is unquestioned. Thus, for a name to be rejected as superfluous, it must be based upon the same specimen as an earlier name whose epithet ought to have been adopted. This is not the case with *Pausandra trianae* Baillon. There is therefore no bar to the acceptance of that name as the correct one for this species.

Additional specimens examined. PANAMA. BOCAS DEL TORO: premontane rainforest between Q. Lugron and Cerro Bonyic, near Terebe, 300–900 ft., *Kirkbride & Duke 647* (MO). SAN BLAS: Río Taindi (Taimdi of maps) 6 km above confluence with Río Mandinga, 9°25'N, 79°11'W, 30–100 m, *de Nevers & Herrera 7674* (F); along newly cut road from El Llano to Cartí-Tupile, near Continental Divide, 300–500 m, *Liesner 1289* (DAV, F, MO), *Mori & Kallunki 5535* (MO); seasonal lowland rainforest on the Aila Tilar (Río Acla), 8°48'N, 77°40'30"W, 25–100 m, *Sugden 424, 588* (MO).

31. *Garcia*

Garcia Vahl in Rohr, Skr. Naturhist.-Selsk. 2: 217. 1792. TYPE: *Garcia nutans* Vahl.

31.1. Garcia nutans Vahl in Rohr, Skr. Naturhist.-Selsk. 2: 217, tab. 9. 1792. TYPE: Colombia. Magdalena: near Santa Marta, *von Rohr* (C, not seen).

Additional specimens examined. PANAMA. CANAL ZONE: Barro Colorado I., *Knight 1090* (MO). LOS SANTOS: between Tonosí and Guánico, *Tyson et al. 3126* (MO).

32. *Croton*

Croton L., Sp. Pl. 1004. 1753. LECTOTYPE: *Croton aromaticus* L. (chosen by Webster, J. Arnold Arbor. 48: 354. 1967).

Seven species new to Panama (including two new species and one new subspecies) are reported here; a few new province records are indicated as well. These additions make it necessary to provide a revised key.

LITERATURE

LANJOUW, J. 1931. The Euphorbiaceae of Surinam. Amsterdam.

KEY TO THE SPECIES OF *CROTON* IN PANAMA

1a. Staminate flowers apetalous; stipules and petiolar glands absent; leaves with stellate-lepidote indumentum above, lepidote beneath (stamens 10–12; filaments hirsutulous; styles usually 3 times bifid; seeds deciduously stellate, 5–6 mm long) .... 20. *C. punctatus*

1b. Staminate flowers petaliferous; leaves stipulate (stipules sometimes early deciduous); indumentum various.

2a. Indumentum lepidote.

3a. Leaves without basal laminar or petiolar glands; petals in flowers not reduced; pistillate calyx lobes valvate but not reduplicate.

4a. Stamens 9–12; filaments glabrous; anthers 0.6–0.8 mm long; petals of staminate flowers not lepidote or with only 1 or 2 scales; seeds mostly 7 mm long or shorter.

5a. Leaves more or less oblong-elliptic, pinnately veined; inflorescences mostly 2 cm long or longer; pedicels of pistillate flowers mostly 10 mm long or longer .... 1. *C. schiedeanus*

5b. Leaves ovate, more or less cordate, (3–)5-veined at base; inflorescences 1 cm long or shorter; pedicels of pistillate flowers 1–2 mm long .... 2. *C. pseudoniveus*

4b. Stamens 14–17, or if fewer, then filaments hirsutulous; anthers 1–1.2 mm long; petals of staminate flowers lepidote; seeds 15 mm long or longer.

6a. Stamens (10 or)11–13; leaves pinnately veined; pistillate flowers mostly 3 or 4 per raceme; seeds 20–22 mm long .... 3. *C. tenuicaudatus*

6b. Stamens 15; leaves 3–5-veined at base; pistillate flowers mostly 1 or 2 per raceme; seeds 15–18 mm long .... 4. *C. pyriticus*

3b. Leaves with basal laminar glands; petals in pistillate flowers reduced; pistillate calyx lobes reduplicate-valvate.

7a. Seeds 3–5 mm long; fruiting pedicels 8–15 mm long .... 5. *C. lanjouwensis*

7b. Seeds 16–17 mm long; fruiting pedicels not over 7 mm long .... 6. *C. pachypodus*

2b. Indumentum not lepidote, the trichomes mostly or entirely stellate or dendritic; petals in pistillate flowers distinctly reduced or absent (sometimes fairly well developed in *C. draco*); petioles with prominent glands at junction with blade (except sometimes in *C. hircinus*); inflorescence (at least in part) terminal.

8a. Leaves deeply 3–5-lobed; staminate calyx lobes distinctly imbricate in bud; staminate receptacle glabrous; seeds tetragonal; annual herb .... 19. *C. lobatus*

8b. Leaves unlobed or shallowly lobed (less than halfway); staminate calyx lobes mostly valvate in bud; staminate receptacle sparsely to densely villose (glabrous in *S. santaritensis*); seeds not tetragonal.

9a. Stamens over 50; styles more than 5 mm long, twice bifid; stipules tomentose, dentate, 3–6 mm long; seeds ventrally ribbed .... 7. *C. speciosus*

9b. Stamens fewer than 50; styles less than 5 mm long.

10a. Lower cymules of inflorescence with both staminate and pistillate flowers at the same nodes; seeds coarsely ribbed.

11a. Styles bifid; pistillate calyx lobes not reduplicate-valvate; stamens 13 or more; filaments glabrous or nearly so; leaves unlobed, without scattered laminar glands.

12a. Pistillate flowers distinctly pedicellate, the pedicels mostly 3–6 mm long; inflorescences mostly 2–4 dm long; stamens 13–20; styles glabrous or nearly so; seeds less than 5 mm long .... 8. *C. draco*

12b. Pistillate flowers subsessile, the pedicels in fruit not over 2 mm long; inflorescences mostly 1–2 dm long; stamens 25–45; styles distinctly stellate-pubescent; seeds at least 5 mm long .... 9. *C. pungens*

11b. Styles multifid, stellate-pubescent; pistillate calyx lobes reduplicate-valvate; stamens 11 or 12; filaments hirsutulous; leaves more or less 3-lobed, with scattered peltate laminar glands above .... 10. *C. smithianus*

10b. Lower nodes of bisexual inflorescences with solitary pistillate flowers (not with staminate flowers at the same nodes), or inflorescences unisexual.

13a. Styles twice bifid to multifid.

14a. Shrubs or trees; pistillate calyx lobes not strongly unequal, the abaxial ones not deeply lacerate.

15a. Pistillate bracts not deeply lacerate; staminate receptacle villose.

16a. Stamens 14–16; seeds costate or verrucose.

17a. Pistillate calyx lobes elliptic to oblong, valvate, neither reduplicate nor accrescent, glabrous within, less than 5 mm broad; staminate petals not over 4 mm long; leaves mostly 7–9-veined at base, entire; petioles mostly 5–20 cm long .... 11. *C. billbergianus*

17b. Pistillate calyx lobes ovate, reduplicate-valvate, accrescent, stellate-tomentose within, becoming 7–8 mm long and broad; staminate petals 4.5–5 mm long; leaves mostly 5-veined at base, entire to denticulate; petioles 1–4 cm long .... 12. *C. fragrans*

16b. Stamens 10–12; seeds smooth; staminate receptacle sparsely villose.

18a. Leaves mostly alternate (occasionally opposite at 1 or 2 distal nodes), 7–9-veined at base, the margins distinctly dentate (teeth 15–40 on a side), the basal laminar glands small or absent; stipules, bracts, and pistillate calyx lobes coarsely glandular-dentate; inflorescence with 3–12 pistillate flowers; filaments densely hirsutulous below; ovary usually densely stellate-tomentose .... 13. *C. hircinus*

18b. Leaves alternate below, opposite or ternate distally, pinnately veined or obscurely triplinerved, the basal laminar glands long-stipitate; stipules and bracts entire; pistillate calyx lobes entire or obscurely dentate; inflorescence with 1 or 2 (rarely 3) pistillate flowers; filaments glabrous; ovary sparsely stellate-pubescent apically ... 15. *C. brevipes*

15b. Pistillate bracts deeply lacerate; staminate receptacle glabrous; stamens 12–15 ... 14. *C. santaritensis*

14b. Annual herbs; pistillate calyx lobes very unequal, the adaxial ones greatly reduced or obsolete, the abaxial ones lacerate, accrescent (6–8 mm long in fruit); seeds smooth ... 16. *C. argenteus*

13b. Styles once bifid; annual herbs.

19a. Leaves coarsely and sharply serrate (major teeth usually not over 10 per side); stamens 8–10; styles less than 1.5 mm long, spreading ... 17. *C. trinitatis*

19b. Leaves more finely and/or bluntly toothed; stamens mostly 11 or 12; styles 1.5 mm long or more, ascending or erect; seeds minutely beaked.

20a. Stems coarsely hispid; leaves mostly ovate, pointed at the tip, petiolar glands stipitate; bracts with long gland-tipped processes ... 18. *C. hirtus*

20b. Stems not coarsely hispid; leaves mostly elliptic or oblong, blunt at tip, the petiolar glands sessile; bracts eglandular ... [C. *glandulosus*]

32.3. Croton tenuicaudatus Lundell, Phytologia 1: 451. 1940. TYPE: Costa Rica. San José: vicinity of El General, *Skutch 2575* (holotype, MICH).

Additional specimen examined. PANAMA. BOCAS DEL TORO: along road to Chiriquí Grande, 10 road mi. from Continental Divide and 2 mi. along pipeline access road E of highway, ca. 8°55′N, 82°08′W, 350–500 m, *McPherson 8767* (F).

32.5. Croton lanjouwensis Jabl., Mem. New York Bot. Gard. 12: 158. 1965. *C. matourensis* Aublet var. *benthamianus* Muell. Arg., Linnaea 34: 95. 1865. *C. benthamianus* (Muell. Arg.) Lanjouw, Euphorb. Surinam 17. 1931, non *C. benthamianus* Muell. Arg., Fl. Bras. 11(2): 106. 1874. TYPE: Brazil: Río Negro, *Spruce Croton 2* (isotype, NY).

Tree to ca. 12 m high; monoecious; twigs densely lepidote. *Leaves* with petioles lepidote, 1.5–3.5 cm long, distally with 2 large yellowish, subsessile, patelliform glands ca. 1.5–2 mm across; stipules linear-lanceolate, entire, densely lepidote, 8–10 mm long, early deciduous; blades chartaceous, elliptic to elliptic-oblong, acute to short-acuminate at tip, cuneate at base, mostly 8–15 cm long, 3.5–6.5 cm broad, smooth and glabrous above, densely lepidote beneath (scales denticulate-margined, ca. 0.25–0.4 mm across and nearly or quite contiguous); venation distinctly pinnate, the major lateral veins (ca. 11–15 on a side) straight; margins entire and lepidote-marginate. *Inflorescences* terminal, racemose, 13–15 cm long, bisexual; pistillate flowers solitary at 3–6 proximal axils; staminate flowers in cymules of 2 or 3 at distal axils; bracts entire, lepidote, up to 3 mm long. *Staminate flowers* with lepidote pedicels 2–5 mm long; calyx lobes 5, valvate, ovate-triangular, lepidote, 2–2.5 mm long; receptacle villose; petals obovate or narrowly elliptic, ca. 2 mm long, glandular-punctate, densely villose on margins, glabrous on back; stamens 12 or 13; filaments glabrous or sparsely hirsutulous; anthers elliptic, 0.6–0.7 mm long. *Pistillate flowers* with stout lepidote pedicels becoming 8–15 mm long; calyx lobes 5, equal, triangular, ± reduplicate-valvate, lepidote without, ± stellate-lepidote within on the recurved margins, 4.5–5 mm long; disk 5-lobed, adnate to calyx; petals rudimentary (shorter than 1 mm long); ovary densely lepidote (scales ca. 0.6–0.8 mm across); styles twice-bifid, ca. 4 mm long, stellate proximally (branches glabrous). *Capsules* not seen entire; cocci lepidote, ca. 5 mm long; columella slender, ca. 4 mm long; seeds plump, scarcely compressed, brownish, smooth, ca. 3.5 mm long.

The Panamanian plants appear to agree in most respects with *C. lanjouwensis* as defined by Lanjouw (1931: 12–17; as *C. benthamianus*); the broad pistillate calyx with adaxially stellate lobes is apparently diagnostic in separating the species from *C. matourensis* Aublet. However, the Panamanian plants occurring in cloud forest at 800–1,000 m would appear to differ ecologically from the Amazonian plants, which have been collected in lowland rainforests. Jablonski (1965: 157–158) cited *C. matourensis* from comparable altitudes in Venezuela; further comparisons of plants from Panama with the South American plants evidently are needed. The specimens from Panamá Province differ rather strikingly in their duplex petiolar glands, sparsely lepidote upper leaf surfaces, and shorter pistillate pedicels.

Specimens examined. PANAMA. BOCAS DEL TORO: along road to Chiriquí Grande, ca. 1.5 mi. along road E of highway, ca. 8°55′N, 82°10′W, 250–350 m, *McPherson & Allen 9640* (F). COCLÉ: Cerro Pilón, near El

Valle, ca. 900 m, *Duke & Correa 14718* (DAV, MO); cloud forest, hills N of El Valle de Antón, *Dressler 4083* (DAV, MO); cloud forest, El Valle, 800–1,000 m, *Duke 13166* (DAV, MO), *Dwyer & Correa 7951* (DAV, MO), *Correa 311* (MO). PANAMÁ: primary forest, road from El Llano to Cartí-Tupile, 200–500 m, *Croat 22905* (DAV, MO).

32.6. Croton pachypodus Webster, sp. nov. TYPE: Panama. San Blas: km 18 of El Llano–Cartí road, 9°19′N, 78°55′W, 350 m, 1 Oct. 1984, *de Nevers & Herrera 3980* (holotype, MO; isotypes, DAV, F).

Species haec ab *C. pyritico* differt foliis supra glabris petiolo glandulato, ab *C. lanjouwense* differt seminibus majores, ab aliis speciebus Centroamericanis differt pedicellis valde incrassatis.

Tree 7–25 m high; twigs obtusely angular, glabrate. *Leaves* with petioles lepidote, 0.8–1.5 cm long, distally (near base of blade) with 2 subsessile or short-stipitate (to 0.7 mm) blackish patelliform glands 0.5–1 mm across; stipules linear-lanceolate, entire, densely lepidote, 4–10 mm long, 0.9–1.2 mm broad, ± persistent; blades chartaceous, elliptic-oblong to somewhat obovate, subacute or acute to abruptly short-acuminate at tip, cuneate to rounded at base, 8–22 cm long, 3.5–7 cm broad, smooth and glabrate above (with sparse scales on major veins when young), evenly and sparsely lepidote beneath (scales 0.25–0.4 mm across, denticulate, with ca. 50 radii), the scales widely separated; venation distinctly pinnate, the major lateral veins (9–13 on a side) straight or slightly curving, the veinlet reticulum prominulous beneath; margins entire, smooth, without lepidote rim. *Inflorescences* terminal and axillary, racemose, (5–)10–15 cm long, bisexual or staminate; pistillate flowers solitary at lowermost (1–)2–4(–5) nodes of bisexual inflorescences, staminate flowers solitary or paired at distal axils; bracts triangular, blackish, sparsely lepidote, 0.5–1 mm long. *Staminate flowers* (buds only observed) with lepidote pedicels 1.5–2.5 mm long; calyx lobes 5, valvate, triangular, lepidote, ca. 3 mm long; receptacle villose; petals narrowly elliptic, ca. 2.5 mm long, densely villose on margins, sparsely lepidote (often a single scale) on the back, densely hirsutulous adaxially; stamens 14–16, the filaments glabrous, the anthers 0.8–0.9 mm long. *Pistillate flowers* with stout lepidote pedicels ca. 2.5–3.5 mm long, becoming in fruit 4.2–6.5 mm long, 3.2–4 mm broad; calyx lobes 5, equal, triangular-ovate, reduplicate-valvate, densely lepidote without, densely tomentose-villose within, 3–3.5 mm long, 2.5–3 mm broad; disk shallowly 5-lobed, nearly 4 mm across, smooth and glabrous; petals obsolete, represented by whitish tufts of hairs; ovary densely lepidote (scales 0.5–0.8 mm across, denticulate, 50–70-radiate, with 20–30 darkened radii); styles blackish, twice-bifid, 3.5–4 mm long, nearly glabrous. *Capsules* not seen entire; valves of cocci ca. 23–25 mm long; columella slender, ca. 20 mm long; seeds elliptic, somewhat compressed, flattened and obscurely carinate on the back, distinctly keeled on inner face, grayish brown, smooth and shining, 16.2–17.2 mm long, 10.3–11.3 mm broad; caruncle hippocrepiform, obscure, tenuous, ca. 2.5 mm long, 1.5 mm broad.

Collections of this species have been determined as *C. lanjouwensis*, to which indeed it is related and superficially very similar. However, it is distinguished by leaves very sparsely lepidote beneath and with margins free of scales, shorter petioles with smaller darker glands, and especially by the much larger fruits borne on greatly thickened pedicels. Among species earlier reported from Panama, the new species resembles *C. tenuicaudatus*; however, that species has eglandular leaves lepidote on both faces, strongly lepidote staminate petals, and more slender pistillate pedicels. *Croton pyriticus* appears to be even less similar because of its ovate palmately veined eglandular leaves, longer and more slender (1.5 mm or thinner) pistillate pedicels, and verruculose capsules; however, the seeds, although larger, are similar in shape to those of *C. pachypodus*.

Additional specimens examined. PANAMA. SAN BLAS: 12 mi. above Pan-American Hwy., 200–500 m, *Croat 22905* (MO); 20.7 km from Pan-American Hwy., 350 m, *Mori & Kallunki 5116* (MO).

32.7. Croton speciosus Muell. Arg. [Linnaea 34: 83. 1865] subsp. **tacarcunensis** Webster, subsp. nov. TYPE: Panama. Darién: Cerro Tacarcuna, S slope, premontane wet forest on ridge below summit, 1,250–1,450 m, *Gentry & Mori 13925* (holotype, MO; isotype, DAV).

Haec a subsp. *specioso* differt stipulis minoribus, glandulis petioli brevioribus, carunculo seminis ca. 2 mm lato.

Monoecious *tree* 5 m high; twigs subterete, densely tawny-villose with dendritic hairs. *Leaves* with petioles (2–)3–11 cm long, tomentose, apically with 4–6 stalked glands on ventral side, the glands ca. 0.8–1.5 mm long, 0.3–0.4 mm across; stipules lanceolate, densely tomentose, toothed, 3–6 mm long; blades membranous, mostly ovate, long-acuminate at tip, rounded to subcordate at base, the larger ones shallowly 3-lobed, 12–21 cm long, 7–12 cm broad; lamina above copiously pubescent with stellate-tufted hairs, beneath copiously tomentose with whitish dendritic hairs ca. 0.5–1 mm across, 3–5-nerved at base, with 7–10 major lateral veins on each side, connected by a scalariform reticulum of straightish veinlets; margins subentire (obscurely denticulate). *Inflorescences* terminal (or pseudolateral), bisexual, racemose, 2.5–6 cm long, with 1 or 3 proximal flowers and 3–7 distal flowers; flowers solitary at each node; bracts 5–7 mm long, attenuate-acuminate, tomentose, with subulate stipules ca. 3–5 mm long. *Staminate flowers* with stellate-tomentose pedicels 5–8 mm long; receptacle densely tomentose; calyx lobes 5, fulvous-tomentose, obtuse, entire, 3.5–5 mm long; petals obovate, 4.5–5 mm long, densely appressed-pubescent without, glabrous within, woolly-villose along margins; stamens ca. 60–70; filaments slender, glabrous, ca. 4–5 mm long; anthers oblong, apiculate, 1.2–1.6 mm long, 0.5–0.7 mm broad. *Pistillate flowers* with stout tomentose pedicels ca. 2–4 mm long at anthesis (becoming up to 1 cm long in fruit); calyx segments 5, valvate, oblong, densely whitish- to fulvous-tomentose without, sparsely tomentose in distal third within, ca. 10 mm long, 3–5 mm broad; disk inconspicuous, adnate to base of calyx, crenulate, stellate-pubescent, ca. 5 mm across; petals rudimentary, densely hirsute, ca. 1–1.5 mm long; ovary densely fulvous-tomentose; styles twice-bifid near the base, densely stellate-pubescent below (and with scattered stellate hairs distally nearly to tips), ca. 7–9 mm long, the branches dark reddish, dilated and crenulate at tips. *Capsules* subglobose, fulvous-hispidulous, ca. 1 cm long and broad; seeds plump, plumbeous brown, distinctly costate ventrally, obscurely costate on back, ca. 7 mm long, 5 mm broad; caruncle roundish, low, ca. 2 mm across.

This striking *Croton* from the cloud forests at the crest of Cerro Tacarcuna appears to be conspecific with *C. speciosus*, which was described from specimens collected near Caracas, Venezuela. I have examined *Moritz 1329* (A, GH) from Galipán, near Caracas, one of the syntypes cited by Mueller (incorrectly located by him as in Colombia rather than Venezuela), as well as three other collections from near Galipán (*Allart s.n.*, *Pittier 221*, *9577*, A, GH). These plants in general rather closely resemble the Cerro Tacarcuna specimens in leaf shape and pubescence, flower configuration, and seeds; there can be little doubt that we are dealing with a single species. The stamen number in the Venezuelan plants varies from 40 to 80 and hence includes the number for the Cerro Tacarcuna plants. Mueller gave the stamen number of *C. speciosus* as ca. 150, which certainly does not agree with *Moritz 1329*, in which two buds yielded ca. 70 and ca. 80 stamens. Possibly the number may become higher in some Venezuelan plants, as Mueller (1866: 529) also cited two other collections from near Caracas, *Fendler 34* and *231* (cited as *Linden 34* and *201*), which we have not seen.

The publication of a separate subspecies for the Tacarcuna population is made diffidently, as intervening collections may close the gap. However, the Panamanian plants differ strikingly in their much smaller and less lacerate stipules, as well as in having distinctly shorter stalked glands at the apex of the petiole. Furthermore, the caruncle in seeds from Panama is roundish and ca. 2 mm broad, whereas it is distinctly laterally expanded and ca. 3 mm broad in seeds from Venezuela. Provisionally, therefore, it seems best to designate the Cerro Tacarcuna plants as a distinct subspecies.

Additional specimens examined. PANAMA. DARIÉN: S slope of westernmost peak of Cerro Tacarcuna, 1,100–1,300 m, *Gentry et al. 16877* (MO); ridgetop below Alto de Nique base camp, *Gentry et al. 28727* (MO).

32.8. Croton draco Cham. & Schldl. [Linnaea 6: 360. 1831] subsp. **panamensis** (Klotzsch) Webster, stat. nov. *Cyclostigma panamense* Klotzsch in Seem., Bot. Voy. Herald 105. 1853. *Croton panamensis* (Klotzsch) Muell. Arg. in DC., Prodr. 15(2): 546. 1866. TYPE: Panama. Chiriquí: Volcán Chiriquí, *Seemann* (K, not seen). (see Webster & Burch, 1968: 254 for additional synonymy.)

Further examination of Mexican and Central American specimens of *Croton draco* indicates that the Panamanian plants cannot reasonably be maintained as a separate species. Except for the larger, broader stipules (mostly 2 mm or more across), the Mexican populations here assigned to subsp. *draco* show no essential differences from plants with narrow stipules that occur from Guatemala (and sporadically in southern Mexico) to Panama and Colombia.

32.10. Croton smithianus Croizat, J. Arnold Arbor. 21: 93. 1940. TYPE: Colombia. Santander: Mesa de los Santos, *Killip & Smith 15283* (holotype, A; isotype, US).

Tree to 18 m high; twigs angled or sulcate, yellowish-scurfy with pedicellate stellate hairs. *Leaves* with petioles mostly 5–15 cm long; patelliform glands at apex of petiole sessile, 0.9–1.2 mm across; stipules linear-lanceolate to spathulate, 5–9 mm long, 1–2 mm broad; blades mostly ovate, sometimes 3-lobed, blunt to acuminate at the tip, cordate to subcordate at base, the larger ones 15–35 cm long, 10–30 cm broad; venation palmate, with 5(–7) major veins at base, 5–8 laterals on each side above the base, the laterals sometimes dichotomizing towards the margin; veins and veinlets prominulous on both sides, the veinlets scalariform; trichomes on upper surface pedicellate-stellate, 0.2–1 mm across, with stalks 0.1–0.5 mm high, beneath denser and ± floccose; small patelliform glands (0.4–1 mm across) occasional on upper surface; margins denticulate, with occasional small stalked glands. *Inflorescences* terminal, mostly 20–50 cm long; 5–15 proximal cymules bisexual, distal ones staminate; staminate bracts subulate, entire, deciduous, ca. 1–2.5 mm long, subtending several flowers. *Staminate flowers* with stellate-tomentose pedicels 1.5–5 mm long; calyx distinctly gamophyllous, 3.5–4 mm long; calyx lobes ovate, acute, valvate, 2.2–3.7 mm long, 2–2.8 mm broad; petals narrowly spathulate, 3.2–4.5 mm long, 0.5–1 mm broad, densely villose ventrally, strigose-hirsutulous dorsally; receptacle densely villose; stamens 11 or 12; filaments flattened, densely hirsutulous in lower ¾, 3–4.5 mm long; anthers elliptic, the connective glandular-pustulate, 1.1–1.5 mm long. *Pistillate flowers* with stellate-lepidote pedicels becoming 9–14 mm long; calyx lobes 5, valvate (not distinctly reduplicate), elliptic to ovate, entire, stellate-lepidote (trichomes 0.1–0.4 mm across) outside, stellate inside near tip and along margins, 5–7.5 mm long, 3.5–6.5 mm broad; disk entire, thickish, ca. 1.7 mm across; ovary yellowish-stellate or stellate-hispid, trichomes 0.5–1.5 mm across in fruit; styles free, multifid, sparsely to copiously stellate-hispid, ca. 5 mm long. *Capsules* subglobose, yellowish with appressed scales; columella ca. 4 mm long; seeds plump, lenticular, brownish, finely costate-rugulose, bluntly pointed at both ends, 3.9–4.1 mm long, 3.3–3.5 mm broad; caruncle flat, bilobed, 1.7–2.1 mm broad.

Croton smithianus is found in lowland and lower montane forests, up to ca. 1,500 m elevation, Nicaragua to Colombia, flowering July to September.

The Panamanian representative of the widespread and variable South American species complex centering on *Croton palanostigma* Klotzsch is here referred to *C. smithianus* Croizat because of its characteristic indumentum of pedicellate stellate trichomes. The populations in Colombia are rather variable and poorly understood; the isotype at US, which is a fruiting specimen, has the characteristic indumentum, and a specimen from Chocó (*Archer 2062*, US) has the characteristic leaf form and margin, but the trichomes are not distinctly pedicellate as in the Panamanian plants. The Panamanian and Colombian plants somewhat resemble *Croton killipianus* Croizat, described from Boyacá; however, the type collection of that species (*Lawrance 588*; isotype, US) has subentire leaf margins and an appressed, rather sparse indumentum more characteristic of *C. benthamianus* Muell. Arg. *Croton nuntians* Croizat from Guyana is somewhat similar but differs in its smaller fruiting calyx and shorter fruiting pedicel. Until this species complex is revised, it seems best to refer our plants to *C. smithianus*. Several collections from Nicaragua and Costa Rica are also referred to that species.

Specimens examined. COSTA RICA. HEREDIA: Finca La Selva, *Hammel & Trainer 12849, 13044* (DAV, DUKE). PUNTARENAS: forest remnants along highway 4 mi. SE of turnoff to Buenos Aires, 9°07′N, 83°17′W, 400 m, *Webster 21883* (DAV, MO); rainforest 17 mi. SE of San Isidro General, 700 m, *Webster & Miller 12394* (DAV). NICARAGUA. RÍO SAN JUAN: Sábalo, *Araquistain 3223* (DAV, MO). ZELAYA: Bluefields, *Neill 2598* (DAV, MO). PANAMA. COLÓN: Río Salud, *Howell 128*, *Lao & Holdridge 224* (MO). DARIÉN: between Manené and Tusijuanda, *Duke 13576* (DAV). PANAMÁ: SE slopes of Cerro Trinidad, *Kirkbride & Duke 1665* (MO).

32.11. Croton billbergianus Muell. Arg., Linnaea 34: 98. 1865; subsp. billbergianus. TYPE: Panama. Colón: Portobelo, *Billberg 316* (not seen).

This species has been collected in three additional provinces.

Additional specimens examined. PANAMA. BOCAS DEL TORO: Súrsuba, Río Changuinola, *Dwyer s.n.* (MO). SAN BLAS: Puerto Obaldía to La Bonga, *Knapp & Mallet 4667* (MO). VERAGUAS: Coquyito mine to Río Barrera, *Hammel 5221* (MO); Santa Fe, *Folsom & Edwards 3392* (MO).

The description in the original treatment (Webster & Burch, 1968: 257–258) applies only to subsp. *billbergianus*. As suggested at that time, *C. pyramidalis* J. D. Smith, extending from Veracruz, Mexico, to Honduras, does not appear to be a distinct species. It may be retained at the subspecific level because of its apparently larger seeds (5.7–6.2 mm in the Veracruz population vs. 4.3–5.5 mm in the Panamanian plants) and longer

stipules (7–15 mm long vs. 5–7 mm in the Panamanian plants). A new combination for the Mexican plant is therefore necessary.[5]

32.13. Croton hircinus Vent., Jard. Malmaison 1: 50, pl. 50. 1804. TYPE: cultivated specimen, *Ventenat* (presumably at G, not seen).

An additional provincial record is cited.

Additional specimen examined. PANAMA. CHIRIQUÍ: Río Cobre bridge, 25 mi. W of Tole, *Dwyer & Hayden 7542* (MO).

32.14. Croton santaritensis Huft, sp. nov. TYPE: Panama. Colón: Santa Rita Ridge Road, 21–26 km from Transisthmian Highway, tropical wet forest, 500–550 m, 9°25′N, 79°37′W, 4 July 1982, *Knapp 5882* (holotype, MO; isotypes, DAV, F, F neg. 62353, PMA). Figure 3.

Frutex monoecus dense villosus, pilis castaneus stellatis. Folia ovata-oblonga vel lanceolata, basi subcordata vel rotundata, apice longicaudata; glandulae petiolares aliquot tubaeformes, stipulae ovatae-deltatae margine fimbriatae. Inflorescentiae unisexuales racemosae, masculinae terminales, femineae axillares; bracteae femineae flabellatae profunde laciniatae flores includentes.

Shrub ca. 1.5 m high; monoecious; twigs subterete, densely villous with brownish stellate hairs. *Leaves* with petioles densely villous as the twigs, 5–20 mm long; petiolar glands several at apex of petiole, stipitate, trumpet-shaped, 0.5–1.5 mm long, 0.3–0.5 mm across; stipules ovate-deltate, membranous, eglandular, appressed, 8–11 mm long, 4–6 mm broad, the margins fimbriate; blades chartaceous, ovate, ovate-oblong, or lanceolate, long-caudate at apex, rounded to subcordate at base, 10–15 cm long, 4–8 cm broad, 1.7–3 times as long as broad, sparsely to moderately stellate pubescent above, sparsely tomentose below, 3–7-nerved at base, the secondary veins 5–8 per side; margin entire to remotely denticulate. *Inflorescences* unisexual, racemose, the staminate ones terminal, the pistillate ones axillary, occurring only at the two subopposite nodes immediately below the terminal staminate raceme; staminate inflorescences 17–22 cm long, densely brown stellate-villous; nodes 15–30; flowers 1–3 at each node on stellately pubescent pedicels 6–9 mm long, the bracts subulate, 2–3 mm long, stellate below, glabrous above; pistillate inflorescences 5–11 cm long, densely brown-villous; bracts flabellate, deeply laciniate, 10–12(–14) mm long, at least the lower ones loosely enclosing the flower buds. *Staminate flowers*: sepals 5, deltate, joined at base, valvate, stellately pubescent, the lobes 2.5–3 mm long, ca. 2 mm broad; petals 5, only slightly exceeding the calyx lobes, ca. 6 mm long, ca. 2 mm broad below the tip, the tip abruptly expanded, ca. 2.5 mm broad, coarsely erose; stamens 12–15; disk consisting of 5 nearly separate glands; receptacle glabrous. *Pistillate flowers* (immature): sepals 5, deltate, fleshy; ovary densely stellate-hispidulous; styles twice-divided. Mature fruits and seeds not seen.

This species may easily be distinguished from all other Central American species of *Croton* by the peculiar arrangement of the inflorescences, the conspicuous fimbriate stipules, and the oblong, laciniate bracts that loosely enclose the young pistillate flowers.

No close relative of *C. santaritensis* is known. Because of its combination of pentamerous calyces in both pistillate and staminate flowers, five petals and glabrous receptacles in the staminate flowers, and the large fimbriate stipules and bracts, it is not easily accommodated in any of the sections recognized by Mueller (1866: 511–700) in the most recent worldwide account of *Croton*. No species closely resembling *Croton santaritensis* has been found among the large holdings of South American *Croton* at the Field Museum or the Missouri Botanical Garden.

32.15. Croton brevipes Pax, Bot. Jahrb. Syst. 33: 290. 1903. TYPE: Costa Rica. Río del Convento, *Pittier 12117* (isotype, US, photo, F).

FIGURE 3. Croton santaritensis.—*A. Habit, with staminate and pistillate inflorescences.—B. Detail of leaf base, showing glands.—C. Trichome from upper leaf surface.—D. Trichome from lower leaf surface.—E. Trichome from stem.—F. Staminate flower.—G. Staminate petals, abaxial view on left, adaxial on right.—H. Pistillate bract, abaxial view.—I. Pistillate flower in bud, cut-away view. Based on* Knapp 5882. *Illustration by Clara Richardson.*

Shrub 1–3 m high; monoecious; twigs pale, appressed-stellate. *Leaves* alternate below, mostly opposite or ternate above; petioles densely appressed-stellate, 3–20(–30) mm long (less than ¼ length of blade); petiolar glands (at base of blade) conspicuous, cylindrical, apically truncate and dilated, 1–2.5 mm long, 0.3–0.5 mm across; stipules subulate to narrowly lanceolate, dark, entire, eglandular, stellate-pubescent, 1.4–2.8 mm long; blades thinly chartaceous, elliptic to ovate-elliptic or obovate, acute to acuminate at tip, cuneate to obtuse at base, 4–13 cm long, (1–)2–5 cm broad, sparsely stellate or appressed-hispid above with few-rayed trichomes, sparsely appressed-stellate and inconspicuously glandular-punctate beneath, pinnately veined (or inconspicuously triplinerved) with mostly 5–7 veins on each side; margins subentire to rather coarsely and irregularly dentate (teeth ca. 8–15 on a side), with stalked glands between some of the teeth. *Inflorescences* mostly terminal and bisexual (some also lateral and staminate), racemose, 1.5–3(–4.5) cm long, with 1 or 2 (rarely 3) basal solitary pistillate flowers, the staminate flowers 1 or 2 per bract at distal axils; bracts narrow, entire, eglandular, stellate-pubescent, mostly 1.5 mm long or shorter. *Staminate flowers* with sparsely stellate or nearly glabrous pedicels 1–2 mm long; calyx lobes 5, elliptic-lanceolate, acute, stellate-pubescent, glandular-punctate, 1.2–1.7 mm long, 0.9–1.1 mm broad; receptacle moderately villose; petals obovate-spathulate, 1.4–1.8 mm long, glandular-punctate, barbate-hirsute on lower margins; stamens 10–12; filaments glabrous, 1.8–2.5 mm long; anthers ovate, 0.5–0.7 mm long. *Pistillate flowers* with stout appressed-stellate pedicels becoming 1.3–3.5 mm long; calyx lobes 5, subequal, narrowly oblong-lanceolate or spathulate, subentire (with 1 or 3 obscure teeth), sparsely stellate outside, glabrous inside, 3.5–6.5 mm long, 1–1.5 mm broad; petals rudimentary, subulate; disk entire, glabrous; ovary sparsely stellate-pubescent apically, glabrous below; styles free, ca. 2 mm long, twice bifid, glabrous to hispidulous. *Capsules* subglobose, sparsely stellate-pubescent or glabrescent, ca. 5 mm diam.; columella slender, 3.2–4 mm long; seeds broadly ellipsoid, compressed, apically beaked, brownish, nearly smooth (minutely striolate), 3.8–4.1 mm long, 2.8–3.4 mm broad, the caruncle small, ca. 0.5–0.8 mm across.

Rainforest below 1,000 m, Costa Rica and Panama.

This plant bears a considerable resemblance in habit to *C. hircinus* but differs in having (distally) opposite or ternate pinnately veined leaves with larger laminar glands; the stipules, bracts, and calyx lobes lack the glandular serrations of *C. hircinus.* Examination of material of *Croton macrodontus* Muell. Arg. from Mexico shows that it is extremely close to *C. brevipes.* Although specimens from Costa Rica and Panama may be easily recognized by their distally opposite, less coarsely toothed leaves with more rounded bases and shorter petioles, they are very similar to the Mexican plants in most details, including pubescence, floral details, and fruits. The seeds of the Mexican plants are somewhat larger, but this difference may disappear upon further sampling. Provisionally, the two species may be kept distinct on the basis of the foliar characters, and because no intermediate populations have yet been discovered in Central America between Costa Rica and Mexico.

Specimens examined. PANAMA. COLÓN: Santa Rita Ridge, ca. 300 m, *Antonio 3739* (DAV, F, MO), *Correa & Dressler 912* (F, MO), *Croat 13898* (MO), *Duke 15291* (MO), *Dwyer 8543* (MO), *Dwyer & Gentry 9395* (F, MO), *Foster 1751* (DAV, DUKE, F), *Gentry 1874* (DAV, F, MO), *Kennedy 2756* (MO), *Knapp 5845* (DAV, F, MO), *Sytsma* 2047 (MO), *2054* (F, MO), *Webster & Dressler 16727* (DAV, MO, US); East Ridge, *Duke 15291* (DAV). 32.16. Croton argenteus L., Sp. Pl. 1004. 1753. *Julocroton argenteus* (L.) Didr., Vidensk. Meddel. Dansk Naturhist. Foren. Kjøbenhavn 1857(8–10): 134. 1857; Muell. Arg. in DC., Prodr. 15(2): 703. 1866; Croizat, Revista Argent. Agron. 10: 125. 1943; Correll & Johnston, Man. Vasc. Plants Texas 939. 1970. TYPE: America (not seen; presumably in Hortus Cliffortianus Herbarium, BM; 1140.8 in LINN).

Annual herb 2–10 dm high; stems pseudodichotomizing, with long internodes and pseudoverticels of leaves, appressed stellate-puberulent. *Leaves* with petioles 1–5 cm long, these without paired apical glands; stipules subulate, (2.5–)5–10 mm long; blades chartaceous, ovate or the upper ones oblong-ovate, obtuse or rounded to subacute at tip, cuneate to rounded at base, mostly 3–7(–15) cm long, 2.5–5 cm broad, 5-veined at base; lateral veins above base 3 or 4 on each side, not prominent; above green and finely appressed-stellate, beneath grayish and more densely stellate; margins finely serrulate. *Inflorescences* terminal, bisexual, ca. 1–4 cm long; bracts subtending solitary flowers, the pistillate flowers 4–6 at base of spike; staminate bracts subulate, entire, ca. 3 mm long. *Staminate flowers* with pedicels ca. 1.5–2.5 mm long; calyx lobes lanceolate, acute, valvate, ca. 1.5–2 mm long; petals linear, 2.1–2.3 mm long, 0.3–0.4 mm broad, glabrous except for the ciliate margins; receptacle copiously villose; stamens usually 11; filaments sparsely to rather copiously appressed-hirsutulous, ca. 2–2.5 mm long; anthers elliptic-oblong, 0.6–0.8 mm long. *Pistillate flowers* with short pedicels ca. 1–1.5 mm long, becoming 3–5 mm long in fruit; calyx lobes 5, imbricate, very unequal, the 3 abaxial lobes much larger, in fruit 6–8 mm long, 2.5–6 mm broad, oblong, laciniate, provided on each side with 5–10 teeth ca. 0.5–3 mm long, the 2 abaxial lobes much smaller, nearly or quite obsolete; petals absent; disk strongly asymmetrical, with larger adaxial lobes 0.9–1.2 mm long, 0.5–0.7 mm broad, the 2 adaxial lobes very small; ovary stellate-tomentellous; styles erect, distally quadrifid, hispid-stellate, ca. 2–4 mm long. *Capsules* ca. 5 mm long; columella 3–4.5 mm long; seeds ellipsoid, smooth, mottled gray and brown, apically beaked, 3.1–4 mm long, 2.4–2.9 mm broad; caruncle ca. 1.5 mm broad.

Scattered in weedy habitats from extreme southern Texas to Panama, reappearing in Venezuela, Paraguay, and Argentina, but not reported from most of tropical South America. The two Panamanian collections may represent recent introductions.

Specimens examined. PANAMA. PANAMÁ: marsh area 2 mi. S of Tocumen Airport, *Tyson & Clewell 5899* (MO); Río Tapia, *Bartlett & Lasser 16629* (MO).

Subfamily IV. EUPHORBIOIDEAE

33. *Mabea*

Mabea Aublet, Hist. Pl. Guiane 867. 1775. TYPE: *Mabea piriri* Aublet.

RECENT LITERATURE

HUFT, M. J. 1987. Notes on *Mabea* (Euphorbiaceae) in Central America, together with comments on sect. *Apodae* in Brazil. Phytologia 62: 339–343.

STEINER, K. E. 1983. Pollination of *Mabea occidentalis* (Euphorbiaceae) in Panama. Syst. Bot. 8: 105–117.

The discovery of a distinctive new species of *Mabea* in Panama makes it necessary to provide a new key to the three species now known from the country.

KEY TO THE SPECIES OF *MABEA* IN PANAMA

1a. Leaves acute or subacuminate at apex, usually 3–5 times as long as broad; bracteal glands of the staminate cymules not elevated above the rachis; stamens 15–20 per staminate flower .... 1. *M. montana*

1b. Leaves cuspidate to long-acuminate at apex, usually less than 3 times as long as broad.
  2a. Bracteal glands of the staminate cymules not elevated above the rachis; stamens more than 30 per staminate flower; undivided portion of the style at maturity 12–20 mm long .... 2. *M. occidentalis*
  2b. Bracteal glands of the staminate cymules elevated above the rachis; stamens 10–15 per staminate flower; undivided portion of the style at maturity 4–9 mm long .... 3. *M. jefensis*

33.1. Mabea montana Muell. Arg. in DC., Prodr. 15(2): 1151. 1866. TYPE: Colombia: *Schlim 1132.* Venezuela: *Fendler 24.* Panama: *Sutton Hayes 715* (syntypes, not seen).

Additional collections examined. PANAMA. VERAGUAS: roadside between Santa Fe and San José, *D'Arcy 10314* (MO); 5 km S of Santa Fe, below 500 m, *Folsom & Collins 1644* (MO); a 1 km del puente sobre el desvío del Río San Juan, *Luna 47* (MO).

33.3. Mabea jefensis Huft, Phytologia 62: 341. 1987. TYPE: Panama. Panamá: newly bulldozed trail off Cerro Jefe Road, 0.4 km beyond turnoff to Alto de Pacora, 29 Sep. 1975, *J. T. & F. Witherspoon 8570* (holotype, MO, F neg. 62352). Figure 4.

Montane and premontane rainforests of Central Panama, 350–1,000 m.

Mabea jefensis is known from abundant collections from both the Cerro Jefe area and from the Continental Divide north of El Llano in eastern Panamá Province, as well as from a single collection from the Cañazas mountain range in the western part of the province. It seems likely that this species will prove to be common in the mountainous region along the border of Panamá and San Blas provinces as this area becomes more thoroughly explored.

Additional specimens examined. PANAMA. PANAMÁ: Cerro Jefe area, *Antonio et al. 3399* (F), *Correa et al. 1601, 1610* (MO), *Croat 13031, 14438* (MO), *D'Arcy & D'Arcy 6253* (MO, 2 sheets), *D'Arcy 12185* (MO), *12201* (F), *D'Arcy & Sytsma 14733* (F, MO), *Duke 9474* (MO), *Dwyer et al. 7296* (MO, 2 sheets), *7364* (MO), *Folsom et al. 6709, 7105* (MO), *Hammel 3735* (MO), *Knapp 867* (F), *Liesner 531* (MO), *Porter et al. 5072* (MO), *Sytsma 1475, 4112* (F), *Sytsma et al. 2849* (F), *Sytsma & D'Arcy 3660* (F), *Tyson et al. 3204* (MO), *4355* (MO, 2 sheets), *Tyson 3399* (MO, SCZ), *Wilbur & Weaver 11360* (MO); La Eneida, *Correa & Dressler 824* (MO), *Maas et al. 1567* (MO); El Llano–Cartí road, 6–22 km N of Inter-American Highway, 300–500 m, *Croat 25127, 33805* (MO), *Hammel 867* (MO), *Huft & Knapp 1594, 1613* (MO), *Huft et al. 1868*

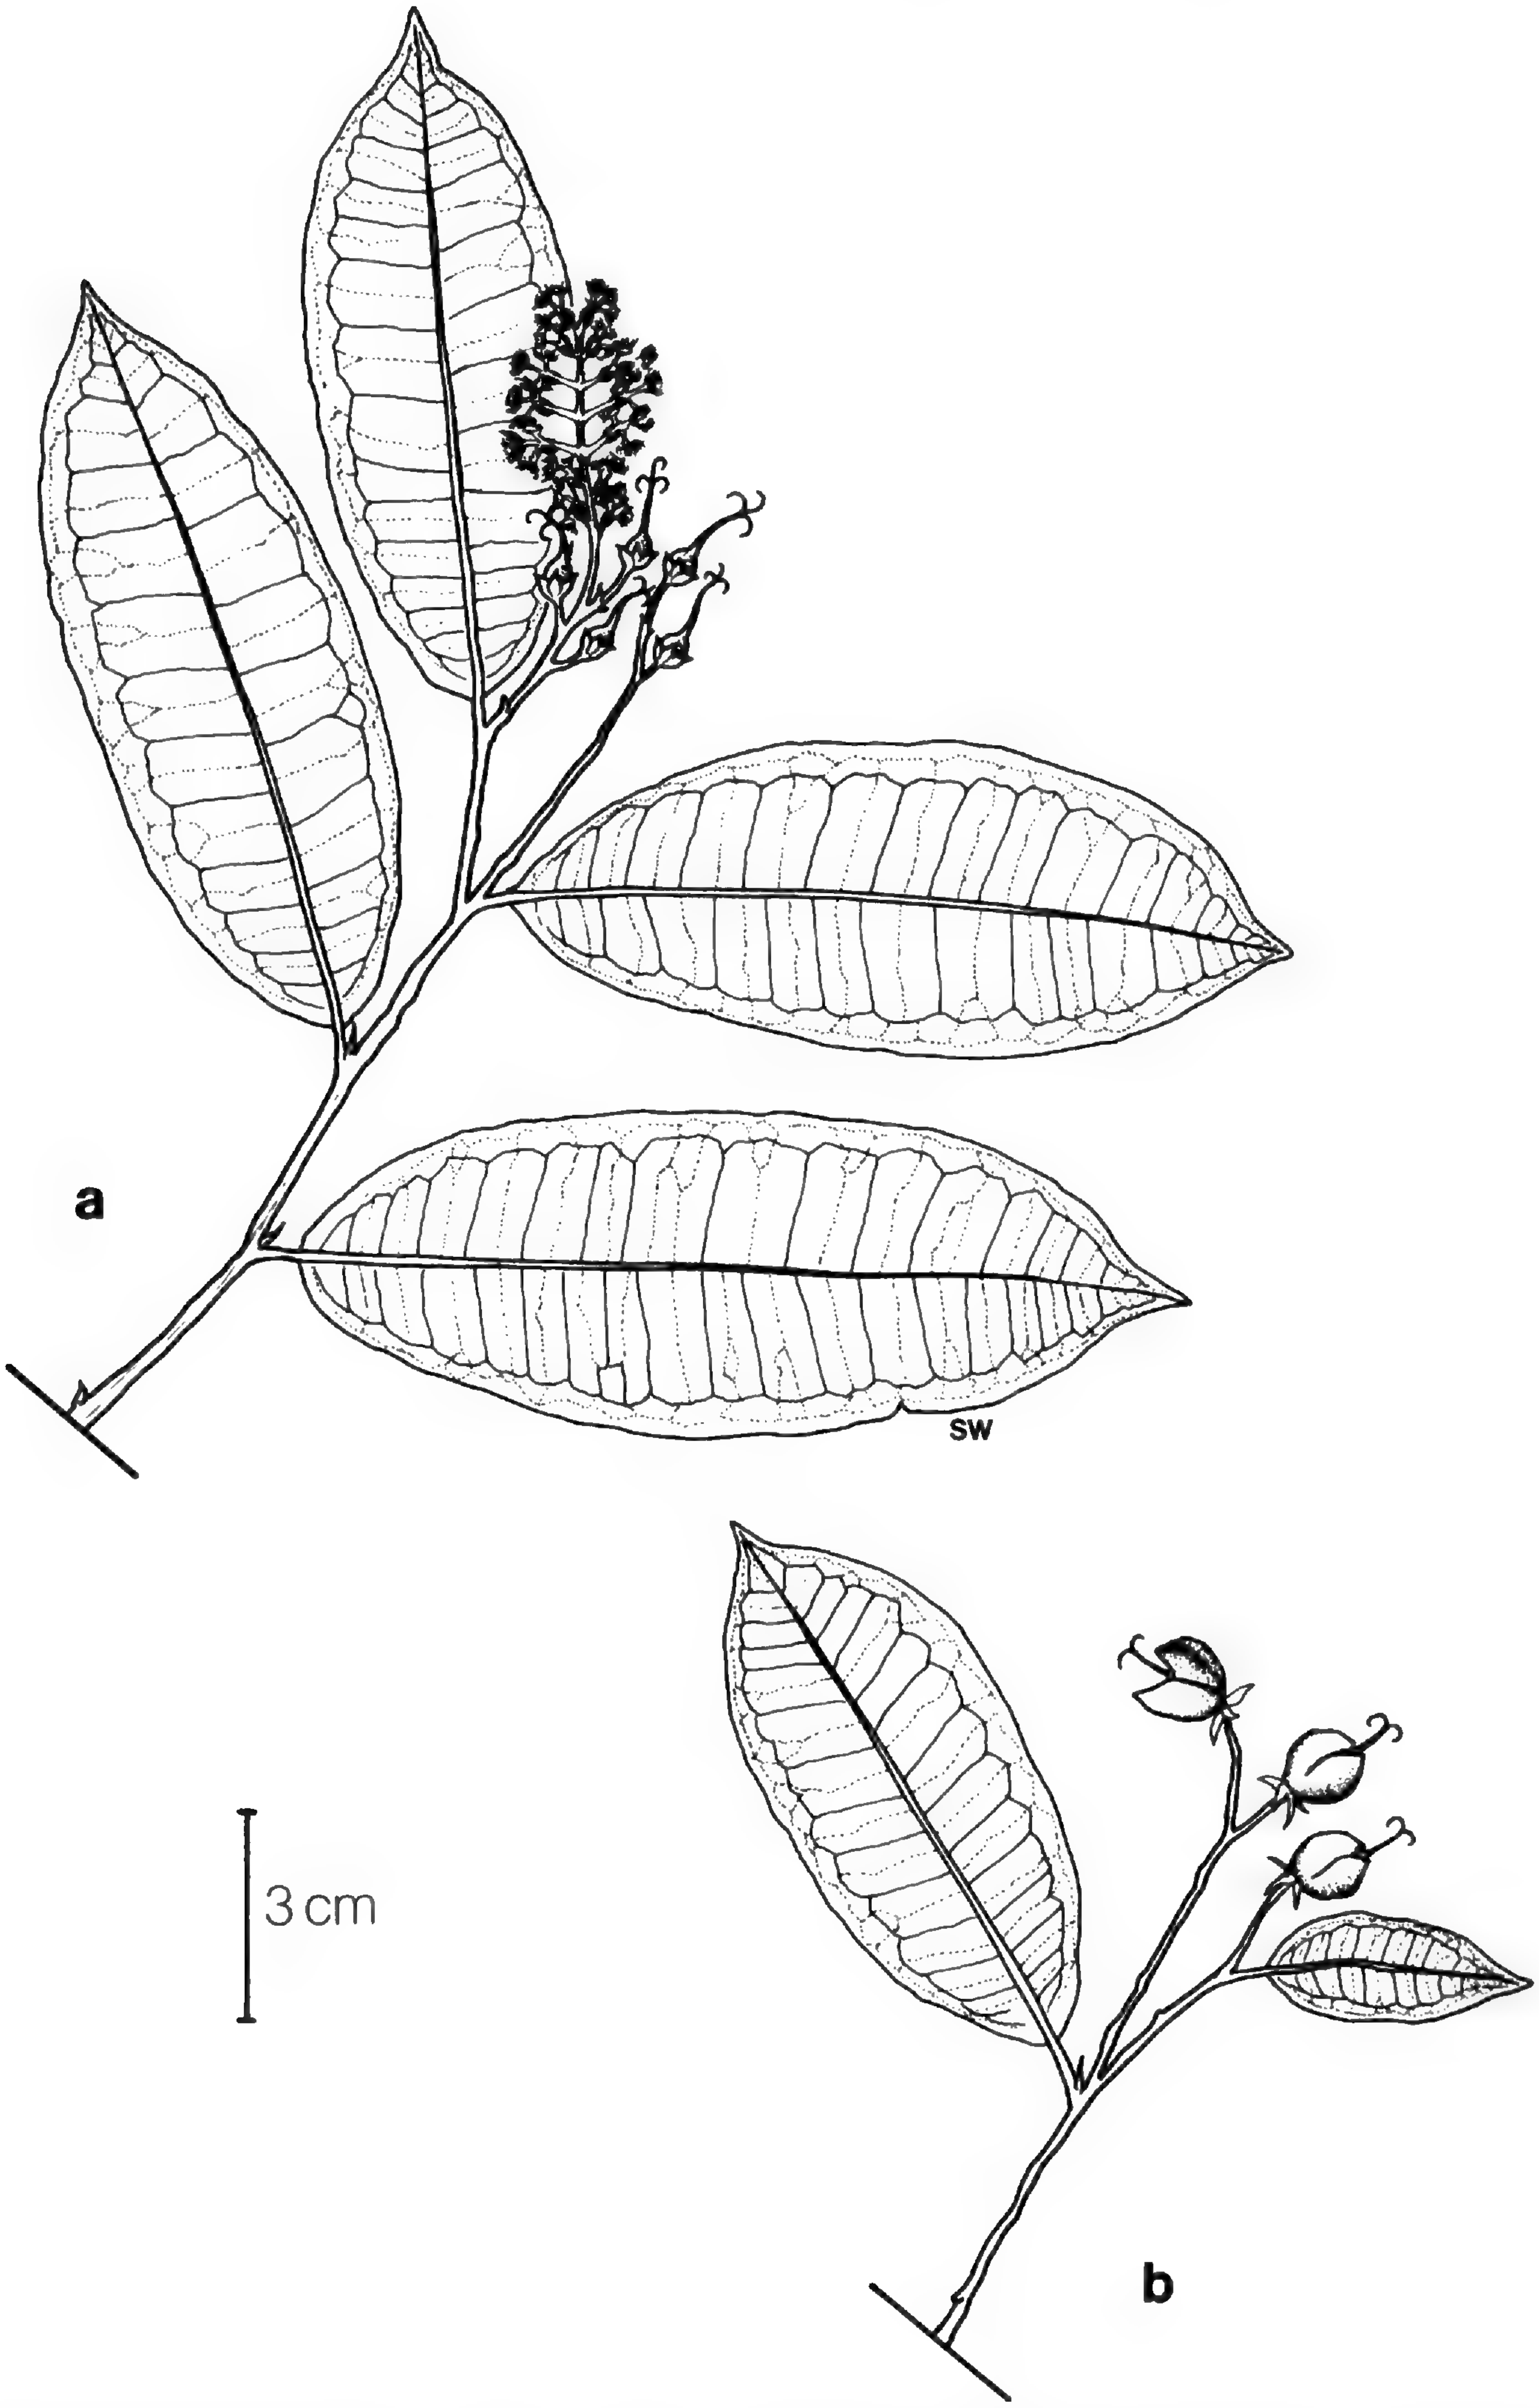

FIGURE 4. Mabea jefensis.—*a. Branch with inflorescence at anthesis and with young fruits.—b. Branch with mature fruits. Based on* Correa et al. 1601 *(a)*, D'Arcy & Sytsma 14733 *(a & b). Illustration by Steve Wilson.*

34. *Senefeldera*

Senefeldera C. Martius, Flora 24 (Beibl.): 29. 1841. TYPE: *Senefeldera multiflora* C. Martius.

Monoecious *shrubs* or trees without evident milky latex; glabrous throughout. *Leaves* alternate (or pseudoverticillate at ends of branches), simple, petiolate; stipules deciduous; blades ± entire, pinnately veined, usually glandular on midrib at base; margins entire. *Inflorescences* terminal, paniculate (of compound spikes or racemes), bisexual. *Staminate flowers* solitary or in glomerules at distal axils of inflorescence axes, subtended by biglandular bracts; calyx 3–5-lobed, sometimes asymmetrical, not covering anthers in bud; petals and disk absent; stamens 5–12; anthers subsessile on an elevated receptacle, extrorse, dehiscing longitudinally; pollen grains subglobose, tectate, 3-colporate; pistillode absent. *Pistillate flowers* solitary at proximal nodes of inflorescence, sessile; calyx 3-parted, segments distinctly imbricate; petals and disk absent; carpels 3, unappendaged, each with a single ovule; styles unbranched, free, or basally connate. *Fruits* capsular, thin-walled; columella slender, usually not persistent; seeds solitary in each locule, plump, carunculate; endosperm copious.

As treated by Jablonski (1965: 171–174), *Senefeldera* is a genus of nine rather poorly understood South American species. It is here recorded from North America for the first time.

34.1. Senefeldera testiculata Pittier, Contr. Fl. Venez. 2: 31. 1923. TYPE: Venezuela. Zulia: Perijá, *Pittier 10910* (US).

Shrub or small tree to ca. 4 m high; twigs subterete, channeled, smooth. *Leaves* with petioles variable in length, 0.5–4 cm long, adaxially channeled; stipules triangular, ca. 2 mm long, deciduous (leaving conspicuous scars); blades chartaceous, elliptic-lanceolate, acuminate at apex, cuneate at base, 12–24 cm long, 4–10 cm broad, usually with a ventral median swollen gland ca. 0.5–1 mm long; major lateral veins ca. 10–15 on a side, slightly curving to margins, the veinlets prominulous on both sides; margins plane to slightly reflexed, entire. *Inflorescences* usually bisexual, mostly 7–20 cm long; lateral axes 5–8, the peduncles 5–11 mm long. *Staminate flowers* 2 or 3 per node; bracts ca. 1–1.5 mm long, acute, the glands infolded on adaxial side; pedicels 0.5 mm long or shorter, subtended by 1 or more bractlets within the bract; calyx segments 3, unequal, acute, as broad as or broader than long, ca. 0.5–0.7 mm long; stamens 5; anthers apiculate, ca. 0.4–0.5 mm long (much longer than the very short filaments). *Pistillate flowers* solitary at the 2 or 3 lowermost nodes of each lateral axis, sessile; bracts apiculate, 1–1.3 mm long, with glands 0.8–1 mm across; calyx segments 3, slightly imbricate, broadly ovate, apiculate, ca. 1.2–1.3 mm long; ovary smooth and unappendaged, 3-locular, carinate; styles nearly free, ca. 1.5 mm long, falcate, thickened below and tapering to an acute tip, ventrally papillate. *Capsules* oblate, ca. 11.5–12 mm diam., 3-lobed, inconspicuously reticulate and ribbed, cocci ca. 7 mm long; columella ca. 5 mm high, unthickened, not persistent; seed plump, ovoid, ca. 5–6 mm long, brownish, streaked or mottled, smooth, ± notched at base; caruncle small; hilum subapical, raphe conspicuous.

Lowland evergreen rainforest, Panama to Venezuela; here reported from Panama for the first time.

The Panamanian specimens are a rather good match for collections of *S. testiculata* from Zulia, Venezuela (*Steyermark 99576, 99917*, VEN). Although they differ from the South American plants in having more acute leaf bases and shorter inflorescences, there seems little doubt that they are conspecific.

Specimens examined. PANAMA. DARIÉN: Río Canglón, *Duke & Bristan 363* (DAV, MO); Río Perrecénico off Río Pirre, *Duke & Bristan 8236* (DAV, MO); ridge 2 hours by piragua upstream above Tucutí, *Duke 5261* (DAV, MO; incorrectly cited as *Caryodendron angustifolium* in the original treatment); Estero Grande off Río Marea, *Duke 10962* (F, MO); Río Ucurgantí, *Bristan 1148* (F, MO); Manené to Río Coasí, *Hartman 12213* (F, MO).

35. *Sebastiania*

Sebastiania Sprengel, Neue Entd. Pflanzenk. 2: 118, pl. 3. 1821. TYPE: *Sebastiania brasiliensis* Spreng.

The discovery of an additional species of *Sebastiania* makes it necessary to provide a key to the two Panamanian species. A third Panamanian species, too fragmentary for identification, is discussed but not included in the key.

KEY TO THE SPECIES OF *SEBASTIANIA* IN PANAMA

1a. Annual herb; leaves linear-lanceolate; staminate flowers borne distichously on the rachis; seeds not over 2.5 mm long .... 1. *S. corniculata*
1b. Shrub 2–3 m high; leaves elliptic-lanceolate; staminate flowers borne spirally on the rachis; seeds ca. 4 mm long .... 2. *S. panamensis*

35.2. Sebastiania panamensis Webster, sp. nov. TYPE: Panama. Chiriquí: N of San Félix at Chiriquí–Bocas del Toro border, on Cerro Colorado copper mine road, 5,000–5,500 ft., 3 May 1975, *Mori & Kallunki 5786* (holotype, DAV; isotype, MO).

A speciebus sect. *Microstachydi* recedit floribus masculinibus spiralibus, seminibus longioribus; a speciebus sect. *Elachocrotoni* differt habitu; a speciebus sect. *Sebastiania* differt ovario armato.

Shrub ca. 2–3 m high, the trunk ± unbranched; twigs slender, subterete, antrorsely ± appressed pubescent. *Leaves* with petioles 3–7 mm long, appressed-pubescent; stipules triangular-lanceolate, dark, 0.8–1.2 mm long; blades thinly chartaceous or membranous, elliptic-lanceolate, ± caudate-acuminate at tip, cuneate at base, (2.5–)5–12 cm long, (1–)2–4 cm broad, concolorous, without laminar glands, glabrous to distinctly hirsutulous on both faces; midrib plane above, distinctly raised beneath; major lateral veins ca. 8–20 on a side, straightish, slightly prominulous beneath, distally anastamosing into intramarginal loops; veinlets forming a delicate inconspicuous reticulum; margins finely crenulate with ca. 8–25 appressed teeth on a side. *Inflorescences* opposite leaves (sometimes pseudoterminal), spiciform, usually bisexual, 2–3 cm long, rachis ± hirtellous; pistillate flowers solitary at base, staminate flowers 1 or 2 per distal bract; bracts spirally arranged, lanceolate, dark, ca. 1 mm long, on each side with a short-stipitate (ca. 0.5 mm) cyathiform gland 0.5–0.8 mm across. *Staminate flowers:* pedicel less than 0.5 mm long; calyx 3-lobed, the lobes obovate, ca. 0.6–0.8 mm long, the anthers ca. 0.3 mm long. *Pistillate flowers:* subsessile or the pedicel up to 1.5 mm long at anthesis, becoming up to 4 mm long in fruit; calyx lobes 3, imbricate (covering ovary in bud), 0.7–1 mm long, eglandular within; ovary glabrous, 3-carpellate, each carpel with a pair of subapical horns; styles nearly free, spreading, tapering, ca. 1.5–2.5 mm long. *Capsules* ca. 6 mm high, ca. 7 mm broad, with 6 subapical lower triangular processes; columella ca. 4.5 mm high; seeds ovoid-ellipsoid, reddish brown and mottled, smooth, ca. 4 mm long; caruncle nearly 1 mm broad.

Montane rainforests or cloud forests, western Panama.

This shrubby species, now represented by several collections from montane rainforests in Chiriquí and Veraguas, does not appear to have been previously described. In overall appearance and floral characteristics it resembles the weedy *S. corniculata* of section *Microstachys* (Adr. Juss.) Muell. Arg. but differs in its woody habit. Its spirally arranged staminate flowers separate it from the woody species of that section. In the treatment of Pax (Pflanzenreich 85: 89ff. 1912) it would key to section *Elachocroton* (F. Muell.) Pax, but it does not resemble any of the species in that section except possibly *S. stipulacea* (Muell. Arg.) Muell. Arg.; that species, however, is entirely glabrous, with broader leaves and multicornute ovaries. The Panamanian plants do not fit into section *Adenogyne* (Klotzsch) Benth. because the staminate calyx is not asymmetric, the fruit is echinate, and the branches are not spiny. Nor do the Panamanian plants agree with species in section *Sebastiania*, because of their leaf-opposed spikes, broader staminate calyx lobes, and echinate fruits.

The sectional divisions used by Pax do not seem to be very well founded, so that a satisfactory systematic placement of *S. panamensis* does not seem to be feasible until the genus is monographed. At present, it appears that *S. panamensis* may represent a possible connecting link between the species of section *Microstachys*, with leaf-opposed spikes and echinate fruits, and the sections with terminal or axillary spikes and usually unarmed fruits.

Additional specimens examined. PANAMA. CHIRIQUÍ: Cerro Colorado, 1,200–1,500 m, *Mori & Dressler 7827* (MO, dupl. at SCZ seen by M. Huft), *Sullivan 391* (MO), *Antonio 1409* (MO, dupl. at PMA seen by M. Huft); above San Félix along mining road, above Chame, 1,200–1,500 m, *Croat 33044* (DAV, MO); near San Félix, 800–1,200 m, *Croat 33437* (MO); Chiriquí Trail, premontane rainforest between Pinola and Quebrada Honda, *Kirkbride & Duke 898* (DAV, MO), *Churchill & Churchill 6083* (F, MO); La Fortune hydroelectric project, 1,100–1,200 m, *Hammel 2165* (DAV, MO), *Knapp 4980* (MO), *Mendoza et al. 110* (MO); E of Fortuna campsite, *Folsom & Dressler 5299* (DAV, MO). VERAGUAS: Cerro Tute, 750–1,400 m, *Antonio 1817* (MO), *Knapp & Kress 4359* (F, MO), *Knapp & Sytsma 2562* (F, MO), *Mori & Kallunki 5232* (DAV, MO), *Mori et al. 7609* (DAV, MO).

35.3. Sebastiania sp. A.

Several fruiting collections from the dry Pacific coast of Panama and Costa Rica and from thorn scrub on the Caribbean coast of Colombia represent a species otherwise unknown in Central America. In its membranous, venose, broadly ovate to rhombiform leaves with crenate to crenulate margins, it closely resembles such species of sect. *Sebastiania* from southern Brazil and Argentina as *S. brasiliensis* Sprengel, *S. anisandra* (Griseb.) Lillo, and *S. warmingii* (Muell. Arg.) Pax. Even closer is *S. macrocarpa* Muell. Arg. of Ceara in northeastern Brazil, with which it shares a large capsule (to 15 mm in diameter).

Until flowering material becomes available, it will remain uncertain whether the Panamanian plant represents an undescribed species or belongs to one of the Brazilian species.

The Costa Rican specimen cited below is the basis for the record of *Ophellantha spinosa* Standley cited by Standley from Costa Rica (Standley, 1938: 1557). That species is definitely known only from northwestern Mexico to Honduras. One of the Colombian collections (*Gentry & Cuadros 47466A*, MO) has an immature inflorescence with a single pistillate flower and the multiparted bracteal glands that are characteristic of several species of section *Sebastiania*.

Specimens examined. COSTA RICA. ALAJUELA: vic. of San Ramón, Los Loros, *Brenes 22679* (CR, NY). PANAMA. LOS SANTOS: 1–2 mi. W of Candelaria, *Duke 12443* (MO, US); Las Tablas, *Dwyer 1100* (MO); Los Santos, 30 m, *Lao 320* (MO). COLOMBIA. ATLÁNTICO: Puerto Colombia, 50–100 m, *Dugand 626* (F, distributed as *S. granatensis* Muell. Arg.). BOLÍVAR: Galerazamba, N tip of Bolívar, thorn scrub forest, 10°48′N, 75°15′W, *Gentry & Cuadros 47456, 47466A, 47474* (F, MO).

36. *Gymnanthes*

Gymnanthes Sw., Prodr. 95. 1788. LECTOTYPE: *Gymnanthes lucida* Sw. (chosen by Grisebach, Fl. Br. W. Ind. 50. 1859).

Actinostemon Klotzsch, Arch. Naturgesch. 7: 184. 1841. TYPE: *A. concolor* (Sprengel) Muell. Arg. (*Gussonia concolor* Sprengel).

Dactylostemon Klotzsch, Arch. Naturgesch. 7: 181. 1841. TYPE: not designated.

Monoecious (rarely dioecious) *shrubs* or trees; latex scanty and scarcely milky; indumentum absent or of simple hairs. *Leaves* alternate, simple, petiolate; stipules small, mostly persistent; blades pinnately veined, entire or crenulate, glandular or eglandular. *Inflorescences* terminal or axillary, bisexual (or less commonly unisexual), spiciform, of 1–several basal solitary pistillate flowers and many distal staminate cymules; bracts mostly biglandular, subtending solitary pistillate flowers and 1–several staminate flowers. *Staminate flowers* mostly pedicellate; calyx of 1 lobe or rudimentary or absent; petals and disk absent; stamens mostly 2–5; filaments free or basally connate; anthers extrorse, dehiscing longitudinally; pollen grains subglobose, tectate, 3-colporate; pistillode absent. *Pistillate flowers* sessile or pedicellate; calyx mostly 3-lobed, the lobes sometimes reduced or obsolete, eglandular within; petals and disk absent; carpels 3, each with a single ovule; styles free or basally connate, unbranched. *Fruits* capsular; columella ± persistent; seeds solitary in each locule, caruncullate; testa smooth; endosperm copious.

As here circumscribed, *Gymnanthes* includes *Actinostemon* Klotzsch and *Dactylostemon* Klotzsch. Although most authors have upheld at least *Actinostemon* as a distinct genus, this seems to have been due more to inertia rather than to critical assessment of diagnostic characters. Pax & Hoffmann (1912: 13) did not provide any convincing distinctions in their key, nor did Jablonski (1967: 164, 178), who candidly stated that "the distinction between *Actinostemon* and *Gymnanthes* is very vague." Even when *Actinostemon* is merged with *Gymnanthes*, the enlarged genus is difficult to distinguish from *Sebastiania*. Mueller (1866: 1164–1165), in fact, combined the two, but called the composite genus *Sebastiania* because the name *Gymnanthes* (which has priority) seemed inappropriate to him. The distinctly reduced staminate calyx of *Gymnanthes* furnishes only a tenuous difference from *Sebastiania*, in which the staminate calyx is presumably usually well developed. As Pax & Hoffmann (1912: 89–90) pointed out, *Sebastiania* may be an unnatural genus, part of which should be combined with *Gymnanthes*. Clarification of these difficulties will have to await the efforts of a very intrepid monographer.

Rothmaler (1944), following a suggestion by Hallier (1918), adopted the name *Ateramnus* P. Browne (1756: 338) in place of *Gymnanthes*. However, this is not justifiable, as has been shown recently (Webster, 1983); *Ateramnus* is best disposed of by lectotypifying it so that it becomes a synonym of *Sapium*.

As here construed, *Gymnanthes* is then a neotropical genus of about 40 species; the two Panamanian species are reported here for the first time.

KEY TO THE SPECIES OF *GYMNANTHES* IN PANAMA

1a. Staminate bracts each with 1 gland on each side, subtending 3 flowers; leaves glandular on margins; staminate calyx of 1 segment; fruiting pedicels 13–21 mm long; seeds 6.3–6.6 mm long .... 1. *G. actinostemoides*

1b. Staminate bracts (at least in part) with paired glands on each side, each bract subtending 1 flower; leaves eglandular on margins; staminate calyx absent; fruiting pedicels 40–50 mm long; seeds ca. 5.5 mm long .... 2. *G. dressleri*

36.1. **Gymnanthes actinostemoides** Muell. Arg., Linnaea 32: 103. 1863; Pax & Hoffmann, Pflanzenreich IV. 147. V(Heft 52): 85. 1912 (as *G. actinostemonoides*). *Sebastiania actinostemoides* Muell. Arg. in DC., Prodr. 15(2): 1184. 1866. TYPE: Mexico. Veracruz: Zacuapan, *Linden 1357* (holotype, G, microfiche seen).

Tree to 10–12 m high; twigs of current year obtusely angled, short-puberulent (glabrate in age). *Leaves* with petioles 3–10 mm long, ± puberulent; stipules lanceolate, ca. 1–2 mm long; blades chartaceous, elliptic-oblong, mostly caudate-acuminate at tip (the acumen acute, ca. 0.5–1.5 cm long), acutely cuneate at base, ca. 6–16 cm long, 2–6 cm broad, without laminar glands but with 1–3 depressed cyathiform glands at proximal marginal crenulations; midrib raised on both sides and puberulent proximally; major lateral veins ca. 10–15 on a side, arcuate; veinlets distinctly prominulous beneath (slightly so above), forming irregular areoles; margins plane, remotely crenulate (teeth mostly 12–17 on a side), the distal teeth with a minute deciduous glandular tip, the proximal teeth with depressed cyathiform glands. *Inflorescences* axillary, racemiform, unisexual or bisexual, 2–7 cm long, the rachis puberulent. *Staminate flowers* in cymules of 3, subtended by umbonate bracts ca. 1 mm long, each bract with a pair of cyathiform glands 0.6–0.8 mm across attached above the base (subapical); pedicels 0.5–1.5 mm long (longer in central flower); calyx usually of 1 triangular segment ca. 0.5–0.7 mm long; stamens 2 or 3; filaments free, ca. 0.8–1.2 mm long; anthers ca. 0.4 mm long. *Pistillate flowers* solitary, 1 or 2 per raceme; bract eglandular; pedicel puberulent, ca. 2–4 mm long at anthesis, increasing to 13–21 mm long in fruit; calyx segments 3, pointed, not imbricate, 0.6–0.7 mm long; ovary unappendaged, smooth, puberulent; styles 3, basally connate for ca. ¼–½ their length, 2.5–5 mm long. *Capsules* not seen entire; cocci 11–13 mm long, smooth; seeds plump, ovoid, ca. 6.3–6.6 mm long, 5.8–6 mm broad, brownish, smooth, obscurely beaked; caruncle 0.8–1.3 mm broad.

Montane and perhaps also lowland rainforests, eastern Mexico (Veracruz) to Panama.

The single Panamanian collection of this species bears only fruits, so the identification of Bristan's plant with a Mexican species must be provisional. However, the characteristic leaf venation and especially the distinctive marginal foliar glands suggest that our plant is conspecific with specimens from Veracruz, Mexico (such as *Purpus 3795, 8060* from Zacuapan, *4410* from Fortín, all at UC, from which the floral characters have been taken).

Specimen examined. PANAMA. DARIÉN.: Río Pirre, *Bristan 1466* (DAV, MO).

36.2. **Gymnanthes dressleri** Webster, sp. nov. TYPE: Panama. Panamá: La Eneida, region of Cerro Jefe, 3 Jan. 1968, *Dressler 3323* (holotype, MO; isotype, DAV).

Species haec aff. *G. granatensi*, differt foliis integris late ellipticis, cuspidato-acuminatis, glandulis bractearum masculinis duplicatis, calyce nullo.

Tree 2 m or more, glabrous; twigs slender, subterete, smooth, brownish. *Leaves* with petioles 3–5 mm long; stipules ovate, rounded, scarious, ca. 1 mm long; blades chartaceous, broadly elliptic, rather abruptly cuspidate-acuminate at tip (the acumen obtuse, 0.5–1 cm long), cuneate at base, 3–8 cm long, 1.5–4 cm broad, appearing eglandular but sometimes with a few scattered minute (diam. ca. 0.2 mm) embedded laminar glands, distinctly paler and glaucous beneath; major lateral veins ca. 6–8 on a side, straightish or distally arcuate; veinlets distinctly prominulous beneath, often as prominent as the laterals, forming areoles partly parallel to the laterals; margins entire, with a plane or slightly reflexed subcartilaginous rim. *Inflorescences* axillary, mostly at the base or lower axils of annual increments, racemiform, unisexual or bisexual, where bisexual with 1 or 2 basal pistillate flowers and ca. 8–13 distal staminate flowers; bracts all subtending solitary flowers, ovate, scarious, ca. 0.5–0.7 mm long, mostly with paired subsessile cyathiform glands on each side at base, the larger gland of each pair ca. 0.3 mm across. *Staminate flowers* with pedicels ca. 0.4–1.2 mm long, articulated at the top; calyx, petals, and disk absent; stamens 2–4; filaments free or basally united, 0.4–0.7 mm long; anthers 0.4–0.5 mm long. *Pistillate flowers* with pedicels ca. 3–5 mm long at anthesis, increasing to 40–50 mm long in fruit; calyx lobes 3, ovate, not overlapping, ca. 0.5–0.7 mm long, eglandular within, the margins minutely crenulate; ovary smooth and unappendaged; styles 3, ca. 1.5–2 mm long, thickish, recurved, slightly connate at base. *Capsules* not seen entire; columella 5.5–6 mm long, subpersistent; seeds ovoid-oblong, ca. 5.5 mm long, ca. 4–4.5 mm broad, essentially smooth, dark brown, shiny, apically beaked; caruncle ca. 1 mm across.

This new species from Cerro Jefe appears to be closely related to *G. granatensis* Muell. Arg., which was described (Linnaea 32: 107. 1863) from the vicinity of Ocaña in northern Colombia. Although the type collection of *G. granatensis (Schlim 586)* has not been examined, study of a photograph of the type and Mueller's description (in DC., Prodr. 15(2): 1189–1190. 1866) suggests that the Panamanian plant differs in some important particulars: the leaves are broader, more abruptly cuspidate, distinctly glaucous beneath, and entire at the margins. The staminate flowers completely lack a calyx, whereas there are two subulate calyx lobes in *G. granatensis*, and the staminate bracts have duplex glands on each side, while in the Colombian species (judging from Mueller's description), the bracteal glands are single on each side.

In the system of Pax & Hoffmann, *G. granatensis* would probably fit best into the "genus" *Actinostemon*, although they listed it under *Sebastiania* (Pax & Hoffmann, 1912: 150). However, because of its glabrous inflorescence and well-developed pistillate calyx, it would not readily fit into either of the sections of *Actinostemon*. Within *Gymnanthes* (sensu Pax), perhaps the species most similar to *G. dressleri* and *G. granatensis* is *G. farinosa* (Griseb.) Webster[6]. That West Indian species has somewhat similar leaves but differs in its three-flowered staminate bracts with a single gland on each side, and in its well-developed staminate calyx. Among the species with bracts subtending solitary flowers, the closest to *G. dressleri* appears to be the Cuban species *G. albicans* (Griseb.) Urban; however, in that species the leaves are more elongated and lack cuspidate tips, the bracts are eglandular, and the staminate flowers have 5–12 stamens.

37. *Maprounea*

Maprounea Aublet, Hist. Pl. Guiane 2: 895. 1775. TYPE: *Maprounea guianensis* Aublet.

Shrubs or trees, glabrous throughout; latex neither copious nor milky; monoecious. *Leaves* alternate, simple, petiolate; stipules small, persistent; blades pinnately veined, entire, glandular or eglandular. *Inflorescences* terminal, usually bisexual, of 1–4 solitary, pedicellate, pistillate flowers at basal nodes, the staminate flowers densely aggregated in a strobiliform mass at the end of the fleshy enlarged rachis, separated from the pistillate portion by an elongated internode (pseudopeduncle); bracts biglandular. *Staminate flowers* mostly 3 per bract; pedicel very short; calyx ± 3-lobed, distinctly gamophyllous, the lobes imbricate, ± covering the stamens in bud; petals and disk absent; stamens usually 2; filaments completely connate into a slender tube that is exserted from the calyx at anthesis; anthers bluntly apiculate, dehiscing extrorsely and longitudinally; pollen grains subglobose, tectate-perforate, 3-colporate, colpi marginate; pistillode absent. *Pistillate flowers* solitary to each bract, distinctly pedicellate; calyx 3-parted, segments imbricate, eglandular within; petals and disk absent; carpels 3, each with a single ovule; ovary unappendaged; styles connate into a column, the tips unbranched, spreading. *Fruits* capsular; columella not persistent; seeds solitary in each locule, the testa distinctly foveolate; caruncle large and partly occluding top of seed; endosperm copious.

A well-marked genus of three or four species, one or two in tropical America and two in tropical Africa, easily distinguished from the genera in the *Gymnanthes–Sebastiania* complex by its characteristic headlike staminate inflorescence, elongated staminal column, and hypertrophied caruncles on the seeds. *Maprounea* is here reported from North America for the first time.

RECENT LITERATURE

[6] **Gymnanthes farinosa** (Griseb.) Webster, comb nov. *Excoecaria farinosa* Griseb., Abh. Ges. Wiss. Goettingen 7: 169. 1857. TYPE: Guadeloupe: *Duchassaing* (presumably GOET, not seen).

37.1. Maprounea guianensis Aublet, Hist. Pl. Guiane 2: 895, tab. 342. 1775. TYPE: French Guiana, *Aublet* (not seen).

Trees to ca. 12 m high, glabrous; twigs subterete, smooth, brownish. *Leaves* with petioles ca. 0.5–1.5 mm long, slender; stipules triangular to lanceolate, scarious, ca. 0.5–1 mm long, persistent; blades thinly chartaceous, ovate to elliptic, rather abruptly short-acuminate at tip, cuneate at base (and minutely auriculate at junction with petiole), ca. (2–)3–7 cm long, 1.5–4 cm broad, usually with 1 or 2 elliptic laminar glands on the underside near midrib (occasionally with a few small circular glands towards the tip, or sometimes entirely eglandular); midrib plane above, distinctly raised beneath; major lateral veins ca. 10–15 on a side, straightish; veinlets prominulous on both sides, forming areoles ± parallel to lateral veins; margins plane or recurved, entire. *Inflorescences* terminal mostly on short lateral branches, 1–2 cm long; pistillate flowers solitary at 1–4 basal nodes; staminate flowers in heads ca. 3–9 mm long; staminate bracts rather fleshy, the tip acute, less than 0.5 mm long, the cyathiform glands subsessile, ca. 0.3–0.4 mm across. *Staminate flowers* articulate above very short pedicels; calyx gamophyllous, basally contracted into a stipe ca. 0.3–0.8 mm long; staminal column slender, mostly 0.7–1 mm long; anthers 0.3–0.4 mm long. *Pistillate flowers* on ascending or recurved pedicels (1–)2–5 mm long at anthesis, these becoming 6–13 mm long in fruit; calyx lobes 3, ovate, pointed, ca. 0.7–1 mm long; ovary smooth; styles 3, 2–3 mm long, united nearly or quite halfway into a stout column. *Capsules* ± oblate, not lobed, 6–6.5 mm diam.; seeds ovoid, somewhat compressed, grayish brown, shiny, distinctly beaked, deeply and coarsely foveolate on both sides, 2.9–3.6 mm long, 2.8–3.5 mm broad (including caruncle); caruncle large, covering nearly half the face of the seed ventrally, appearing 2-armed dorsally.

Rainforests at low elevations, Panama and Trinidad south to Peru and Brazil (localities in South America summarized by Jablonski, 1967: 180).

It is curious that this distinctive plant has been collected only a single time in a well-known area in the center of the Canal Zone. Presumably it will eventually turn up in various lowland areas toward the Colombian border.

Specimen examined. PANAMA. CANAL ZONE: 1 mi. N of summit on road to FAA radar tower, *Tyson et al. 2761* (MO, US).

38. *Stillingia*

Stillingia Garden ex L., Syst. Nat. ed. 12. 2: 637. 1767; Mant. Pl. 19. 1767. TYPE: *Stillingia sylvatica* L.

39. *Sapium*

Sapium P. Browne, Civ. Nat. Hist. Jamaica 338. 1756. TYPE: *Sapium jamaicense* Sw.

In the original treatment, the account of *Sapium* was avowedly tentative, pending the appearance of Jablonski's study of the Caribbean and Central American species. Jablonski's work, as well as a study of more recently collected specimens, necessitates an entirely new treatment of the Panamanian species. Of the four species recognized in the original treatment, only *S. eglandulosum* remains unchanged. We have followed Jablonski in referring the species called *S. aucuparium* by Burch to *S. jamaicense* and in uniting *S. caudatum* and *S. biglandulosum* under the name *S. aucuparium*. Jablonski's action in restoring the name *S. jamaicense* seems straightforward and is adopted here. The nomenclatural subtleties connected with *S. aucuparium* are still unresolved, however, and Jablonski's choice is followed as a tentative conclusion only.

Three additional species of *Sapium* are now known from Panama, bringing the total to six. Recent sterile collections of a seventh, possibly undescribed, species have been made on Barro Colorado Island.

KEY TO THE SPECIES OF *SAPIUM* IN PANAMA

1a. Petioles eglandular .... 2. *S. eglandulosum*
1b. Petioles with two apical glands.
  2a. Leaf tips plane, not inflexed or cucullate.
    3a. Style base persistent on mature capsule; capsule pedicellate; secondary foliar veins straight ...... 6. *S. rigidifolium*
    3b. Style base not persistent on mature capsule; capsule subsessile; secondary foliar veins arcuate-ascending .... 5. *S. pachystachys*
  2b. Leaf tips inflexed or cucullate.
    4a. Spikes clustered at tips of branchlets;

secondary foliar veins straight, slightly arcuate near margin ...... 3. *S. jamaicense*
- 4b. Spikes solitary at tips of branchlets; secondary foliar veins strongly arcuate-ascending.
    - 5a. Leaves oblong or oblong-elliptic, less than 2.5 times as long as broad; the secondary veins usually 10–15 per side .... 3. *S. oligoneurum*
    - 5a. Leaves usually elliptic-lanceolate, more than 3 times as long as broad, usually longer than 10 cm, the secondary veins usually more than 20 per side .... 1. *S. aucuparium*

39.1. Sapium aucuparium Jacq., Select. Stirp. Amer. Hist. 249. 1763. LECTOTYPE: Jacquin, Select. Stirp. Amer. Hist., pl. 158 (chosen here).

?*Sapium biglandulosum* (L.) Muell. Arg. (Linnaea 32: 116. 1863) sensu auctt. *Hippomane biglandulosa* L., Sp. Pl. ed. 2, 1431. 1762, correction of *H. glandulosa* L., Sp. Pl. ed. 1, 1191. 1753. *Excoecaria biglandulosa* (L.) Muell. Arg. in DC., Prodr. 15(2): 1204. 1866.

Sapium salicifolium Kunth, Nov. Gen. Sp. Pl. 2: 65. 1817. TYPE: Colombia: *Humboldt & Bonpland* (P, not seen).

Panama: *Seemann 1243* (syntypes, not seen); no specimens cited in protologue.

Sapium caudatum Pittier, Contr. U.S. Natl. Herb. 20: 127. 1918. LECTOTYPE: Panama. Canal Zone: hill near Gamboa, 25 June 1911, *Pittier 3713* (US) (chosen by Jablonski, 1968).

Sapium giganteum Pittier, Contr. U.S. Natl. Herb. 20: 128. 1918. TYPE: Panama. Colón: Fato, sea level, 10 Aug. 1911, *Pittier 4141* (holotype, US).

Stillingia haematantha Standley, Ann. Missouri Bot. Gard. 27: 314. 1940. TYPE: Panama. Coclé: N rim of El Valle, 9 July 1939, *Allen 1915* (holotype, F; isotype, MO, F neg. 62368).

Monoecious *tree* to 10 m. *Leaves* membranous to chartaceous, rarely coriaceous; petiole 1–5 cm long, the 2 apical glands prominent, cylindrical, ca. 1 mm long; stipules ovate-deltate, 1–1.5 mm long, 1.5–2 mm broad, persistent; blades elliptic-lanceolate to oblong-obovate, 5–40 cm long, 1.5–8 cm broad, 3–5 times as long as broad, the base rounded to acute, the margins entire, obscurely toothed or coarsely serrate, the apex short-acuminate or cuspidate, strongly cucullate. *Spikes* solitary, terminal, to 22 cm long, bisexual or staminate. *Staminate flowers* in groups of 7–10, the subtending bract flabellate, ca. 0.5 mm long, biglandular, the glands circular to oblong, 0.5–3 mm long, 0.5–1 mm broad; calyx ca. 1 mm long, cupular, 2-lipped; stamens 2. *Pistillate flowers* to 10, solitary at basal nodes, the bracts and glands as those of the staminate flowers; calyx cupular, 2-lobed; ovary orbicular, the style simple, the style-branches strongly reflexed, the tips expanded. *Capsules* ovoid, to 1 cm long, smooth; seeds ovoid, flattened laterally, the surface warty.

There has been considerable controversy concerning the proper name of this species. The name *S. aucuparium* Jacq. had long been applied to it, but Croizat (1943: 175), whom Burch followed in the original treatment, referred that name to the species usually known as *S. jamaicense* Sw. and resurrected *S. biglandulosum* for this species. Jablonski correctly restored Jacquin's name to the present species, but rejected the name *S. biglandulosum* as a *nomen confusum*, leaving *S. aucuparium* as the earliest available name. It would seem, however, that the application of *S. biglandulosum* can be fixed by a proper lectotypification. More study is needed before that can reasonably be done, and, in any case, it is not clear to the present author whether any of the elements originally cited under *S. biglandulosum* actually belong to this species. The best course, then, seems to be the tentative acceptance of *S. aucuparium* Jacq. for this species until the matter can be satisfactorily resolved.

We are following Jablonski (1968) in uniting *Sapium caudatum* and *S. biglandulosum* (sensu Croizat and Burch) under *S. aucuparium*. Examination of a wide range of collections from Panama and from northern South America shows that the leaf characters used by Burch to distinguish these species are continuously variable and do not correlate with other characters. This is a commonly collected, highly variable species of lowland tropical forests.

39.2. Sapium eglandulosum Ule, Bot. Jahrb. Syst. 35: 673. 1905. TYPE: Brazil. Amazonas: Bom Fin on the Rio Juruá, Nov. 1900, *Ule 5356* (holotype, B, F neg. 5522).

The following collection records a considerable westward range extension for this species, which was previously known in North America only from eastern Darién.

Additional specimen examined. PANAMA. PANAMÁ: Cerro Jefe region, 2 km N of turnoff to radio tower on roadside of Alto de Pacora, 2,600 ft., *Hammel 4868* (F, MO).

39.3. Sapium jamaicense Sw., Adnot. Bot. 62. 1829. TYPE: Jamaica: *Swartz s.n.* (BM, not seen).

Sapium aucuparium sensu Croizat, J. Arnold Arbor. 24: 174. 1943, sensu Burch, Ann. Missouri Bot. Gard. 54: 325. 1967, *non* Jacq. 1763.

Sapium pleiostachys Schumann & Pittier, Contr. U.S. Natl. Herb. 12: 164. 1908. TYPE: Costa Rica. Puntarenas: Golfito de Osa, near seashore, Mar. 1896, *Pittier s.n., Inst. Fis. Geog. Costa Rica no. 9906* (holotype, US-578902; isotypes, F, F neg. 62366, GH, F neg. 62360).

Sapium anadenum Pittier, Contr. U.S. Natl. Herb. 12: 164. 1908. TYPE: Costa Rica. Cartago: Hacienda Valverde at Orosi, 1,200 m, Mar. 1902, *Pittier s.n., Inst. Fis. Geog. Costa Rica no. 16366* (holotype, US-578045; isotype, F, F neg. 62364).

Rainforests, West Indies, Mexico to Panama, and recently discovered in Colombia.

The correct name of this species has also been a matter of some confusion. *Sapium jamaicense* had been used universally until Croizat (1943: 174) asserted that *S. aucuparium* sensu Jacq., *Enum. Pl. Carib.* 31, 1760, properly refers to this plant, in contradistinction to Jacquin's intention stated in his *Selectarum Stirpium Americanum Historia* (1763), which had been followed by most other authors, who had applied the name *S. aucuparium* as in this paper. Jablonski (1968), however, correctly pointed out that Jacquin's publication of *S. aucuparium* in 1760 is invalid, since a description is lacking, and that the traditional application of *S. aucuparium* as published by Jacquin in 1763 is correct.

Jablonski (1968) recognized *Sapium pleiostachys* as distinct from *S. jamaicense,* referring all collections from Panama and Costa Rica, as well as a few from Guatemala and Chiapas, to the former species, and restricting the latter to the West Indies and northern Central America. The only difference he adduced was the presence of petiolar glands on *S. pleiostachys* and their absence on *S. jamaicense.* Even granting this difference, recognition of *S. pleiostachys* would be tenuous indeed, given the inadvisability of maintaining a species on the basis of a single morphological feature and the assertion that both variants occur in northern Central America (indeed, specimens collected by Matuda at Escuintla, Chiapas, are cited under each species by Jablonski). A thorough examination of collections from throughout the range, however, shows that even these meager grounds are untenable. Plants with petiolar glands occur commonly in the West Indies (cf. *Ekman 5512* from Hispaniola, *Harris 9156* from Jamaica, and *Pringle 104* from Cuba, all F), and thus there is no morphological discontinuity. *Sapium jamaicense* is simply a variable species in regard to the presence or absence of petiolar glands, and there is no justification for recognition of *S. pleiostachys.*

A few new provincial records are recorded below.

Additional specimens examined. PANAMA. DARIÉN: Río Pirre, *Bristan 1475* (MO). PANAMÁ: N of highway ca. 2 mi. E of El Llano, 200 m, *Foster & Kennedy 1971* (F, NY). VERAGUAS: Isla de Coiba (Penal Colony), *Dwyer 1566* (MO). COLOMBIA. ANTIOQUIA: Municipio de San Luis, Cañon del Río Claro, 330–425 m, *Cogollo 965, 1232* (MO).

39.4. Sapium oligoneurum Schumann & Pittier, Contr. U.S. Natl. Herb. 12: 168. 1908. *Sapium biglandulosum* (L.) Muell. Arg. var. *oligoneurum* (Schumann & Pittier) Monach., Bull. Torrey Bot. Club 67: 772. 1940. TYPE: Costa Rica: near San Rafael on road from Cartago to Cot, 1,500 m, July 1899, *Pittier s.n., Inst. Fis. Geog. Costa Rica no. 13403* (holotype, US-578903).

Sapium sulciferum Pittier, Contr. U.S. Natl. Herb. 12: 169. 1908. *Sapium biglandulosum* (L.) Muell. Arg. var. *sulciferum* (Pittier) Monach., Bull. Torrey Bot. Club 67: 772. 1940. TYPE: Costa Rica. La Palma, 1,500 m, 15 Aug. 1898, *Tonduz s.n., Inst. Fis. Geog. Costa Rica no. 12428* (holotype, US-577588; isotype, NY).

Sapium schippii Croizat, Amer. Midl. Nat. 29: 477. 1943. TYPE: Belize. Toledo District: Forest Home, Punta Gorda, *Schipp 1049* (holotype, A, F neg. 62361; isotypes, F, F neg. 62365, MO, F neg. 62363).

Monoecious *tree* to 20 m. *Leaves* membranous or chartaceous; petiole 1–3(–6) cm long, the two glands near the apex opposite or subopposite, cylindrical, 1–2 mm long; stipules ovate-deltate, oblique, 2–3 mm long, 1.5–2 mm broad, appressed, persistent; blade oblong or elliptic-oblong, 4–10(–18) cm long, 2.5–4.5(–8) cm broad, 1.2–2.4 times as long as broad; midvein prominent, the secondary veins 10–15(–20) per side, somewhat inconspicuous; base rounded to obtuse; margin appearing entire, remotely denticulate with minute glandular teeth; apex acute or more often abruptly short-cuspidate, conspicuously and tightly cucullate. *Spikes* solitary, terminal, to 22 cm long, bisexual or staminate. *Staminate flowers* in groups of 5–7, the subtending bract short, broad, 1–1.2

mm long, 1.8–2.1 mm broad, rounded, hyaline, slightly erose, biglandular, the glands suborbicular to oblong, 1.8–3 mm long, 1.8–2.5 mm broad, flattened; calyx cupular, 1.7–2 mm long, 2-lipped; stamens 2, the filaments free. *Pistillate flowers* 10–22, borne singly at basal nodes of bisexual spikes; bracts and calyces as in the staminate flowers; ovary globose; styles simple. *Capsules* subglobose to slightly obovoid, subsessile, 5–9 mm long, 5–12 mm diam., smooth; seeds subglobose, slightly compressed, yellowish, the surface warty.

Montane and cloud forests, forest edges, and clearings, Chiapas, Mexico, to Panama.

Specimens examined. PANAMA. BOCAS DEL TORO: region of Cerro Colorado, 3.3 mi. above Camp Chamí, 8°35′N, 81°45′W, ca. 1,350 m, *McPherson 9587* (F). CHIRIQUÍ: E of Boquete on Cerro Azul near Quebrada Jaramillo, 1,500–1,620 m, *Croat 26820* (MO, NY); along road between Gualaca and Fortuna Dam site, 10.1 mi. NW of Los Planes de Nornito, 8°45′N, 82°17′W, 1,250 m, *Croat 50032* (MO); Boquete, 4,000 ft., *Davidson 852* (MO, US; cited in the original treatment as *S. aucuparium* sensu Burch); near Cerro Colorado, ca. 3.5 mi. along road from Chamí Camp, ca. 8°35′N, 81°45′W, ca. 1,350 m, *McPherson 8997* (F); pastures around El Boquete, 1,000–1,300 m, *Pittier 2880* (F, US); valley of the upper Río Chiriquí Viejo, *G. & P. White 95* (MO).

These specimens have been distributed under the names *S. caudatum*, *S. aucuparium*, *S. oligoneurum*, or *S. sulciferum*.

39.5. Sapium pachystachys Schumann & Pittier, Contr. U.S. Natl. Herb. 12: 168, tab. 16. 1908. TYPE: Costa Rica. San José: Dota Mountains, El Copey, 1,800 m, Feb. 1898, *Tonduz s.n.*, *Inst. Fis. Geog. Costa Rica no. 11875* (holotype, US-333961; isotype, F, F neg. 62367).

Monoecious *tree* to 25 m; older twigs covered with crowded persistent stipules. *Leaves* membranous or chartaceous; petiole 2–5 cm long, the 2 glands near the apex subopposite, cylindrical, 1–3 mm long; stipules deltate, 4–6 mm long, 2–3 mm broad, appressed, persistent; blade elliptic, elliptic-obovate, or elliptic-lanceolate, 5–20 cm long, 2.5–7.5 cm broad, 1.6–2.4(–4.5) times as long as broad; base rounded or obtuse, rarely acute; margins entire or obscurely crenate; apex obtuse or acute, occasionally short-acuminate, plane. *Spikes* solitary at the apex of smooth lateral shoots, to 20 cm long, bisexual. *Staminate flowers* in groups of 7–10(–12), the subtending bract short, broad, to 2 mm long, hyaline, erose, biglandular, the glands oblong, 2.5–3 mm long, 1–1.5 mm broad, flattened, calyx 1–1.5 mm long, cupular, 2-lipped; stamens 2, the filaments free. *Pistillate flowers* 14–22, solitary at basal nodes; bracts as in the staminate flowers; calyx 1–1.5 mm long, cupular, 2-lipped; ovary globose; styles simple, fused for ⅓–½ their length, the free portion strongly coiled. *Capsules* globose, subsessile, 7–10 mm long, smooth; seeds subglobose, flattened laterally, ca. 4 mm diam., the edges short-winged, the surface somewhat warty.

Montane rainforest and cloud forest, 700–2,000 m, Costa Rica and Panama.

The twigs densely covered with persistent stipules and the large, broad leaves with noncucullate apices are characteristic features of this species. A related species, *S. allenii* Huft, has recently been described from eastern Costa Rica (Huft, 1987) and may eventually be discovered at lower elevations in western Panama. It differs from *S. pachystachys* in having axillary spikes, smaller, stipitate capsules, and a small membranous calyx that does not persist on the mature capsules.

Specimens examined. PANAMA. BOCAS DEL TORO: border with Chiriquí, Cerro Colorado mine area, from Chamí Station to ca. 9 mi. along road, 8°35′N, 81°54′W, 1,100–1,700 m, *Hammel & Trainer 15004* (F). CHIRIQUÍ: Boquete, Finca Collins, *Blum & Dwyer 2558* (MO); SO de campamento Fortuna (8°45′N, 82°15′W), sitio de presa, desde la finca Pitti hasta e filo del Cerro Fortuna, 1,000–1,200 m, *Correa et al. 2797* (MO, 2 sheets); Cerro Colorado, along road to copper mine 24.1 km beyond bridge over Río San Félix (13.1 km beyond turnoff to Escopeta), 1,390 m, *Croat 37305* (MO); Cerro Punta, 2,000 m, *Lao 328* (MO); above Los Llanos, 8°47′N, 82°38′W, ca. 2,100 m, *McPherson 9258* (F, MO); Cerro Colorado, 50 km N of San Félix on the Continental Divide, 1,200–1,500 m, *Mori & Dressler 7819* (MO, NY); between Río Ladrillo and Las Siquas Camp, southern slope of Cerro de la Horqueta, 1,200–1,700 m, *Pittier 3165* (US); slopes of Volcán Barú near town of Cerro Punta, 6,300 ft., *Stern & Chambers 97* (MO, US). COCLÉ: N of El Copé on road past sawmill, 2,400 ft., *Antonio 3264* (F, MO). PANAMÁ: 5–10 km NE of Altos de Pacora, on trail at end of road, 700–800 m, *Mori & Kallunki 6065* (MO, NY, 2 sheets).

39.6. Sapium rigidifolium Huft, Phytologia 63: 444. 1987. TYPE: Costa Rica. Heredia: pastures above San Rafael, 30 km W of Vaca Blanca, 1,750 m, 8 Aug. 1971, *Lent 2041* (holotype, F; isotypes, MO, NY, US), distributed as *Sapium thelocarpum* Schumann & Pittier. Figure 5.

Sapium rigidifolium, which is known only from high altitudes in Costa Rica and Chiriquí Province in Panama, belongs to the otherwise wholly South American subsection *Emmenostylum* (Hemsley)

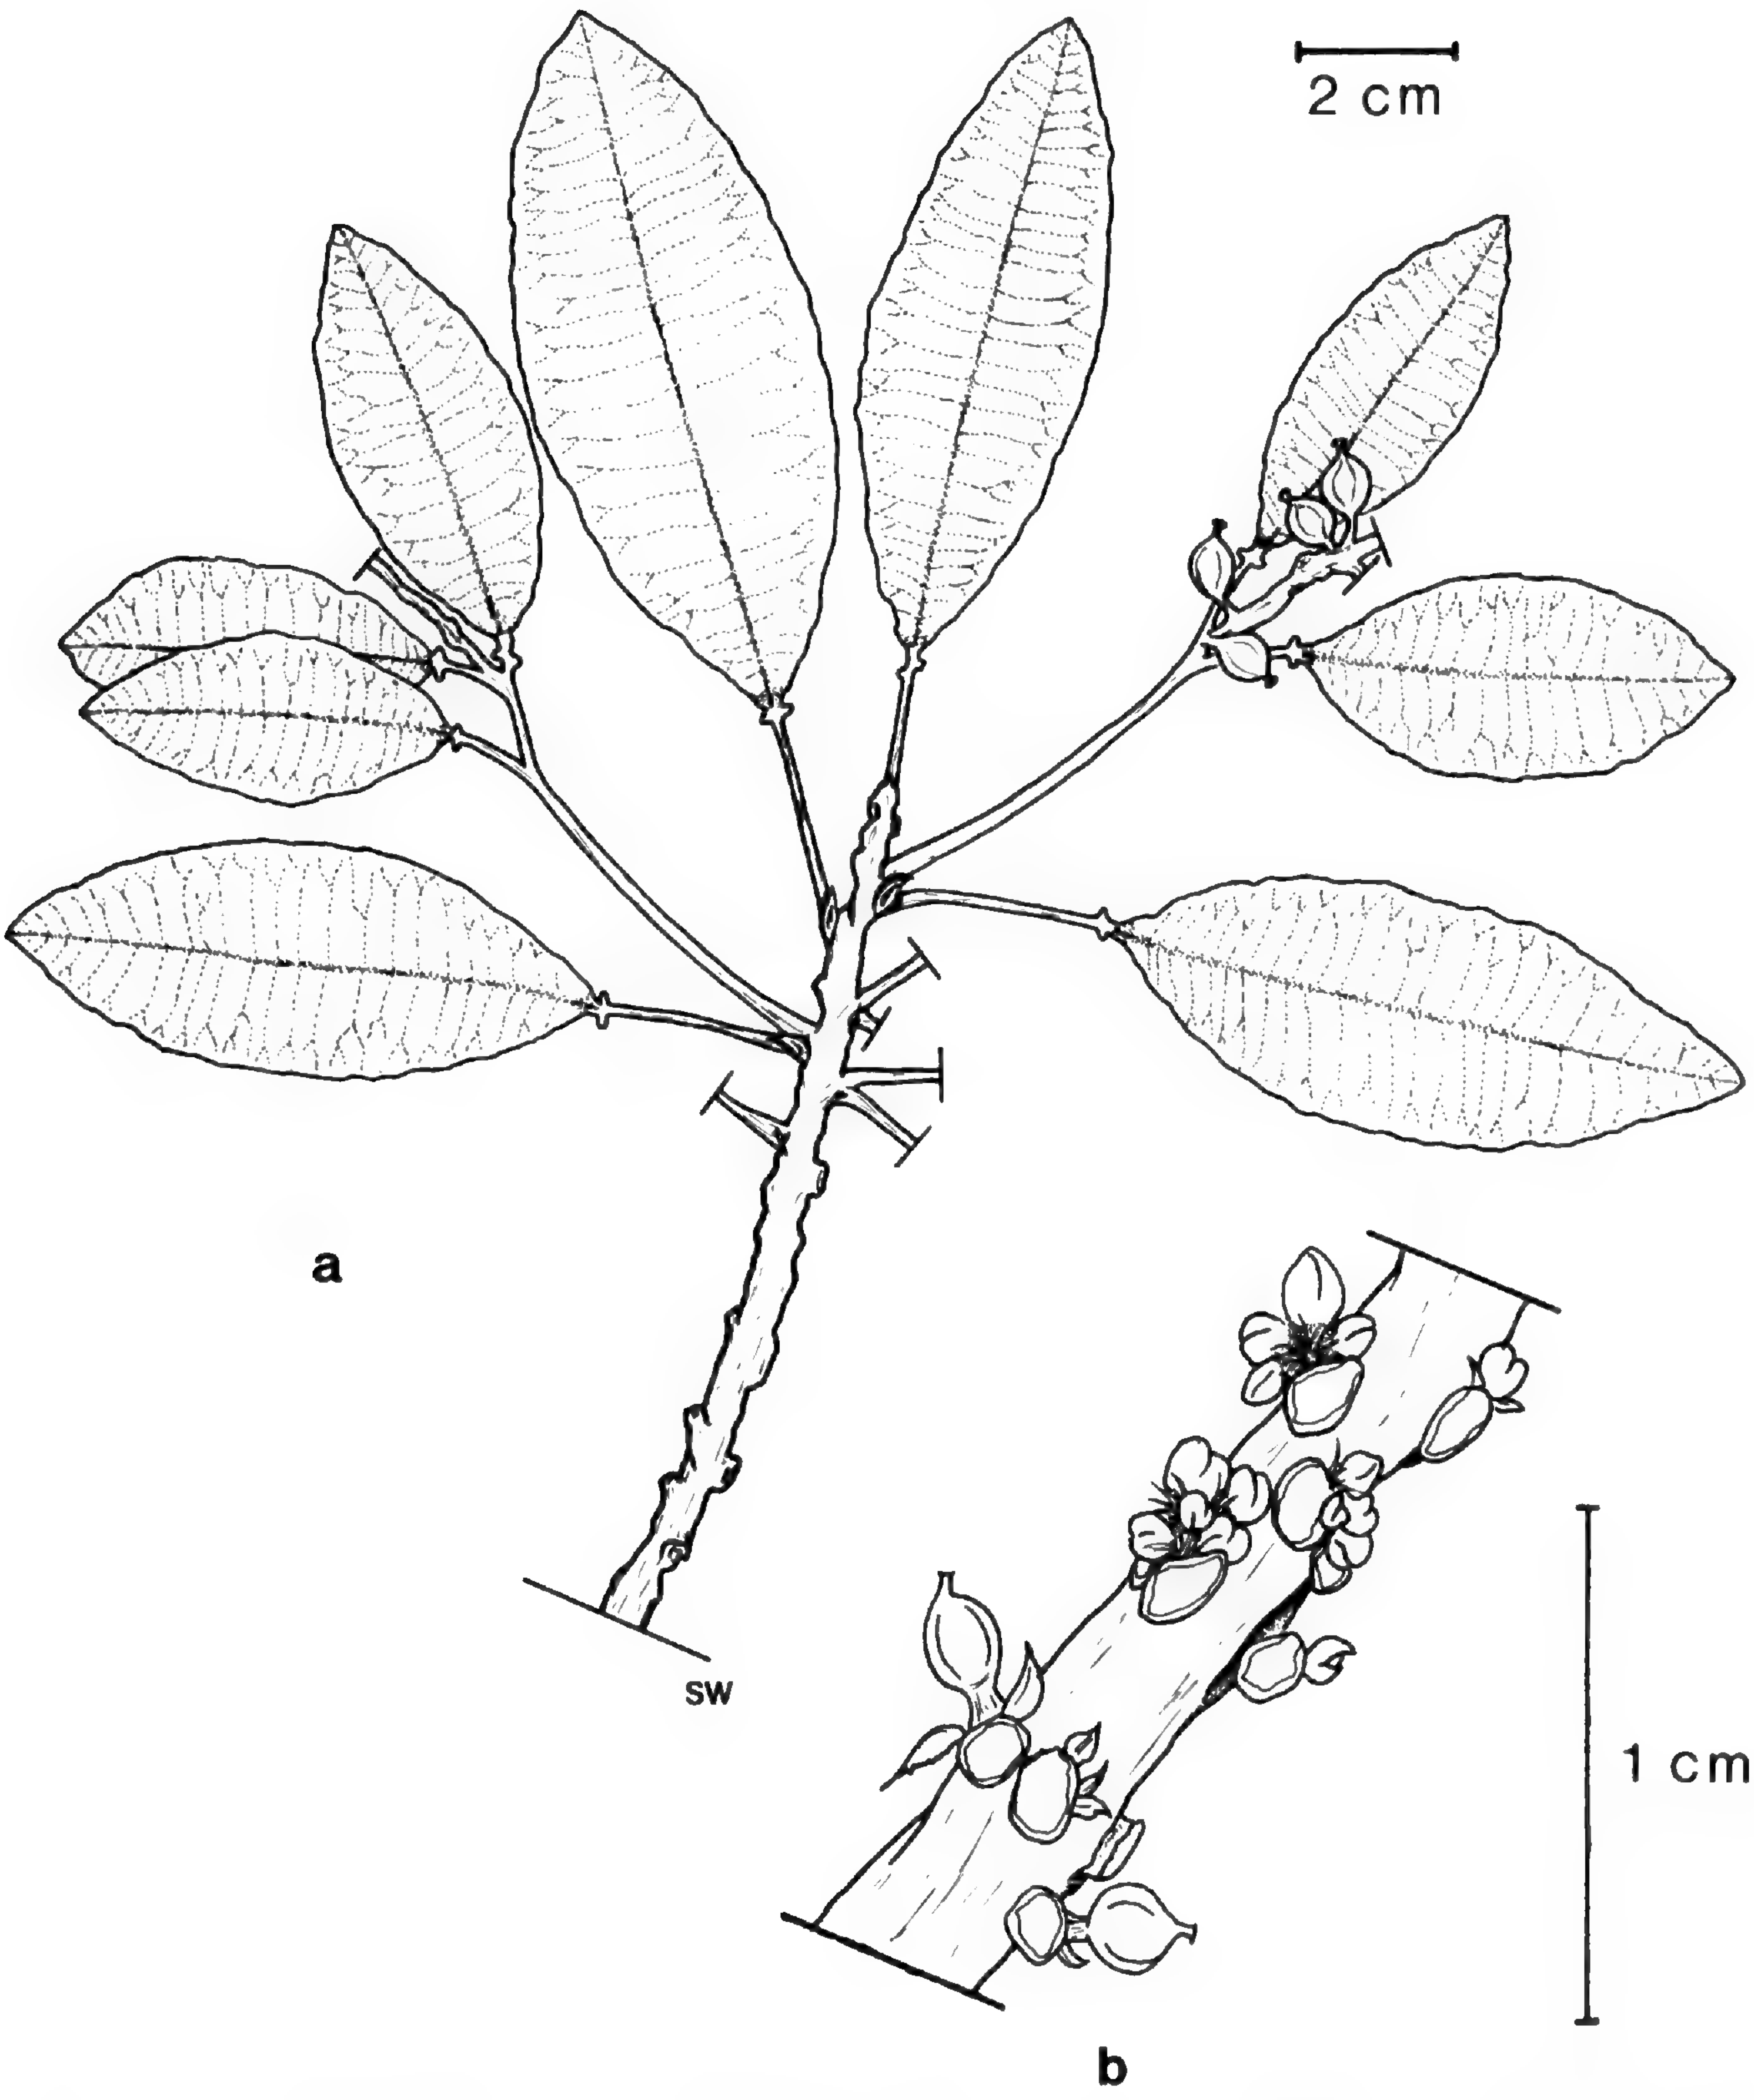

FIGURE 5. Sapium rigidifolium.—*a. Branch with mature capsules.—b. Detail of portion of inflorescence, showing staminate flowers at anthesis and pistillate flowers in young fruit. Based on* Lent 2041. *Illustration by Steve Wilson.*

Pax (Pflanzenr. IV. 147. V(Heft 52): 211. 1912), characterized by styles that are connate for most of their lengths and whose columns persist on the mature capsule, and by leaves with planar apices and nearly horizontal, prominent, closely spaced secondary veins. The South American representatives are restricted to high altitudes in the northern Andes and include such species as *S. verum* Hemsley, *S. stylare* Muell. Arg., and *S. putumayense* Croizat.

Specimens examined. PANAMA. CHIRIQUÍ: Guadalupe Arriba, above Cerro Punta, 8°52′N, 82°33′W, 2,100 m, *de Nevers & Charnley 6057* (F); Boquete, Cerro Horqueta, 5,000–6,000 ft., *Dwyer & Hayden 7685* (MO); Cerro Punta, 2,000 m, *Lao 391* (MO, PMA); slopes of Volcán Barú, near town of Cerro Punta, 6,000 ft., *Stern & Chambers 85* (A, MO, US).

40. *Hippomane*

Hippomane L., Sp. Pl. 1191. 1753. TYPE: *Hippomane mancinella* L.

41. *Hura*

Hura L., Sp. Pl. 1008. 1753. TYPE: *Hura crepitans* L.

42. *Euphorbia*

Euphorbia L., Sp. Pl. 450. 1753. LECTOTYPE: *Euphorbia antiquorum* L. (chosen by Millspaugh, Publ. Field Columbian Mus., Bot. Ser. 2: 306. 1909).

Poinsettia Graham, Edinburgh New Philos. J. 20: 412. 1836. *Euphorbia* sect. *Poinsettia* (Graham) Baillon, Etud. 284. 1858. *Euphorbia* subg. *Poinsettia* (Graham) House, New York State Mus. Bull. 254: 472. 1924. TYPE: *Poinsettia pulcherrima* (Willd. ex Klotzsch) Graham.

Four species new to Panama are reported here. In addition, the Panamanian endemic, *Euphorbia apocynoides*, which was merely mentioned in passing in the original treatment, is here treated in full. These changes make it necessary to provide a new key. Both of the present authors are agreed that *Poinsettia*, treated as a separate genus in the original treatment, is best regarded as a subgenus of *Euphorbia*; thus *Poinsettia* is suppressed in the generic key, and the two Panamanian species are included in the key to *Euphorbia*.

LITERATURE

DRESSLER, R. L. 1961. A synopsis of *Poinsettia* (Euphorbiaceae). Ann. Missouri Bot. Gard. 48: 329–341.

KEY TO THE SPECIES OF *EUPHORBIA* IN PANAMA

- 1a. Leaves more than 15 cm long, leathery; cyathia 4–6 mm long .... 3. *E. elata*
- 1b. Leaves less than 8 cm long, membranous; cyathia less than 3 mm long.
  - 2a. Gland of cyathium 1; floral bracts usually with pale or colored spots; seeds coarsely tuberculate.
    - 3a. Involucral gland cup-shaped; floral leaves green, white, or purple-spotted at base, never red; seeds angulate, coarsely tuberculate .... 1. *E. heterophylla*
    - 3b. Involucral gland bilabiate; floral leaves red, at least at base; seeds ovoid-cylindrical, finely and sharply tuberculate .... 2. *E. cyathophora*
  - 2b. Glands of cyathium 4 or 5 (rarely 2).
    - 4a. Leaves all whorled; stems articulate; trees or large shrubs.
      - 5a. Floral leaves white .... 4. *E. leucocephala*
      - 5b. Floral leaves green (unknown in *E. apocynoides*).
        - 6a. Leaf blades ovate, 3–5 cm broad; petioles 2–6 cm long .... 5. *E. cotinifolia*
        - 6b. Leaf blades oblong or narrowly obovate, 1.5–2 cm broad; petioles to 1 cm long .... 6. *E. apocynoides*
    - 4b. Leaves alternate; herbs.
      - 7a. Involucres and capsules pubescent.
        - 8a. Inflorescence glandular-pilose; leaf blades mostly 1 cm long or shorter .... 7. *E. ocymoidea*
        - 8b. Inflorescences nonglandular; leaf blades mostly longer than 2 cm.
          - 9a. Cyathial glands 4 or 5, plane .... 8. *E. xalapensis*
          - 9b. Cyathial glands 2, bilabiate .... 9. *E. oerstediana*
      - 7b. Involucres and capsules glabrous.
        - 10a. Cyathial appendages obsolete; glands with 2 conspicuous lateral horns .... 10. *E. peplus*
        - 10b. Cyathial appendages present; glands elliptic.
          - 11a. Seeds terete, the surface smooth; cyathia ca. 2 mm in diameter; glands 4, dark; appendages equaling glands, ciliate-pubescent above .... 11. *E. dwyeri*
          - 11b. Seeds strongly angled, the surface deeply punctate with pits in regular longitudinal rows; cyathia ca. 1 mm in diameter; glands 4 or 2, green; appendages obsolete (Panamanian specimens) to prominent and white, several times size of gland, glabrous .... 12. *E. graminea*

42.3. Euphorbia elata Brandegee, Univ. Calif. Publ. Bot. 6: 55. 1914. TYPE: Mexico. Chiapas: Finca Irlanda, *Purpus 7026* (holotype, UC; isotypes, A, BM, F, GH, MO, F neg. 62362, UC, US).

Euphorbia valerii Standley, J. Wash. Acad. Sci. 17: 11. 1927. TYPE: Costa Rica. Guanacaste: Los Ayotes, near Tilarán, 600–700 m, *Standley & Valerio 45338* (holotype, US; isotype, US).

Shrub or small tree to 3.5 m high, glabrous; branches few or none. *Leaves* alternate, clustered at apex of stem; petioles 2–4(–6) cm long, ca. 2 mm thick; stipules fleshy, light-colored, deltate to rounded, 3–4 mm long, 3–4 mm broad; blades coriaceous, glabrous, oblanceolate or narrowly elliptic, the apex rounded to bluntly short-acuminate at tip, acute to cuneate at base, 15–35 cm long, 4–10(–12) cm broad, 3–5(–7) times as long as broad; midrib prominent below, to 2 mm thick; lateral veins 17–30 pairs on a side, obscure, nearly at right angles to midrib; margin entire. *Inflorescences* single, terminal or rarely axillary, long-pedunculate, cymose; peduncle 10–30 cm long, glabrous, minutely brown-puberulent, or covered with a waxy brown reticulum; cyme up to 5 times divided, the cyathia ultimately in 2–4 compact groups; bracts opposite, scalelike, attached to the stem along a broad base, deltate, ca. 4 mm long, 2.5–3 mm broad; margin entire, sometimes ciliate, hyaline; apex blunt, somewhat cucullate. *Involucres* campanulate, glabrous, minutely brown-puberulent or covered with a waxy brown reticulum, green, drying to brown, 4–6 mm high, (3–)4–5.5 mm diam.; pedicels 1.5–3 mm long, 1–1.5 mm thick; lobes 5, 1.5–2 mm long, ca. 2 mm broad, erose to fimbriate, rarely entire, erect, concolorous or dark red; glands 5, round, 1.7–2 mm diam., placed vertically on rim of involucre, looking outwards, but positions of lobes making glands appear below rim; gland sometimes erect and thick-stalked so that surface is flat with respect to orifice, the margin then crisped; appendages none. *Capsules* exserted from the cyathium no more than 1 mm (the gynophore erect), green, glabrous, 8–9 mm high, 10–11 mm diam.; styles ca. 1.5 mm long, united at base for ca. ⅓ of their length, strongly recurved, bifurcate; seeds subglobose, truncate at apex, 4.7–5 mm diam., ca. 4.5 mm long, ecarunculate, dark brown, with lighter, low, broken, irregular longitudinal ridges.

Euphorbia elata, which occurs in moist evergreen forests of low to middle elevations, is definitely known to range from southern Veracruz, Mexico, to Colombia, and may occur as far south as Bolivia. It is the most widespread species of sect. *Adenorima* (Raf.) Webster, a group of several highly divergent species of trees and shrubs from the West Indies, western and southern Mexico, and the northern Andes. The species closest to *E. elata* are all highly restricted in range and are poorly understood. *Euphorbia sinclairiana* Benth. (in Seemann, Bot. Voy. Sulphur 163. 1844), known only from the island of Gorgona off the Pacific coast of Colombia, is characterized by a deeply bifurcate and much-branched inflorescence with conspicuous foliaceous bracts, but is otherwise similar to *E. elata*. The Peruvian *E. tessmannii* Mansf. (Ber. Deutsch Bot. Ges. 46: 674. 1929; Notizbl. Bot. Gart. Berlin-Dahlem 11: 137. 1931) is known only from the type collection, and no original material is definitely known to be extant. Until either new or original material is available, the status of that species cannot be determined. *Euphorbia capansa* Ducke (Arq. Inst. Pesq. Agron. 1: 21. 1938), described from western Amazonian Brazil, appears to be synonymous with *E. elata*. Another collection from Bolivia (*Bang 619*, MO, NY, US) was given an unpublished name but will probably also prove to be *E. elata*.

Specimens examined. PANAMA. BOCAS DEL TORO: road to Chiriquí Grande, 300 m, *McPherson 10085* (MO). COLÓN: trail from end of Santa Rita Ridge Rd. to Río Pedros, 600 m, *Antonio 3750* (F, MO); Distr. Portobelo, stream off N slope of Río Gatún, 2,200 ft., *Antonio 3804* (MO); Santa Rita, E of mountainous zone, *Correa & Dressler 973* (PMA); Santa Rita Ridge, E of Colón, *Dressler 3338* (PMA), *3348* (F, PMA); Santa Rita lumber road, ca. 15 km E of Colón, *Dressler & Lewis 3728* (MO, PMA); Santa Rita Ridge, 4 hour walk from end of road, *Hammel 6318* (MO); ca. 2–3 mi. up the Río Guanche, 10–20 m, *Kennedy & Foster 2170* (MO); Santa Rita Ridge Rd., ca. 6 km from Boyd-Roosevelt Hwy., *Mori & Kallunki 2151* (MO, NY); Santa Rita Ridge, on fork in road on main Santa Rita Ridge Road, *Mori & Kallunki 3053* (MO, NY). DARIÉN: Cerro Pirre, valley between Pirre and next most southerly peak, sloping hillside, *Folsom 4385* (MO). PANAMÁ: on road near slopes of Cerro Jefe, 2,400 ft., *Antonio et al. 3426* (F, MO); just before La Eneida along new trail beside Lopez House, *Correa & Dressler 724* (DUKE, 2 sheets), *Correa et al. 816* (MO); El Llano–Cartí road, 14–18 km from road to Chepo, 400 m, *Correa et al. 1867* (PMA); El Llano–Cartí road, 12 mi. above Pan-Am Hwy., *Liesner 1244* (MO); El Llano–Cartí road, 11 km from Pan-Am Hwy., *Mori & Kallunki 3057* (MO, NY). VERAGUAS: Escuela Agricultura, Alto Piedra near Santa Fe, 0.3 mi. beyond fork in road near school, toward Atlantic slope along trail to top of Cerro Tute, 3,400–3,800 ft., *Antonio 3498* (MO); 6.4 km outside of Santa Fe on road past agricultural school, toward the cordillera, *Folsom 2970* (F, MO).

42.4. Euphorbia leucocephala Lotsy, Bot. Gaz. (Crawfordsville) 20: 350, pl. 24. 1895. LECTOTYPE: Guatemala. Huehuetenango: Cuilco, Dec. 1891, *Shannon 305* (presumably US, not seen; chosen by Standley & Steyermark, Fieldiana, Bot. 24(6): 107. 1949).

Shrub to 3 m high; branches terete, glabrous, swollen at the nodes. *Leaves* verticillate; petioles (1–)2–6 cm long, slender, glabrous; stipules glanduliform, 0.3–0.5 mm long; blades glabrous, elliptic to linear-elliptic, mucronate and rounded or bluntly acute at tip, acute at base, (2–)3–7 cm long, (0.7–)1.5–2.7 cm broad, 2–3(–4) times as long as broad; margin entire. *Inflorescences* terminal, cymose; bracts white, narrowly spatulate; petioles 3–7 mm long, thinly pilose; blades 5–10 mm long, 1.2–2 mm broad; base narrowly acute; margin entire; apex rounded, mucronate. *Cyathia* on peduncles 1–2.5 mm long; involucre campanulate, 1–1.8 mm high, 1.1–1.7 mm diam., densely tomentose just below the glands, otherwise sparsely pilose; glands 5, green, 0.8–1 mm long parallel to the rim of the cyathium, 0.4–0.5 mm broad, the center of the inner margin strongly inflexed forming a deep convex trough; appendages white, linear-lanceolate, exceeding glands by 2–3(–3.5) mm, 0.5–1 mm broad, the apex narrowly rounded. Gynophore erect, exserted from cyathium 1–1.5 mm. *Capsules* glabrous, smooth, 5–6 mm high, 4.5–5.5 mm diam., shallowly 3-lobed, the cocci distinctly 3-angled; styles 0.6–0.7 mm long, united at base, deeply trifid, the style branches strongly recurved; seeds (immature) ca. 3.5 long, trigonous, ca. 1.8 mm wide, caruncuIate.

The reports of this species from central Panama represent a considerable range extension; the previously known range is from western and southern Mexico to Honduras. *Euphorbia leucocephala* is a commonly cultivated ornamental in Central America, and the Panamanian collections may be from cultivated trees, but the label data are not clear on this point.

Capsules are unknown in Panamanian collections and are scarce in the numerous collections from northern Central America. Our description of the capsules is taken from a specimen collected in Depto. Huehuetenango, Guatemala (*Molina 21389*, F).

Specimens examined. PANAMA. COCLÉ: El Valle de Antón, 1,000–2,000 ft., *Lewis et al. 2570* (MO); El Valle, *Ramos 19* (MO, PMA). PANAMÁ: Panama Viejo, *Girón 1* (MO); near Cerro Azul, *Cambra 49* (MO, PMA).

42.6. Euphorbia apocynoides Klotzsch in Seemann, Bot. Voy. Herald 99. 1853. TYPE: Panama. Darién: Punta Garachiné, *Seemann 1096* (holotype, BM; isotype, K; photo of isotype, K, MO).

Shrub to 2 m high; stems glabrous, terete, swollen at nodes; internodes 2–4 cm long. *Leaves* ternate; petioles slender, 7–10 mm long, very sparsely pilose; blades membranous or chartaceous, dark green above, lighter or even somewhat glaucous below, oblong to narrowly obovate, rounded at tip, acute at base, 4.5–6 cm long, 1.5–2 cm broad, 3–3.5 times as long as broad, glabrous or with very few hairs below; margin entire. *Inflorescences* unknown. *Cyathia* turbinate, ca. 2.5 mm high, ca. 2.5 mm diam. below the appendages, sparingly to evenly appressed-pubescent, the hairs short, straight, nonoverlapping; peduncles 3–4 mm long, subglabrous; appendages 5, narrowly flabellate, white, pubescent as the involucre below toward the base, ciliate on the margins near the juncture with the involucre, otherwise glabrous, entire in the lower half, deeply and coarsely crenellate along the distal margin. *Flowers* and *fruits* not seen.

This poorly known species is apparently endemic to Panama and is still known only from the fragmentary type collection and an equally fragmentary recent collection from the type locality. The type is sufficiently complete, however, to enable the species to be placed with reasonable certainty in section *Alectoroctonum* (Schldl.) Boissier, a group characterized by verticillate branching and swollen nodes, and to say that it is unlike any other species in the section. Contrary to the statement in the original treatment (Webster & Burch, 1968: 335), the cyathium is quite unlike that of sect. *Dichilium* Boissier, which is characterized by a reduced number (usually 2) of bilabiate glands and small, erect, or often obsolete, appendages. The species of sect. *Dichilium* are also characterized by alternate leaves and stems that are pinched just above the nodes.

A plant vegetatively very similar to *Euphorbia apocynoides*, collected near Puerto Colombia on the Caribbean coast of Colombia (*Elias 1197*, F), has been identified as *E. nudiflora* Jacq., a West Indian species. The cyathium, however, differs from that of *E. apocynoides* in that it is campanulate, the pubescence is crisped with overlapping hairs, and the appendages are completely glabrous, obovate, and with smaller and more numerous crenellations on the distal margin. In all of these characters it matches *E. nudiflora*, which differs vegetatively in its more highly branched habit and shorter, broader leaves. An elucidation of the relationship of the Colombian plant to the Panamanian one, and of both to *E. nudiflora*, must await fuller collections from Panama and Colombia.

We are indebted to Mr. A. Radcliffe-Smith of Kew for providing a description and a sketch of the cyathium from the isotype of *E. apocynoides* at K, from which our description has been taken.

Additional collection examined. PANAMA. DARIÉN: thorn forest near Punta Garachiné, *Duke 10485* (MO, 2 sheets).

42.7. Euphorbia ocymoidea L., Sp. Pl. 453. 1753. TYPE: Mexico. Campeche: *Houston s.n.* (BM, not seen).

E. astroites Fisch. & Mey., Index Sem. Hort. Petrop.

10: 44. 1845. TYPE: Mexico: Tampacoala, *Karwinsky* (LE, not seen).

A thorough examination of collections from throughout the range of this species (western Mexico to Panama) makes it clear that *Euphorbia astroites* cannot be separated from *E. ocymoidea.* The only consistent character separating the two is the glandular-pilose stems of the former, as opposed to the glabrous or short-pilose, eglandular stems of the latter. The two forms occupy roughly the same geographical range (the glandular form is not yet known from western Mexico, and the eglandular form has not been collected south of Nicaragua) and the same habitats, and they exhibit similar variation patterns, particularly in the shape of the leaves, which range from broadly ovate or deltate to somewhat reniform. As suggested by McVaugh (1961: 177), several names based on collections from western Mexico, particularly *E. subreniformis* S. Watson, undoubtedly belong here.

The only known Panamanian collections are glandular-pilose, a fact that was omitted from the original treatment, and thus would have been placed under *E. astroites.* The species has apparently not been collected in Panama since the appearance of the original treatment.

42.8. Euphorbia xalapensis Kunth, Nov. Gen. Sp. Pl. 2: 61. 1817. *Poinsettia xalapensis* (Kunth) Klotzsch & Garcke, Monatsber. Königl. Preuss. Akad. Wiss. Berlin 1859: 253. 1859. TYPE: Mexico. Veracruz: near Xalapa, *Humboldt & Bonpland s.n.* (P, not seen).

Euphorbia enalla Brandegee, Univ. Calif. Publ. Bot. 6: 54. 1914. TYPE: Mexico. Chiapas: Cerro del Boquerón, *Purpus 7035* (holotype, UC; isotypes, F, F neg. 60269, GH, MO, NY; distributed under an unpublished name).

Euphorbia amphimalaca Standley, Publ. Field Columbian Mus., Bot. Ser. 4: 313. 1929. TYPE: Honduras. Comayagua: near Siguatepec, Feb. 1928, *Standley 56341* (holotype, F; isotypes, F, F neg. 60244, US).

Perennial rhizomatous *herb* to 50 cm high, the stems shaggy brown-pilose. *Leaves* opposite or verticillate above, alternate below; petioles 1.5–2.5 cm long, brown curly-pubescent; stipules glanduliform, brown or black, minute, 0.1–0.2 mm long; blades ovate, acute at tip, rounded to obtuse at base, dark green, 1.5–3.5 cm long, 1–2 cm broad, 1.5–1.8 times as long as broad, densely shaggy-pilose below, more sparsely so above, base rounded to obtuse; margins entire, ciliate, acute. *Inflorescences* terminal, cymose, often appearing one-sided by the abortion of one branch at a node, shaggy-pubescent; bracts similar to the leaves but greatly reduced, often aborting. *Cyathia* on pedicels 1–3 mm long; involucre campanulate, 0.7–1.3 mm high, 0.5–1.3 mm diam., crisp-pubescent; glands 5, green, elliptic to reniform; appendages whitish or greenish, broadly ovate, exceeding the gland by 1–2 mm, 1.5–2 mm broad, the margin entire or crenate; gynophore glabrous, erect or somewhat recurved, exserted from the cyathium 1.5–2 mm. *Capsules* sparsely to densely pilose, 1.5–1.9 mm high, 1–1.5 mm diam.; styles 0.7–0.8 mm long, free to the base, deeply bifid, thinly pilose; seeds ca. 1.5 mm long, 0.9–1 mm diam., ovoid, grayish, coarsely pitted, tuberculate, ecarunculate.

Euphorbia xalapensis is a common species of forest borders and thickets that ranges from western Mexico to Honduras, and thus the new reports cited here from Panama and Costa Rica represent a considerable range extension. This species was erroneously treated in the *Flora of Guatemala* (Fieldiana, Bot. 24(part 6): 108. 1949) as *E. oerstediana* (Klotzsch & Garcke) Boissier, a very different species that has mostly glabrous stems, articulated nodes, two cyathial glands that are more or less bilabiate and that have inconspicuous or obsolete appendages, and densely white-pubescent capsules. The latter species, which belongs to section *Dichilium* Boissier, is very rare in Central America and is somewhat better known from the West Indies and northern South America. It is still unknown from Guatemala, and nearly all of the putative collections from there are referable to *E. xalapensis.* It has not been re-collected in Panama since the collection cited in the original treatment.

Euphorbia xalapensis is also frequently confused with *E. graminea,* a highly variable and widespread species of the same section, *Cyttarospermum* Boissier, and the two are indeed very similar in aspect. *Euphorbia xalapensis,* however, can be distinguished by the distinctly perennial and often strongly rhizomatous habit; the shaggy brown pubescence of the stems, leaves, and inflorescence; the one-sided appearance of the inflorescence, which is due to the frequent abortion of one branch at a node; and the five glands that have ample, usually greenish appendages.

Additional specimens examined. COSTA RICA. SAN JOSÉ: along Quebrada Tablazo and on forested slope above creek, NE part of Altos Tablazo, 9°50′N, 84°03′W, 1,700–1,800 m, *Grayum & Schatz 5157* (MO). PANAMA. CHIRIQUÍ: Volcán Chiriquí above Boquete, roadside, *D'Arcy 9805* (DAV, MO), distributed as "*Euphorbia graminea* Jacq. (s. lat.)."

42.10. Euphorbia peplus L., Sp. Pl. 456. 1753. TYPE: Europe (presumably in Hortus

Cliffortianus Herbarium, BM, not seen; 630.24 in LINN).

Annual glabrous *herb* 18–35 cm high. *Leaves* alternate below, opposite or ternate above, sessile or short-petiolate, numerous, early deciduous below; stipules obsolete; blades bright green, membranous, spatulate, rounded at tip, acute or cuneate at base, 10–14 mm long, 8–12 mm broad; margins entire; floral leaves slightly smaller, somewhat reflexed, congested. *Cyathia* solitary in forks of upper branches, on peduncles 0.6–1 mm long; involucre campanulate, light green, ca. 1 mm high, 0.5–0.7 mm diam.; glands 4, green, crescent-shaped, exappendiculate, ca. 0.5 mm long parallel to the rim of the involucre, with prolonged narrow horns 0.5–0.7 mm long; gynophore exserted, ca. 1.3 mm long, recurved. *Capsules* green, 1.8–2 mm high, 2–2.2 mm diam., broadest below the middle, shallowly 3-lobed, the cocci each with 2 narrow longitudinal ridges; styles ca. 0.1 mm long, bifurcate, the style branches bifurcate; seeds ovoid-oblong, weakly 6-angled, gray, ca. 1.5 mm long, ca. 0.8 mm diam., caruunculate, deeply pitted, minutely white-tuberculate.

This is apparently the first report from southern Central America of this cosmopolitan weed of temperate Eurasian origin.

Specimens examined. PANAMA. CHIRIQUÍ: trail from Paso Respingo to Bajo, Chorro Cerro Punta to Boquete, along stream near Guadalupe, *Hammel et al. 7077* (MO); forest remnant beside Las Cumbres, 1 mi. from road near Cerro Punta dairy, 8,000 ft., *D'Arcy et al. 13193* (F, MO); Cerro Punta, *Tyson 7058* (MO, PMA).

42.11. Euphorbia dwyeri Burch, Ann. Missouri Bot. Gard. 54: 182. 1967. TYPE: Panama. Chiriquí: Cerro Horqueta, NW of Boquete, *Dwyer et al. 434* (holotype, MO; isotypes, GH, K, US).

A second collection of this species has been found, misidentified as *E. caracasana* Boissier.

Additional specimen examined. PANAMA. CHIRIQUÍ: humid forest of Cuesta de Las Palmas, southern slope of Cerro de la Horqueta, 1,700–2,100 m, *Pittier 3216* (US).

43. *Chamaesyce*

Chamaesyce Gray, Nat. Arr. Brit. Pl. 2: 260. 1821. TYPE: *Chamaesyce maritima* Gray = *C. peplis* (L.) Prokh. (*Euphorbia peplis* L.) (See Wheeler, 1943: 461, for a discussion of the type.)

NOTES

A NEW SPECIES OF *HYMENOLOBIUM* (LEGUMINOSAE—PAPILIONOIDEAE) FROM CENTRAL AMERICA

Among the numerous trees of the Amazonian Hylea, the genus *Hymenolobium* is considered to be one of the main suppliers of excellent timber. It is closely related to the genus *Andira* (tribe Dalbergieae) but is distinguished by having a flat, reticulately veined fruit with one or two prominent submarginal nerves. Although delimitation of the species still presents various difficulties due to insufficient collections in herbaria, the 15–17 taxa previously recognized (Mattos, 1979; Lima, 1982) are restricted to South America from Venezuela and Surinam to southeastern Brazil.

During examination of material in the herbarium of the Missouri Botanical Garden (MO), some new collections from Central America were encountered. These represent a new species:

Hymenolobium mesoamericanum Lima, sp. nov. TYPE: Costa Rica. Heredia: alt. 220 m, Río Tirimbina, Istarú Farm, Tiribina, Sarapaquí, 16 July 1971 (fl), *Roy W. Lent 2003* (holotype, MO; isotypes, NY, US). Figure 1.

A omnibus specibus fructibus alatis adhuc cognitis floribus majoribus (18–20 mm) et calycibus tenue-coriaceis pubescentis differt.

Large tree to 40 m, dbh to 90 cm. Trunk with smooth, grayish bark; wood yellow. Terminal branches grayish, with numerous scars of caducous leaves, pubescent on the newest growth. Stipules caducous, ovate-lanceolate, 1–1.4 × 0.5–0.9 cm, stipels filiform, 0.1–0.2 cm long. Leaves imparipinnate, aggregated at the branch apices, 8–17-jugate (up to 25-jugate on regrowth branches or young plants); petiole pubescent, 2.5–4 cm long (to 6 cm long on regrowth branches or young plants); rachis pubescent, 12–28 cm long (to 56 cm long on regrowth branches or young plants); leaflets oblong, oblong-elliptic or ovate-oblong, the terminal one elliptic, 2.5–7 × 1.5–3 cm, the base rounded, subcordate or obtuse, the apex retuse or obtuse, mucronate, the lower face pubescent, the upper face sparsely pubescent to subglabrous; petiolules 1.5–2.5 mm long. Panicles 10–15 × 15–22 cm, the branches pubescent; bracts and bracteoles caducous, the bracteoles ovate-lanceolate, pubescent, 1–1.5 × 0.5–0.7 mm. Flowers 18–20 mm long; pedicels 5–8 mm long; calyx campanulate, slightly coriaceous, pubescent, 5-toothed, 8–10 mm long; corolla rose, the petals papery; vexillum 16–18 × 14–15 mm, wings 15–17 × 5–6 mm; keel 14–16 × 5–6 mm; stamens 10, monadelphous, 15–16 mm long; anthers 0.8–1 × 0.3–0.4 mm; ovary long-stipitate, pilose along the margins; ovules 2–3; style sparsely pilose, the stigma punctiform. Immature fruit flat, with wide lateral wings.

Habitat and distribution. Emergent tree of gallery forests of low altitude (50–300 m), or left uncut in pasture land, in Costa Rica, Nicaragua, and Panama.

Additional material examined. COSTA RICA. HEREDIA: along Río Frio Road, after entrance to Starke's hacienda, 25 Apr. 1976 (fl, lvs), *G. S. Hartshorn 1843* (MO, NY). NICARAGUA. Standley 27584* (US).

Hymenolobium mesoamericanum is distinguished from other species in the genus principally by its large flowers (18–20 mm) with slightly coriaceous, pubescent calyces. It shows affinities with *H. heterocarpum*, which possesses slightly larger flowers (22–23 mm) with coriaceous, tomentose calyces and suborbicular to oblong-reniform fruits with rudimentary lateral wings. The young fruit of *H. mesoamericanum* is provided with wide lateral wings, which suggest a samaroid fruit type as found in the majority of the species in the genus. However, collections of completely mature fruit are necessary to confirm this character.

Size and consistency of leaflets frequently vary in species of *Hymenolobium* (Lima, 1982). The

variation is related to leaf fall and/or to environmental factors, mainly intensity of solar radiation. The latter element determines the development of smaller, more rigid leaflets on the upper branches of the crown of adult individuals than on lower (regrowth) branches or on young individuals (Fig. 1f, g).

The wood of this species supplies planks for construction and is commonly called "colepáo" (Costa Rica, Prov. Heredia) and "carolillo" or "nogal" (Nicaragua, Dept. Zelaya).

I am grateful to Dr. Gwilym P. Lewis, who reviewed and translated the manuscript from Portuguese. I also express appreciation to Dr. Warren D. Stevens for cooperation in lending the MO material and to Maria Helena Pinheiro for the illustration.

A NEW SPECIES OF *VANTANEA* (HUMIRIACEAE) FROM PANAMA

Recently collected flowering material of the central Panamanian species of *Vantanea* hitherto considered conspecific with the Colombian *V. occidentalis* Cuatr. (Gentry, 1975; Croat, 1978) has forced a reconsideration of the taxonomic status of the Panamanian entity. It is here recognized as a new species, *V. depleta*, differing most importantly in stamen number and ovary pubescence from *V. occidentalis*, which it otherwise strongly resembles.

Of significance to the current generic concept of *Vantanea* is the low number of stamens diagnostic of the new species. Cuatrecasas, in his revision of the family (1961), characterized *Vantanea* (sole member of the Vantaneoideae) as having 50–180 stamens, among other attributes, but *V. depleta* rejoices in no more than 15–18. Nevertheless, since the new species has the bilocular anther thecae, biovulate ovary locules, and the drupe morphology typical of the genus, there can be little doubt that it is correctly placed in *Vantanea*.

Vantanea depleta McPherson, sp. nov. TYPE: Panama. Panamá: Cerro Jefe, 650 m, 2 May 1987, *McPherson & Stockwell 10892* (holotype, PMA; isotypes, F, MO). Figure 1.

Species floribus parvis (6 mm longis), petalis glabris, staminibus paucis (15–18), et ovario puberulo dignoscenda.

Tree 9–40 m; twigs often strongly angled, glabrous, marked by elongate lenticels. Leaf blades elliptic or elliptic-ovate, (5.5–)8.5–16 cm long, (3–)4–8 cm wide, entire, coriaceous; base acute, often somewhat reflexed abaxially, extending down the petiole as a pair of tapering wings; apex obtuse, not or only obscurely acuminate; midrib prominent on upper surface, somewhat raised on the lower surface; secondary veins (6–)7–9(–11), only slightly raised; both surfaces dull, glabrous, 1 or 2 small sunken laminar glands in most cases associated with each of the secondaries. Petiole somewhat poorly delimited from blade, 3–9 mm long, swollen at the base, glabrous. Inflorescences terminal as well as sometimes also from the uppermost axils, broadly paniculate, the branches puberulent. Pedicels 1.5–3 mm, less puberulent than the rachises. Sepals semicircular, 1 mm long, 1.5–2 mm wide, obtuse, puberulent, mostly bearing one centrally placed raised crateriform gland. Petals narrowly triangular-ovate, slightly imbricate in bud, 5 mm long, 2 mm wide, glabrous on both surfaces, white. Stamens 15–18, the filaments 3–5 mm long, fused basally for ca. 1 mm, glabrous, white; anthers ca. 0.7 mm long, the thecae bilocular, about as long as the distal prolongation of the connective. Disk ca. 1 mm high, sharply dentate, glabrous. Ovary 2 mm long, densely puberulent, the hairs much shorter than the width of a filament; style 3 mm long, geniculate. Fruit 2.5–3.5 cm long, 1.5–1.7 cm diam., puberulent, rounded basally, acute distally; endocarp smooth, with 5 broad ribs alternating with 5 oblong valves, 2.4–3.3 cm long, 1.5–1.8 cm in diam.

Additional specimens examined. PANAMA. VERAGUAS: Cerro Tute, 1,200 m, *Lao & Gentry 530* (MO). CANAL AREA: Barro Colorado Island, *Garwood 440* (MO); Pipeline Road, *Gentry 1931*, *7406* (MO). PANAMÁ: Cerro Jefe, 650 m, *McPherson 11008* (MO), *11296* (MO, PMA). SAN BLAS: between Río Irgandí and Río Cartí Senni, *de Nevers & Herrera 6597* (MO).

Vantanea depleta is known from central Panamanian forests from near sea level to 1,200 m.

I thank John K. Myers for the illustration.

NOMENCLATURAL CHANGES IN THE GENUS *FUCHSIA* (ONAGRACEAE)

In Berry (1982), ten new species of *Fuchsia* were described. A typographical error was made in one of these descriptions (the first "i" was omitted) and is corrected as follows:

Fuchsia coriacifolia P. Berry, Ann. Missouri Bot. Gard. 69: 150. 1982.

Examination of specimens from Cambridge University revealed that the type of *F. parviflora* Lindley, treated by Breedlove (1969) as a species of the Mexican and Central American sect. *Encliandra*, does not belong to that group. Instead, it belongs to the monotypic sect. *Kierschlegeria* and is conspecific with the earlier described *F. lycioides*. As a result, the following nomenclatural changes are needed:

Fuchsia lycioides Andrews, Bot. Rep. 2: pl. 120. 1800. TYPE: plate 120 of the Botanists Repository, vol. 2 (lectotype, here designated).

Fuchsia parviflora Lindley, Bot. Reg. 13: 1048. 1827. TYPE: cultivated in the Chiswick Garden, England, from seed presented to the Horticultural Society by George Canning in 1824, *without collector*, July 1826 (holotype, CGE).

The type of *F. parviflora* has alternate leaves and both series of stamens erect, clearly excluding it from sect. *Encliandra*, in which all members have opposite leaves and the antipetalous stamens reflexed back into the floral tube (Breedlove, 1969). Lindley, in fact, noted the close similarity of *F. parviflora* to *F. lycioides*, distinguishing his species mainly by the smaller flower size and the longer petioles. *Fuchsia lycioides* is subdioecious, however, with the pistillate flowers nearly half the size of the hermaphrodite ones (Atsatt & Rundel, 1982). Lindley's type was from a pistillate individual, whereas Andrews's type of *F. lycioides* was from a hermaphrodite plant with larger flowers. Leaf size in *F. lycioides*, on the other hand, is too variable to distinguish it from *F. parviflora*. Quite likely Lindley's report of *F. parviflora* as a native of Mexico was in error, since *F. lycioides* is restricted to a narrow coastal area of central Chile, and his type was from a specimen cultivated in England.

Fuchsia cylindracea Lindley, Bot. Reg. 24: 66. 1838. TYPE: cultivated at the Horticultural Society, London, England, raised from Mexican seeds presented by George Barker, *without collector* (lectotype, CGE).

Fuchsia parviflora Lindley, sensu Breedlove, Univ. Calif. Publ. Bot. 53: 56. 1969.

The type sheet of *F. cylindracea* has two separate branches, one male and the other female. The male portion is here designated as the lectotype, since the species is dioecious (Breedlove, 1969), and an illustration of a male branch accompanies the type description.

BACTRIS DIVISICUPULA AND *BACTRIS FUSCOSPINA* REEXAMINED

Work on a forthcoming paper on the palms of western San Blas, Panama required the determination of similar-looking specimens labeled *Bactris divisicupula* Bailey (Palmae, Cocoeae) or *B. fuscospina* Bailey. Bailey (1943a) described both species, from one specimen each, from semi-isolated peaks in west-central Panama. The type collections actually intergrade, and collections since then also bridge the distinctions, indicating that the two taxa are synonymous.

Bailey (1943b) used the following couplet to distinguish the types of *B. divisicupula* (*Allen 1817*) and *B. fuscospina* (*Allen 2086*):

e.	Pinnae short-caudate or only acuminate, marked on upper surface with cross-lines between the nerves: cupule of an outer series (calyx) of 3 deep lobes and an inner series (corolla) with nearly entire margin and setose	*B. fuscospina*
ee.	Pinnae long-caudate and [with] no elevated cross-lines: cupule divided into deep lobes in both series	*B. divisicupula*

Collections amassed since 1943 demonstrate that leaf shape and venation in this species are variable and do not provide consistent separation. *Allen 2086* bears an inflorescence just past flowering, while *Allen 1817* has mature fruits. The difference in developmental stages may have been a reason Bailey described two species. He stated (1943a: 230) that the setae of the calyx of *B. fuscospina* (from the less-developed material of *Allen 2086*) are "likely to perish with handling," which does occur, thus rendering the vestiture indistinguishable from that of the more-developed *B. divisicupula*. *Allen 1817* actually retains some setae on the calyx, identical to those of *Allen 2086*. The lobing of the "cupule" (corolla) is also an artifact of development, the corolla being parted into lobes by the expanding fruit.

I here include *B. fuscospina* in synonymy with *B. divisicupula*.

Bactris divisicupula Bailey, Gent. Herb. 6: 230. 1943. TYPE: Panama. Cocle: Él Valle de Antón, 21 May 1939, *Allen 1817* (hololectotype, MO; isolectotypes, BH, GH, here designated).

B. fuscospina Bailey, Gent. Herb. 6: 228. 1943. TYPE: Panama. Panamá: Cerro Campana, 31 Dec. 1939, *Allen 2086* (hololectotype, MO; isolectotype, BH, here designated).

Bailey did not designate a holotype. The BH and GH specimens are fragments. The description appears to be based on the MO sheet, which is the only one containing the information included in the description. For these reasons the MO duplicate is here chosen as lectotype.

When Bailey described the two palms, the flowers were unknown. The collections *de Nevers 6127*, *Moore 6531*, and *Johnston 1552* allow the following description:

Flowers crowded on the rachillae; pistillate flowers in triads with 2 staminate flowers; the triads mixed with numerous solitary staminate flowers in proximal third of rachillae; distal ⅔ of rachillae with exclusively staminate flowers; staminate sepals 3, unequal, linear, connate at base, 1 mm long; staminate petals connate in lower third, free and valvate above, 5 mm long, thick, apically acute, inequilateral; stamens 6, the filaments adnate to the petals basally, free distally, twice folded or bent, ca. 2 mm long; anthers ovate, dorsifixed just below the middle, dehiscing longitudinally; pistillode minute; pistillate sepals connate into a vertically striate tube 3–4 mm long, minutely 3-lobed at apex; pistillate petals connate into a tube 2 mm long, truncate to obscurely 3-lobed apically, minutely spinescent without, striate within; staminodes absent; stigma sessile, truncate, 0.5 mm long; ovary oblong. Ovule basal.

Bailey (1943a) described the rachillae of the two species as "pubescent" (*B. divisicupula*) and "indifferently pubescent" (*B. fuscospina*). The pubescence is strongly eroded in the material he saw: the indument of the rachillae is a dense mat of multicellular hairs, each reminiscent of a string of beads. *Moore 6531* has these hairs well developed and is unique among the flowering specimens seen in having the spinescent indument of the corolla tube continue onto the rim of the tube as a fringe.

Bactris divisicupula ranges from the provinces of Limón and Puntarenas in Costa Rica to the Department of Valle in Colombia. It inhabits tropical moist forest, tropical wet forest, premontane wet forest, and premontane rain forest (sensu Holdridge et al., 1971) between sea level and 1,000 meters. The Colombian material has larger fruits than the Panamanian material and may tie *B. divisicupula* to additional specimens at MO from Amazonian Peru and Venezuela. Comparison with the Amazonian material is deferred to a later date pending collections from Amazonian Colombia and Ecuador.

CHROMOSOMAL OBSERVATIONS ON *FUCHSIA* SPECIES AND ARTIFICIAL HYBRIDS

The two largest sections of *Fuchsia*, sects. *Fuchsia* and *Hemsleyella*, are concentrated in the tropical Andes and together comprise 75 of the nearly 105 species of the genus. Both sections have been recently revised by Berry (1982, 1985), who reported chromosome numbers for 52 species. Species from both sections are primarily diploid ($n = 11$; 43 species), but seven are tetraploid ($n = 22$), and one species has both diploid and tetraploid populations. In an effort to obtain counts for the remaining species and for interesting new collections or interspecific hybrids in these sections, we examined eight specimens cultivated by members of the Dutch Circle of Fuchsia Friends in 1986. Young floral buds were fixed in Carnoy's solution and stained in 1% aceto-orcein, as described in Berry (1982). Photomicrographs were taken with a Nikon Biophoto camera using Kodak Technical Pan film.

Results of the chromosomal observations are presented in Table 1 and Figure 1. The diploid counts for *F. decussata*, *F. furfuracea*, *F. scabriuscula*, and *F. simplicicaulis* are the first reports of chromosome numbers for these species, all belonging to sect. *Fuchsia*. They lend further support to Berry's (1982) finding of predominant diploidy in that section. The collection of *F. cinerea* studied, however, proved to be tetrapoloid, unlike an earlier diploid count for another population of this species (Berry, 1982). *Fuchsia cinerea* occurs in the same high-elevation areas of northern Ecuador as *F. corollata* and *F. vulcanica*, two members of the *F. petiolaris* species group that also have tetraploid populations, as well as problematical species limits. A more extensive cytological sampling of the *Fuchsia* populations in this area would be helpful in resolving the complex variation patterns observed in this group and to determine if tetraploidy has arisen repeatedly in these taxa.

Fuchsia magdalenae (sect. *Fuchsia*) was introduced into cultivation just over ten years ago

TABLE 1. *Additional chromosome counts in* Fuchsia.[1]

Taxon	Meiotic Chromosome Number	Collection Data[2]
F. cinerea P. Berry	$n = 22$	*Berry 004-86*, from seed of *Koenen 153-06-81*, Prov. Carchi, Ecuador, 6 km NE of El Angel
F. decussata R. & P.	$n = 11$	*Berry 014-86*, from seed of *Berry 3049*, Dept. Ayacucho, Peru
F. furfuracea Johnst.	$n = 11$	*Berry 010-86*, from seed of *Solomon 12573*, Dept. La Paz, Bolivia
F. scabriuscula Benth.	$n = 11$	*Berry 012-86*, from seed of *Berry 3574*, Prov. Pichincha, Ecuador
F. simplicicaulis R. & P.	$n = 11$	*Berry 016-86*, from plants long established in cultivation in Europe, originally from Peru
F. magdalenae Munz	$n = 22$	*Berry 017-86*, from progeny of the type collection of *F. lampadaria* J. O. Wright, originally from Santa Marta, Colombia
F. magdalenae × *F. denticulata*	$2n = 33$[3]	*Berry 009-86*, artificial cross made by D. Reiman
F. magdalenae × *F. pilaloensis*	$2n = 33$[3]	*Berry 018-86*, artificial cross made by D. Reiman

[1] All species belong to sect. *Fuchsia* except for *F. pilaloensis*, from sect. *Hemsleyella*.

[2] All collections from plants cultivated by Mrs. Drude Reiman-Dietiker in Hollandsche Rading, the Netherlands, with vouchers at MO.

[3] Many laggard and bridge chromosomes at Anaphase I.

FIGURE 1. *Photomicrographs of meiotic metaphase (A, B), anaphase (C), and telophase (D) chromosomes of* Fuchsia.—*A.* F. magdalenae *(2n = 22II)*.—*B–D.* F. magdalenae × F. denticulata *(2n = 33); note the numerous laggard and bridge chromosomes in C and D. Scale = 10 µm.*

(Wright, 1978) and has since been used to produce a novel series of attractive interspecific crosses in England and the Netherlands. The original, parental stock of *F. magdalenae* was cytologically reexamined, showing it to be tetraploid with normal bivalent formation (Fig. 1A). This agrees with previous counts by Wright (1978) and Berry (1982).

The first *F. magdalenae* hybrid, with the diploid *F. denticulata* (Berry, 1982), yielded triploid progeny with meiotic irregularities such as bridges and laggard chromosomes (Fig. 1B–D). The second *F. magdalenae* hybrid was with *F. pilaloensis*, a member of the apetalous sect. *Hemsleyella*. The chromosome number of this species was not reported in Berry's (1985) revision of the section, but the triploid chromosome number of the F_1 hybrid with *F. magdalenae* indicates that it must be diploid. Unless spontaneous or induced chromosome doubling occurs in the F_1 of these triploids, they are likely to prove infertile and will need to be propagated vegetatively.

We wish to thank Mrs. Drude Reiman-Dietiker for providing buds from her extensive collection of living *Fuchsia* species and hybrids, and Lois Brako for assistance in collecting the bud material.

UNA NUEVA COMBINACION EN *BAUHINIA* (FABACEAE—CAESALPINIOIDEAE)

La especie *Amaria sessilifolia* fue descrita por De Candolle (1825) con base en material coleccionado por Mutis (*Mutis 2724*) en Colombia. Wunderlin (1976, 1983) sugirió que esta especie debería ser considerada como sinónimo de *Bauhinia petiolata* (Mutis ex DC.) Triana ex Hook. f. Sin embargo, el examen de las iconografías de la Real Expedición Botánica del Nuevo Reino de

FIGURA 1. *Fotografía de* Bauhinia sessilifolia *(*Mutis 2397, *MA)*.

ANN. MISSOURI BOT. GARD. 75: 1155–1156. 1988.

Granada lo mismo que del material tipo y otros ejemplares de las dos especies en cuestión en el Real Jardín Botánico de Madrid me ha convencido de que existen características vegetativas y florales que permiten mantenerlas como entidades taxonómicas independientes en el género *Bauhinia*. Por lo tanto, la siguiente nueva combinación se hace necesaria:

Bauhinia sessilifolia (Mutis ex DC.) L. M. Quiñones, comb. nov. *Amaria sessilifolia* Mutis ex DC., Prodr. 2: 519. 1825. TIPO: Colombia: *Mutis 2724* (holotipo, MA).

Bauhinia sessilifolia se caracteriza por presentar hojas sésiles, de base profundamente cordada; inflorescencias axilares, umbeliformes; pétalos emarginados; estambres insertos, 5 mayores que los otros 5; y fruto más ancho (2 cm de ancho). *Bauhinia petiolata* tiene peciolos 0.5–3 cm de longitud; base truncada o redonda; inflorescencias terminales o axilares en racimos cortos; pétalos agudos; estambres exertos, todos de igual longitud; y fruto delgado 1.5 cm de ancho.

Distribución. Se conoce solamente de Colombia.

Ejemplares adicionales estudiados. COLOMBIA. Sin localidad precisa: *Mutis 2397* est. (MA), *4203 fr* (MA).

UNA NUEVA ESPECIE DE *GUETTARDA* L. (RUBIACEAE, GUETTARDEAE) PARA COSTA RICA

English Summary

A new species of the genus Guettarda *(*G. turrialbana *Zamora & Poveda) is named and described from Costa Rica. Its distribution, habitat, and affinities are discussed.*

La presente especie se enmarca dentro de la tribu Guettardeae por poseer un ovario con dos o varios lóculos, cada uno con un óvulo anátropo; los estambres insertos en la boca del tubo de la corola; y una inflorescencia por lo general cimosa (Standley, 1934).

En base a la revisión bibliográfica hemos encontrado que las características de diagnóstico entre el género *Guettarda* y *Antirhea* no son convincentes para separar ambos géneros, ya que el traslape de caracteres es muy amplio (ver Cuadro 1), por lo tanto consideramos que la especie aquí tratada corresponde al género *Guettarda.* Esta es una especie muy particular debido a que los frutos son lisos, glabros y sus lóculos estan distribuídos al azar.

Guettarda turrialbana Zamora & Poveda, sp. nov. TIPO: Costa Rica. Cartago: Turrialba, CATIE, Bosque los Espaveles, 625 m, 26 June 1986 (fl, fr), *N. Zamora V., M. M. Chavarría y H. Gómez 1263* (holotipo, CR; isotipos, F, K, MO, NY). Figura 1.

Arbor 30 metralis. Folia petiolata; laminis oblongo-ellipticis, supra glabris, subtus glabris vel minute sericeis, 8–24 cm longis 3–12 cm latis. Inflorescentiae axillares oppositae, cymis dicotomis, pedunculo 3.5–7 cm longo. Flores sessiles, extus glabratis intus pubescentibus; calyce cupuliformi, truncato, 1.5–4 mm longo 2–3 mm lato; corolla alba, tubo 5.2–6.5 cm longo, 5 lobis 5–6 mm longis 3–4 mm latis; staminibus coralinis, antheris 5, 3.5–4 mm longis 0.5 mm latis. Fructus drupaceus glabratus laevis ovoideo-ellipsoideus 3.3–3.8 cm longus 1.4–1.6 cm latus; semine 8–9 cylindrico 1.5–1.8 cm longo 2 mm lato.

Arbol de 30 m de altura y 80 cm DAP, fuste derecho, cilíndrico, pardo-claro o pardo-grisáceo; corteza exfoliándose en pequeñas plaquitas escamosas, dejando a veces cicatrices crateriformes, corteza interna rosado-rojiza, gruesa hasta de 2.5 cm de espesor, muy suave; ramitas glabras, pardo-claras, cilíndricas; entrenudos muy juntos, 3–15 mm de largo; estípulas triangulares, ápice acumi-

CUADRO 1. *Algunas características morfológicas de diagnóstico entre* Guettarda *y* Antirhea.

Característica	*Guettarda*	*Antirhea*
Cáliz	truncado o dentado persistente o decíduo	truncado o dentado persistente o decíduo
Corola	hipocrateriforme o tubular serícea lóbulos 4–9, imbricados, 2 de ellos exteriores	hipocrateriforme glabra o serícea lóbulos 4–5, imbricados, 2 de ellos exteriores
Estambres	4–9, insertos filamento corto o ausente	4–5, insertos o subexsertos filamento corto o raramente elongado
Ovario	lóculos 2–9 estigma capitado, subcapitado o con 2 o 3 lóbulos óvulos solitarios, cilíndricos y péndulos	lóculos 2–10 o más estigma capitado o con 2 o 3 lóbulos óvulos solitarios, cilíndricos y péndulos

FIGURA 1. Guettarda turrialbana *Zamora & Poveda.—a. Rama.—b. Inflorescencias.—c. Fruto.—d. Corte transversal del fruto.—e. Flor con corte longitudinal de la corola.—f. Superficie interna de la estípula.—g. Semillas.*

nado, 1.2–3.3 cm de largo y hasta 7 mm de ancho en su parte media, glabras en la superficie externa, con un grupo de pelos gruesos en la base de la superficie interna, persistentes sólo en el ápice de las ramitas. Hojas decusadas; pecíolo 1.8–3.8 cm de largo, acanalado adaxialmente; lámina oblongo-elíptica, 8–24 cm de largo y 3–12 cm de ancho, ápice apiculado o corto-acuminado, base cuneada, glabra en la haz y con escasos pelos principalmente en la axila de los nervios o diminutamente seríceo-pubescente por el envés, cartáceo-membranácea, nervaduras secundarias broquidódromas, prominentes en el envés. Inflorescencia una cima dicótoma, axilar y opuesta, con 3–5 flores en cada ramificación, pedúnculo 3.5–7 cm de largo; flores sésiles, sostenidas por una bracteola glabra, cupuliforme, 0.5–0.9 mm de largo, caediza; cáliz truncado, cupuliforme, 1.5–4 mm de largo y 2–3 mm de ancho, glabro en ambas superficies; corola blanca, hipocrateriforme; tubo cilíndrico, 5.2–6.5 cm de largo y hasta 3 mm de diám. en su parte media, glabro en el exterior y con densa pubescencia argenteo-seríceo-reflexa en el interior debajo de los estambres, hasta 7 mm arriba de la base; lóbulos 5, imbricados en los botones, de ovados a elíptocos, hasta de 6 mm de largo 3–4 mm de ancho, reflexos, ápice redondeado u obtuso, algunos planos y otros cocleados en el ápice; estambres 5, coralinos, insertos, interlobulares, sésiles, 7–12 mm abajo de la boca; anteras con dos tecas, lineares, subuladas, 3.5–4 mm de largo y hasta 0.5 mm de ancho en su parte media, ápice agudo por sobresalir el conectivo, base estrechamente sagitada; estilo glabro, 1.6–2.3 cm de largo, estigma bífido, a veces una de las ramas levemente bifurcada, las dos ramificaciones principales con el ápice curvado o algo circinado; ovario glabro, obovoide, ápice truncado, 2 mm de largo, 2.6 mm de ancho, con 8–9 lóculos, óvulos solitarios y péndulos, disco glabro, 1.9 mm de largo y 2.5 mm de diám. Fruto drupáceo, ovoide elípsoide, 3.3–3.8 cm de largo, 1.4–1.6 cm de diám. en su parte media, verde claro, glabro, liso, pericarpo delgado y carnoso; cáliz caduco; semillas 8–9, en cavidades de paredes leñosas, prácticamente cilíndricas, elongadas, 1.5–1.8 cm de largo y 2 mm de diám., péndulas, finamente esponjas, presentando en su base restos del funículo, éstos cilíndricos y cóncavos en los extremos, 5 mm de largo, 3 mm de diám. y de consistencia también finamente esponjosa.

Ejemplares examinados adicionales. COSTA RICA. CARTAGO: Turrialba (IICA), *J. León 2858* (CR); Bajo del Chino (CATIE), *R. Morales y L. J. Poveda s.n.* (CR); Cajón (CATIE), *L. J. Poveda y J. A. Sáenz s.n.* (CR). PUNTARENAS: Bahía de Rincón de Osa, *S. Salas 5718* (CR); Parque Nacional Corcovado cerca de Playa Llorona, *L. J. Poveda et al. s.n.* (CR).

Distribución y habitat. La nueva especie hasta el momento parece endémica para Costa Rica, conocida de Turrialba (Prov. Cartago), y de Península de Osa (Prov. Puntarenas), además de Fila de Cal entre San Vito de Java y Ciudad Neily (Prov. Puntarenas) y de Florencia de San Carlos (Prov. Alajuela) (B. Hammel, com. pers., 1987). Se distribuye principalmente desde el nivel del mar hasta los 625 m, creciendo en Bosque muy Húmedo Premontano y Bosque muy Húmendo Tropical (Tosi, 1969). En Turrialba, se ha observado asociada con *Anacardium excelsum, Oreamunnea pterocarpa, Sideroxylon contrerasii, Spondias radlkoferi, Guarea pterorhachis, Lafoensia punicifolia,* y otras. Se encuentra en lugares planos, de buen drenaje, y en laderas con pendientes medias. Se han observado flores de junio a agosto y frutos de agosto a octubre.

Nuestro sincero agradecimiento a Julian A. Steyermark, David H. Lorence, y J. D. Dwyer por la revisión del manuscrito y sus valiosas sugerencias al mismo, y a Francisco Hodgson F. por la ilustración.

UNA NUEVA ESPECIE DE *CARYODAPHNOPSIS* AIRY SHAW (LAURACEAE) PARA LA REGION NEOTROPICAL

ENGLISH SUMMARY

Caryodaphnopsis *was previously known only from Yunnan to Indochina, with the exception of* C. tonkinensis, *which extends as far as the Philippines and Borneo (Kostermans, 1974). Recently, van der Werff & Richter (1985) transferred two species of* Persea *from South America (*P. theobromifolia *Gentry and* P. inaequalis *A. C. Smith) to* Caryodaphnopsis. *Dr. R. Foster collected some specimens of this genus in the Parque Nacional Manú, Perú, that turned out to be a new species (*C. fosteri *van der Werff, 1986). We describe in this paper a new species of* Caryodaphnopsis *from Costa Rica. Its distribution, habitat, affinities, specimens studied, and wood anatomy are discussed.*

Caryodaphnopsis Burgeri Zamora & Poveda, sp. nov. TIPO: Costa Rica. Puntarenas: Península de Osa, Estación Biológica Marenco, 50 m, *N. Zamora V., F. Almeda & B. Anderson 1208* (holotipo, CR; isotipos, F, K, MO, NY). Figura 1.

Arbor 30 m alta, 80 cm diam., trunco cylindrico, corona ovata-rotundata, ramulis tetrangulatis vel subteretis, pilis brevibus sericeis vel glabratis. Folia opposita mediocri breviter petiolata, chartacea vel tenue chartacea, trinervata; petiolis 0.5–1.4 cm longis, supra canaliculatis, sparse minute sericeis vel glabratis; lamina oblongo-elliptica, 5–16.3 cm longa, 1.9–7.3 cm lata, apice acuta, acuminata vel cuspidata, basi cuneata, supra glabra, lucida, nervis impressis, subtus glaucae, sparse minute sericeis, nervis elevatis. Inflorescentia paniculata, pedunculis brevibus vel sessilibus, axillaribus, ramis decussatis, sparse minute sericeis, ramis floribusque bracteis minutis, caducis, acutis, minute sericeis; pedicellis ad 2.5–9 mm longis, minute sericeis, gracilibus; tepalis 6, 3 externis ovato-deltoideis, minute puberulis sericeis utrimque, 1.9 mm longis, 0.9 mm latis; 3 internis subulatis, minute sericeis extrinsecus, dense argenteo-sericeis intrinsecus, 7–10 mm longis, 2–2.2 mm latis; staminibus 9, libris, 5 mm longis, dense pilosis, staminum interiorum filamentis 2 glandulis basibus sessilibis conspicuis munitis; antheris rectangularibus vel oblongis, 4-loculatis; staminoidiis 3, sagittatis, 2–2.8 mm longis, filamentis brevibus dense pilosis; ovario obovoido, 1.9 mm longo, 1.5 mm lato, fere glabro; stilo fere 3 mm longo, basi sparse minute sericeo. Fructus globosus, glaber, 18–20 mm longus, usque 17 mm latus, lucidus, viridi-pallidus, sparse rubro-maculatus in siccitate; seminibus sphaericis, 12 mm longis, usque 12 mm latis.

Arbol de 30 m de altura, 80 cm DAP, con pequeñas gambas; tronco cilíndrico, gris-oscuro, exfoliándo en plaquitas, finamente fisurado, corteza muy gruesa, internamente blanquecina, sin olor característico; follaje verde claro, las hojas jóvenes de un tono verde pálido; ramitas tetrangulares, glabras o diminuto y esparcidamente seríceas. Hojas opuestas; pecíolo 0.5–1.4 cm de largo, acanalado adaxialmente, glabro o con diminutos y esparcidos pelos seríceos; lámina oblongo-elíptica, 5–16.3 cm de largo, 1.9–7.3 cm de ancho, ápice agudo, acuminado o cuspidado, base cuneada, brillante, lisa y glabra en la haz, glauca, con diminutos y muy esparcidos pelos seríceos en el envés, trinervada, los nervios principales impresos en la haz y prominentes en el envés, proyectándose hasta el ápice, los terciarios marginales arqueados y los terciarios centrales onduladamente perpendiculares al nervio central, cartáceas a delgadamente cartáceas. Inflorescencia panícula corimbiforme, axilar, decusada, flores terminales en grupos de 3 o más, pedúnculo ausente o hasta 1 mm de largo, ejes de la panícula 8–15 mm de ancho, 10–30 mm de largo o altura y diminutamente seríceos; ramificaciones y flores sostenidas por bracteolas muy pequeñas, agudas, seríceo-pubescentes y caducas en la madurez; algunas veces aparecen de 1–3 flores en la base de la panícula; pedicelos 2.5–9 mm de largo, delgados, diminuto-seríceo-pubescentes; tépalos 6, fuertemente desiguales, los 3 externos 1.9 mm de largo, 0.9 mm de ancho, ovado-deltoides, diminuto-seríceo-pubescentes en ambas superficies, los 3 internos 7–10 mm de largo, 2–2.2 mm de ancho, subulados, externamente diminuto seríceos e internamente con densa pubescencia, de pelos más largos, argenteo-seríceos. Estambres 9, libres, 5 mm de largo, aplanados y densamente pilosas; 3 de los internos con 2

Dedicamos esta especie en honor al Dr. William C. Burger, editor de *Flora Costaricensis*, por su gran aporte en las investigaciones botánicas de nuestro país. El actualmente está elaborando la monografía de la familia Lauraceae de Costa Rica.

La identificación a nivel genérico fue posible gracias al análisis anatómico de maderas y hojas realizado por el Dr. Henk van der Werff en 1984.

El descubrimiento de esta nueva especie es de mucha importancia pues amplia la distribución conocida del género en América (ver van der Werff & Richter, 1985; van der Werff, 1986), y abre nuevas posibilidades para entender la distribución geográfica de las especies de esta familia.

Distribución y habitat. Hasta el momento la especie es endémica para Costa Rica, conocido en Santa Rosa y Mastatal de Puriscal (Prov. San José) y la Península de Osa (Prov. Puntarenas), de 50 a 400 m de elevación, ocupando la Zona de Vida Bosque Muy Húmedo Tropical (Tosi, 1969). Se

encuentra en laderas de pendientes medias y sitios planos. Se ha observado buena regeneracíon natural, principalmente en claros de luz. Produce flores desde finales de enero hasta principios de febrero, y hemos encontrado frutos maduros a mediados de mayo.

En las localidades de Santa Rosa y Mastatal de Puriscal, se le conoce el nombre de "carne" o "cocobola" los habitantes mencionan que la madera tienen excelentes propiedades para la construcción de viviendas.

Se compara *C. Burgeri* con *C. fosteri* en Cuadro 1.

DESCRIPCIÓN ANATÓMICA DE LA MADERA DE *CARYODAPHNOPSIS BURGERI*

Propiedades generales

Madera dura y pesada. Duramen color pardo-claro a pardo-rojizo, con vetas longitudinales oscuras, casi negras. Presenta olor característico, pero ningun sabor en especial; textura media y lustre de mediano a elevado.

Descripción macro- y microscópica

Presenta anillos de crecimiento visibles debido a bandas (zonas) tangenciales oscuras, de espesor irregular con poca concentración de poros.

Poros pequeños, visibles a simple vista, con diámetro tangencial promedio de 225 μm, abundantes (60 o más por 5 mm^2), distribuídos en una porosidad difusa con ligera tendencia a formar hileras oblicuas con respecto a los radios de más de 4 poros (rango de 3 a 7). En su mayoría son solitarios, algunos múltiples radiales de 2 a 4, y ocasionalmente racemiformes. Hay abundancia de tilides.

En las caras longitudinales, los vasos a simple vista como estrias claras sobre un fondo ligeramente más oscuro. Segmentos vasculares cortos con platinas de perforación simples, éstas de poco a medianamente inclinadas. Su punteado intervascular alterno, con punteaduras aeroladas de tamaño mediano (10 μm) y de aperturas angostas.

El parenquima axial invisible a simple vista o con lupa. Paratraqueal muy escaso, con algunas pocas células alrededor de los poros. El parenquima radial (radios), apareciendo a simple vista en sección transversal como líneas finas de color claro sobre un fondo más oscuro, hasta 1 mm de altura. Los radios multiseriados en su mayoría, de 3 a 6 células de ancho. Los uniseriados escasos. Heterogéneos tipo II (según clasificación de Kribs, 1968) con 2 o 3 hileras de células marginales erectas y el cuerpo formado por células procumbentes. Hay presencia de radios agregados. Células oleiferas frecuentes, y con gran cantidad de gomas rojizas en las células del cuerpo. Punteado radio-vascular de alterno a opuesto, con punteaduras semi-aeroladas grandes de redondeadas a oblicuas.

Fibras del tipo fibro-traqueidas con punteaduras areoladas pequeñas, de pared muy gruesa y frecuentemente septadas. Contenidos gomozos rojizos en el lumen de las mismas.

No presenta marcas de estratificación.

Nuestro sincero agradecimiento a Henk van der Werff por la revisión del manuscrito y sus valiosas sugerencias al mismo, a Frank Almeda por facilitarnos literatura reciente, y a Francisco Hodgson F. por su excelente ilustración.

TOWARDS MOLECULAR GENETICS IN *CLARKIA*: GENE DUPLICATIONS AND MOLECULAR CHARACTERIZATION OF PGI GENES[1,2]

L. D. Gottlieb[3]

ABSTRACT

I review the phylogenetic implications of eight duplications of nuclear genes encoding isozymes in Clarkia *(Onagraceae). These include ADH, cytosolic PGI, and both plastid and cytosolic isozymes of PGM, 6PGD, and TPI. The PGI duplication has been studied intensively from biochemical and genetic standpoints. Recent results have identified two levels of regulation that operate in species with this duplication, one that reduces cytosolic PGI activity to the level characteristic of species without the duplication (dosage compensation), and the second that results in differential accumulation of the products of the duplicate genes. These factors appear to reduce the impact of the duplication on metabolic function. I also describe our recent cloning and sequencing of two genes encoding PGI obtained from a genomic DNA library of* C. unguiculata, *a species with the duplication. The two genes encode proteins of 548 and 543 amino acids, respectively, and their predicted amino acid sequences are 58% homologous. They show 65% homology to a previously published partial amino acid sequence of pig muscle PGI. Both genes lack introns. The two genes are the first nuclear genes sequenced in wild plants. They are being studied as part of a research program on gene evolution and the application of nuclear gene sequences for phylogenetic reconstruction in higher plants.*

Questions about phylogeny have the form, "Is A more closely related to B than to C?" For flowering plants, the best phylogenies are thought to take into account the "maximum number of attributes possible" (Davis & Heywood, 1967: 485), with evidence from morphology, cytology, chemistry, reproductive compatibility, and other fields somehow combined. However, accurate phylogenetic reconstruction is more often a goal than an achievement because of problems brought about

ANN. MISSOURI BOT. GARD. 75: 1169–1179. 1988.

by character convergence, functional and developmental correlations, and unequal rates of evolution in different lineages. The essential difficulty is that little or nothing is known about how genetic changes that affect developmental processes result in differences in character expression.

The consequence is that no present procedure can translate the extent of morphological divergence into a measure of the closeness of phylogenetic relationship. I believe the way out of this impasse is to utilize a new source of evidence to assess phylogenetic relationships. The data of morphology, the traditional source of information about phylogeny, should be viewed as relevant to studies of plant development.

There is good reason to believe that information derived directly or indirectly from the structure and sequence of protein and DNA can be used to settle many phylogenetic questions. Interestingly, in this context, the molecular data are self-sufficient in that their usefulness does not depend on concordance with other lines of phenotypic evidence. For example, certain types of changes, particularly duplications of nuclear genes encoding enzymes (Gottlieb & Weeden, 1979; Gottlieb, 1983; Odrzykoski & Gottlieb, 1984) and large inversions of the chloroplast genome (Jansen & Palmer, 1987) appear to occur only once within a lineage. Thus taxa that now possess them probably descended from a single common ancestor and can be considered monophyletic without regard to their present morphological and cytological divergence.

In addition to phylogenetic inferences made on the basis of unique genetic and molecular traits, cladograms based on shared derived mutations or the extent of overall similarity can be constructed by comparing nucleotide sequences of genes or the size pattern of fragments cut from homologous DNAs by restriction endonucleases. The increasing availability of molecular data suggests that biosystematics no longer has to be considered an "unending synthesis" (Constance, 1964).

Phylogenetic relationships can now be determined accurately and reliably at many taxonomic levels. When this is done, the phylogeny can be used as a framework to ask important questions in other areas of biology. For example, how the attributes of species reflect both genetic legacy and selected and other changes since their origins, how genetic changes lead to specific modifications of ontogeny that result in new characters, and how and whether these new traits facilitate adaptation to different habitats. From this perspective, phylogeny can begin to inform both developmental and ecological analyses by providing evidence that A indeed derived from B and not from C.

In this paper, I review genetic and biochemical studies from my laboratory on gene duplications in *Clarkia* with emphasis on their phylogenetic implications. In addition, I describe very recent studies in which we have cloned and sequenced several genes encoding the glycolytic enzyme phosphoglucose isomerase from genomic libraries of *Clarkia* DNA. One purpose of these studies is to infer correct phylogenetic relationships in this well-studied plant genus. When the beginning and end points of species' genealogies are identified, we can ask about the steps in between.

BACKGROUND

Previous to our studies and, indeed, making them appropriate, were the intensive investigations by Professor Harlan Lewis and his students and colleagues in the 1950s and 1960s (Lewis, 1953, 1962, 1973; Lewis & Lewis, 1955; Lewis & Raven, 1958). They correlated evidence from field studies, morphology, and a major program of hybridization and cytogenetical analysis. *Clarkia* was found to comprise at least 43 species, 33 being diploid. The diploid species were distinguished by substantial amounts of chromosomal repatterning in addition to aneuploidy. The extent of morphological divergence varied from a difference in a single character between some pairs of species to differences in entire suites of traits that might serve as evidence of generic distinction in other plant groups. The degree of morphological resemblance was frequently not concordant with the amount of chromosomal rearrangement. Nevertheless it was possible to discern meaningful phylogenetic patterns among the diploid species, and they were assigned to seven taxonomic sections (Lewis & Lewis, 1955). Allopolyploid species linked several sections so that as a whole the genus was considered a natural unit.

Lewis formulated an elegant model of speciation to account for these relationships. The critical features of this model included the following: (1) species were regarded as progenitor and derivative and not as siblings; (2) a new species differed from its parent by gross chromosomal rearrangements and sometimes by a change in basic number; (3) the speciation process was rapid and abrupt; (4) speciation was independent of the evolution of new adaptations and therefore was largely fortuitous; (5) speciation, in general, occurred at the xeric margin of the distribution of the parent species.

Lewis's model and his proposed examples of progenitor-derivative species made *Clarkia* appropriate for the first studies carried out in plants that applied electrophoretic analysis of enzymes to assess the amount of genetic divergence correlated with speciation (Gottlieb, 1973, 1974a). The rationale behind these studies has been reviewed by Crawford (1983, 1985) and by me (Gottlieb, 1977, 1981, 1986).

In addition to information about variation (presence, number, frequency) and divergence of alleles at loci coding enzymes, electrophoretic patterns provide evidence about the number of isozymes of particular enzymes and, thereby, the number of coding loci. As more and more species of *Clarkia* were examined, it became apparent that they sometimes differed among themselves or from other diploid seed plants in the number of isozymes of many particular enzymes. Subsequent genetic studies revealed that increased isozyme number resulted from duplications of the coding genes (Gottlieb, 1977; Gottlieb & Weeden, 1979; Pichersky & Gottlieb, 1983).

Examination of the number of isozymes in a broad array of higher plants, including conifers and angiosperms, showed that isozyme number was highly conserved and depended on the number of subcellular compartments in which a particular catalytic reaction occurred (Gottlieb, 1982). For example, in diploid plants, enzymes of glycolysis and the oxidative pentose phosphate pathway are encoded in the nucleus and are generally found as two isozymes, one located in the plastids and the other in the cytosol. When the number of isozymes within a particular compartment is more than one, it probably results from duplication of the structural gene or, in polyploid plants, from additive expression of the genes in the several constituent genomes. Since the conserved number of isozymes reflects the metabolic requirements of plant cells, a reduced number is not possible because it would be lethal. (Failure to observe bands of enzyme activity following electrophoresis of plant extracts should not be taken as evidence that the enzyme is not present in the extract, a common error in many surveys of electrophoretic variation in plants that report the absence of an expected enzyme band as a null allele.) The rules for recognizing duplicate isozymes, following electrophoresis of plant extracts, have been thoroughly described (Gottlieb, 1982). It is worth noting again that subcellular location furnishes the best criterion for recognizing the homology of isozymes from different species, and that the rules apply only to enzymes assayed with natural in vivo substrates. No regularities have been identified in the number of isozymes of enzymes such as esterases, phosphatases, and peroxidases that are generally assayed with artificial substrates.

GENE DUPLICATION IN *CLARKIA*

The first duplicate isozyme discovered in *Clarkia* was that of alcohol dehydrogenase (ADH) in *C. franciscana* (Gottlieb, 1974b). Its absence from the closely related *C. amoena* and *C. rubicunda*, along with the very low genetic identity between *C. franciscana* and these species (Gottlieb, 1973), helped reject the hypothesis (Lewis & Raven, 1958) that *C. franciscana* was a recent derivative of *C. rubicunda*. The genetic evidence for duplication of ADH in *C. franciscana* was based on its exhibiting a true-breeding, three-banded electrophoretic pattern, whereas similar three-banded patterns in the related species resulted from heterozygosity at a single locus as evidenced by segregation patterns in progeny. Since *C. franciscana* did not display polymorphism for ADH, the duplication model was tested by making interspecific hybrids between it and *C. amoena*. The *C. amoena* plants used were homozygous at a single locus for an allele that encoded a slow ADH variant. The F_1 hybrids displayed a five-banded pattern that could only have resulted from the dimeric associations of three different polypeptides and, consequently, they must have possessed three genes (Gottlieb, 1974b). The ADH duplication was the second duplication of a gene encoding an enzyme discovered in plants. The first, in maize, was also an ADH (Schwartz & Endo, 1966).

Seven additional duplications of genes in *Clarkia* have since been described and, for each, the taxonomic distribution within the genus has been determined (Table 1). These duplications are cytosolic phosphoglucose isomerase (PGI) (Gottlieb, 1977; Gottlieb & Weeden, 1979), plastid and cytosolic triose phosphate isomerase (TPI) (Pichersky & Gottlieb, 1983), plastid and cytosolic 6-phosphogluconate dehydrogenase (6PGD) (Odrzykoski & Gottlieb, 1984), and plastid and cytosolic phosphoglucomutase (PGM) (Soltis et al., 1987). Detailed information about them is available in the individual reports. Five of the seven duplications (plastid and cytosolic 6PGD, plastid and cytosolic TPI, and plastid PGM) are present in species of all diploid sections of *Clarkia* (Table 1), suggesting they are at least as old as the genus. But only the duplicated plastid TPI was found in every species.

PLASTID AND CYTOSOLIC 6PGD

Four species of *Clarkia* appear to lack one or both 6PGD duplications (Odrzykoski & Gottlieb, 1984). *Clarkia rostrata* and *C. epilobioides* have a single plastid isozyme and a single cytosolic one and, consequently, lost both duplications. *Clarkia lewisii* and *C. cylindrica* have duplicated plastid 6PGDs but only a single cytosolic 6PGD (Table 1). The four species have been assigned to sect. *Peripetasma*, with the morphologically similar and crossable (Davis, 1970) *C. rostrata*, *C. lewisii*, and *C. cylindrica* to one subsection and the distinctive and highly self-pollinating *C. epilobioides* to a monotypic subsection (Lewis & Lewis, 1955). The close relationship of the former three species suggested that the loss of the duplicated cytosolic 6PGD occurred in their common ancestor and was subsequently followed in *C. rostrata* by an additional mutation or chromosomal deletion that silenced a duplicated gene encoding a plastid 6PGD. Since *C. epilobioides* also lacked both duplications, it seemed reasonable to suggest that it was closely related, although it was not possible to decide if the loss of its plastid 6PGD duplication was independent of the loss in *C. rostrata*.

The matter was settled by a restriction endonuclease analysis of chloroplast DNA carried out on all the species in this section, which revealed that *C. rostrata* and *C. epilobioides* were sister species and that *C. lewisii* and *C. cylindrica* comprised a second pair of sister species (Sytsma & Gottlieb, 1986a). The chloroplast DNA study also showed that the two pairs of species share a common ancestor well removed from the other species of the section. Thus, even though *C. rostrata* is not morphologically similar to *C. epilobioides* and was placed in a different subsection, the two species have a close genealogical relationship. Since this phylogenetic inference was based on evidence from both nuclear genes and chloroplast DNA, it is particularly strong.

PLASTID AND CYTOSOLIC TPI

Both TPI duplications appear to be present throughout *Clarkia* (Table 1), although some uncertainty remains in regard to the cytosolic TPI in sect. *Eucharidium* for which the genetic analysis is incomplete (Pichersky & Gottlieb, 1983). Electrophoretic studies of TPI have also been carried out on a number of species of other genera of Onagraceae to ascertain the taxonomic distribution of the duplications outside of *Clarkia*. Since sufficient (or appropriate) material was not available to conduct genetic analysis, three criteria had to be met to warrant the hypothesis that a given species possessed a TPI duplication. The minimum number of electromorphs per individual for each isozyme had to be at least three (TPI is dimeric), the multiple isozymes had to be located in the same subcellular compartment, and a side-by-side comparison of leaf and pollen extracts had to show the same number of cytosolic isozymes (the criteria are discussed in detail in Gottlieb, 1983). On the basis of satisfying all of these criteria (although sample sizes were very limited), the cytosolic TPI duplication was identified in five of the seven tribes of the family, including Jussiaeeae (*Ludwigia*), Fuchsieae (*Fuchsia*), Hauyeae (*Hauya*), Onagreae (*Clarkia, Heterogaura, Camissonia, Calylophus, Gongylocarpus*, and *Oenothera*), and Epilobieae (*Boisduvalia*) (Pichersky & Gottlieb, unpubl.). The presence of the duplication in both *Fuchsia* and *Ludwigia*, the two most ancient lineages in the family (Raven, 1979), suggests its great antiquity. In contrast, the plastid TPI duplication was not identified outside of *Clarkia* and must have arisen much more recently. Although these results should be regarded as exploratory, they point out the possibility that certain taxonomically widespread duplications may be useful to group genera (and eventually families) into monophyletic assemblages. However, since the time spans in these comparisons are great, it would be appropriate and necessary to validate the conclusions by examination of the nucleotide sequences of the duplicated genes.

PLASTID AND CYTOSOLIC PGM

In contrast to the situation in 6PGD in which the absence of duplicated genes could be assigned to some type of mutation in common ancestors of extant species, the loss of the plastid PGM duplication (Table 1) in *C. concinna* and in *C. lassenensis* (Soltis et al., 1987) must be regarded as independent events in lineages directly ancestral to these species but to no others, since the two species belong to distantly related sections of *Clarkia* (Lewis & Lewis, 1955).

The presence of the cytosolic PGM duplication in *C. arcuata* (sect. *Rhodanthos*) and in all species of sections *Godetia* and *Myxocarpa* (Table 1) is consistent with a taxonomic assignment previously made by Lewis & Lewis (1955). They proposed (p. 261) that sect. *Rhodanthos* (then designated sect. *Primigenia*) was "probably directly ancestral" to sect. *Godetia* and "perhaps" to sect. *Myxocarpa*. Within sect. *Rhodanthos*, the relevant lineage is now represented by *C. arcuata*

TABLE 1. *The phylogenetic distribution of duplicate isozymes in diploid species of* Clarkia. *The PGI data are from Gottlieb & Weeden (1979), the PGM data from Soltis et al. (1987), the 6PGD data from Odrzykoski & Gottlieb (1984), and the TPI data from Pichersky & Gottlieb (1983). The numeral 1 indicates the species has a single isozyme and the numeral 2 indicates duplicated isozymes. For each enzyme, plastid (Pl) and cytosolic (Cy) isozymes are indicated.*

	Isozyme Number						
	PGI	PGM		6PGD		TPI	
Section Species	Cy	Pl	Cy	Pl	Cy	Pl	Cy
Eucharidium							
C. breweri	2	2	1	2	2	2	?

C. amoena subsp. *huntiana*	1	2	1	2	2	2	2
C. franciscana	1	2	1	2	2	2	2
C. rubicunda	1	2	1	2	2	2	2

which, together with *C. lassenensis*, was placed in a distinct subsection. The other subsection containing diploid species includes *C. amoena*, *C. rubicunda*, and *C. franciscana*, and it then would represent the lineage from which the other four sections of *Clarkia* (Table 1) eventually evolved. Alternatively, the cytosolic PGM duplication may have had independent origins in *C. arcuata* and sections *Godetia* and *Myxocarpa*. Sequence comparisons of the PGM genes will make it possible to distinguish these models.

Regardless of the outcome of such comparisons, the taxonomic distribution of the cytosolic PGM duplication is independent of the sectional phylogeny suggested (Lewis, 1980) following the discovery of the cytosolic PGI duplication (Gottlieb, 1977; Gottlieb & Weeden, 1979), since the two duplications are not present together in any species (Table 1). The PGM evidence suggests that the four sections that have the PGI duplication (Table 1) arose from the lineage within sect. *Rhodanthos* that also gave rise to *C. amoena*, *C. rubicunda*, and *C. franciscana*. It is also an interesting possibility that since the two enzymes catalyze adjacent reactions in glycolysis and gluconeogenesis (PGI interconverts fructose-6-phosphate and glucose-6-phosphate, and PGM interconverts the latter and glucose-1-phosphate), there may be metabolic reasons that select against the occurrence of both duplicated enzymes in the same cytosol.

Overall, the genetic and biochemical evidence from the several gene duplications provides a remarkably consistent and coherent picture of the phylogenetic relationships within *Clarkia*. The evidence is also consistent with the recent discovery based on restriction endonuclease patterns in chloroplast DNA that the monotypic *Heterogaura heterandra* (Table 1) is actually a *Clarkia* and closely related to *C. dudleyana* (Sytsma & Gottlieb, 1986b).

PGI

The PGI duplication in *Clarkia* has been studied intensively because it was one of the first duplications identified that is present in some but not all species of a single genus. Thus, it is possible to compare duplicate PGI genes and their products with their nonduplicate homologues, and the comparisons can be done in species having a relatively similar genomic background. The example provides an unusual opportunity to examine the critical early stages of gene evolution and to test the general model that major changes in gene regulation, structure, and function cannot evolve without the availability of duplicate sequences.

The PGI duplication characterizes all of the species (except *C. rostrata*) in the morphologically advanced and diverse sections *Eucharidium*, *Fibula*, *Phaeostoma*, and *Peripetasma*, and is absent from sections *Godetia*, *Myxocarpa*, and *Rhodanthos* (Table 1). Consequently it identifies a specific branching point in the phylogeny of *Clarkia* and serves to group the former four sections into a monophyletic lineage (Gottlieb & Weeden, 1979; Lewis, 1980). The realignment was effected without having to move any species into or out of any section (Lewis, 1980).

Genetic studies revealed that the duplicate PGI genes assort independently (Gottlieb, 1977; Gottlieb & Weeden, 1979; Weeden & Gottlieb, 1979), which is thought to mean that they arose by a process involving overlapping reciprocal translocations or insertional translocations rather than unequal crossing-over. The relevant arguments were presented in Gottlieb (1983). Many other duplicate genes in plants also assort independently (Tanksley, 1987). The mode of origin is important for phylogenetic reconstructions because chromosomal rearrangement is much more likely than unequal crossing-over to occur only once for a particular chromosome segment in a particular linkage. Linkage relationships for the other duplications in *Clarkia* have not been studied in similar detail, although we do know that the duplicate genes encoding plastid TPIs and one of them and a cytosolic TPI gene also assort independently (Pichersky & Gottlieb, 1983).

A number of biochemical studies were carried out to determine how much and what type of divergence marked the duplicate PGI isozymes. Three results are noteworthy, one having to do with the molecular weight of PGI subunits and the other two with the evolution of regulatory factors that appear to modulate the expression of the duplicate PGI genes.

PGI subunits encoded by the duplicate genes have different apparent molecular weights (apparent because the values were obtained from their electrophoretic mobility on SDS gels), with PGI-2 being 60,400 and PGI-3 59,000, or values closely similar (Gottlieb & Higgins, 1984a). Species in sect. *Myxocarpa* that lack the duplication have PGI subunits with molecular weight of 60,400, and PGIs from sections *Godetia* and *Rhodanthos* weighed in at 59,000. The presence of two molecular weight forms in species with the duplication and each molecular weight form by itself in species without the duplication was unlikely to have come about by chance. The result suggested the novel possibility that the PGI locus in an ancestal *Clarkia* was translocated to different nonhomologous chromosomes, that the genes then accumulated mutational changes that encoded different molecular weight subunits, and that lines carrying the different chromosomes eventually hybridized with both PGI genes becoming segregated into a single genome by a process originally documented in maize (Burnham, 1962) involving overlapping reciprocal translocations. The scenario seems feasible for *Clarkia*, in which species are distinguished by gross amounts of chromosomal rearrangement, and which all have a self-compatible breeding system permitting chromosomal heterozygotes to be made homozygous and true-breeding by self-pollination. The merits of this speculation can be directly tested by comparing nucleotide sequences of PGI genes from species with and without the duplication (see below).

After it became apparent that the catalytic properties of the duplicate and nonduplicate PGIs were alike (Higgins & Gottlieb, 1984), studies turned to questions about increased gene dosage and whether it caused increased levels of cytosolic PGI activity and protein. The PGI levels in clarkias with and without the duplication were assessed by immunological means using an antiserum specific to cytosolic PGI (i.e., one that does not cross-react with plastid PGI). The result was clear-cut. The two types of species had the same levels of cytosolic PGI activity and protein, suggesting that some form of regulation had evolved that "compensated" for the duplicated genes (Gottlieb & Higgins, 1984b). The activity level proved to be the same as that in a number of diploid vegetables, indicating that green plants generally maintain a similar PGI level. This finding provided an important rationale for the evolution of dosage compensation because it restored an activity level characteristic of typical diploid plants having a single cytosolic PGI. Thus a regulatory mechanism had evolved that reduced the impact of the duplication on metabolic function.

To determine whether the regulation operated via metabolic or genetic factors, a series of null activity mutants of each duplicate gene was induced by ethyl methanesulfonate (EMS) treatment of seedlings of *C. xantiana* (Jones et al., 1986). Metabolic factors would be implicated if lesions induced in either gene did not change PGI levels. In homozygous state, each mutant completely lacked the homodimer activity normally specified by the affected gene. The mutants were backcrossed to wildtype for five generations, making it possible to assign changes in PGI activity directly to the mutation and not to unknown factors in the background. Immunological analysis revealed that they reduced PGI activity in direct proportion to the normal contribution of each gene. The homozygous mutants at *Pgi2* reduced cytosolic PGI activity to 36% of wildtype, and the mutant at *Pgi3* to 64%. The effects of the mutations at the two loci were additive. Thus, $Pgi2^{null}2^{null}$, $Pgi3^{a}3^{null}$ plants synthesized in an F_2 progeny from experimental hybrids between the two mutants exhibited only 14% of wildtype activity. The double homozygous null was lethal. The results demonstrated that PGI activity in plants having the duplication is not directly regulated by metabolic factors, warranting the suggestion that the dosage compensation depends on factors that regulate the levels of transcription or translation (Jones et al., 1986). Since *Pgi3* contributes less than *Pgi2* to the total cytosolic PGI activity, the regulatory factors appear to operate to a greater extent on the former locus. Thus, two levels of regulation were identified, one that reduces cytosolic PGI activity in species with the duplication to the level characteristic of species without the duplication, and the second that results in differential accumulation of the products of the duplicate genes.

The genetic and biochemical analyses of PGI in *Clarkia* identified a number of interesting questions that can be answered only with evidence from the sequences of the coding genes. For example, in terms of phylogenetics, it is necessary to test the major hypothesis that the duplication had a unique origin, with the consequence that the four sections that possess it are monophyletic. A corollary hypothesis is that the origin of the duplication involved hybridization between lineages now represented by *Myxocarpa* (which has the higher molecular weight subunit) and *Godetia/Rhodanthos* (with the low molecular weight subunit). The hypotheses can be tested by comparing the sequences of duplicate and nonduplicate PGI genes. On the hypothesis, *Pgi2* from a species with the duplication should be similar to *Pgi* from *Myxocarpa*, and *Pgi3* from the species with the duplication should be similar to *Pgi* from *Godetia/Rhodanthos*. In other words, the duplicate genes should be more similar to genes from different species than they are to each other.

Other questions of interest in a context of evolutionary biology have to do with the extent of PGI sequence divergence in species with the duplication versus those without the duplication, the extent of polymorphism for PGI genes in natural populations of *Clarkia*, and the value of the sequences to demonstrate phylogenetic relationships outside of *Clarkia*, particularly among the diverse genera included in tribe Onagreae.

A different set of questions must be answered to explain how the cytosolic PGI level is reduced in species with the duplication to that characteristic of those without it, to determine the basis for the near 2:1 difference in PGI activities attributable to the duplicate genes, to learn why *Pgi2* encodes a higher molecular weight unit than *Pgi3*, and the nature of the mutations that eliminated PGI activity in the EMS-induced null mutants.

CLARKIA PGI GENE SEQUENCES

Headway on these questions can now be made because we have cloned and sequenced PGI genes from several *Clarkia* genomic libraries. Here I describe how these genes were obtained, evidence that they encode PGI, and their general structure. Detailed characterizations and sequences will be presented separately. To my knowledge, the *Clarkia* PGI genes are the first nuclear genes from wild plants that have been sequenced.

Our first genomic library was constructed with DNA isolated from seedlings of a horticultural strain

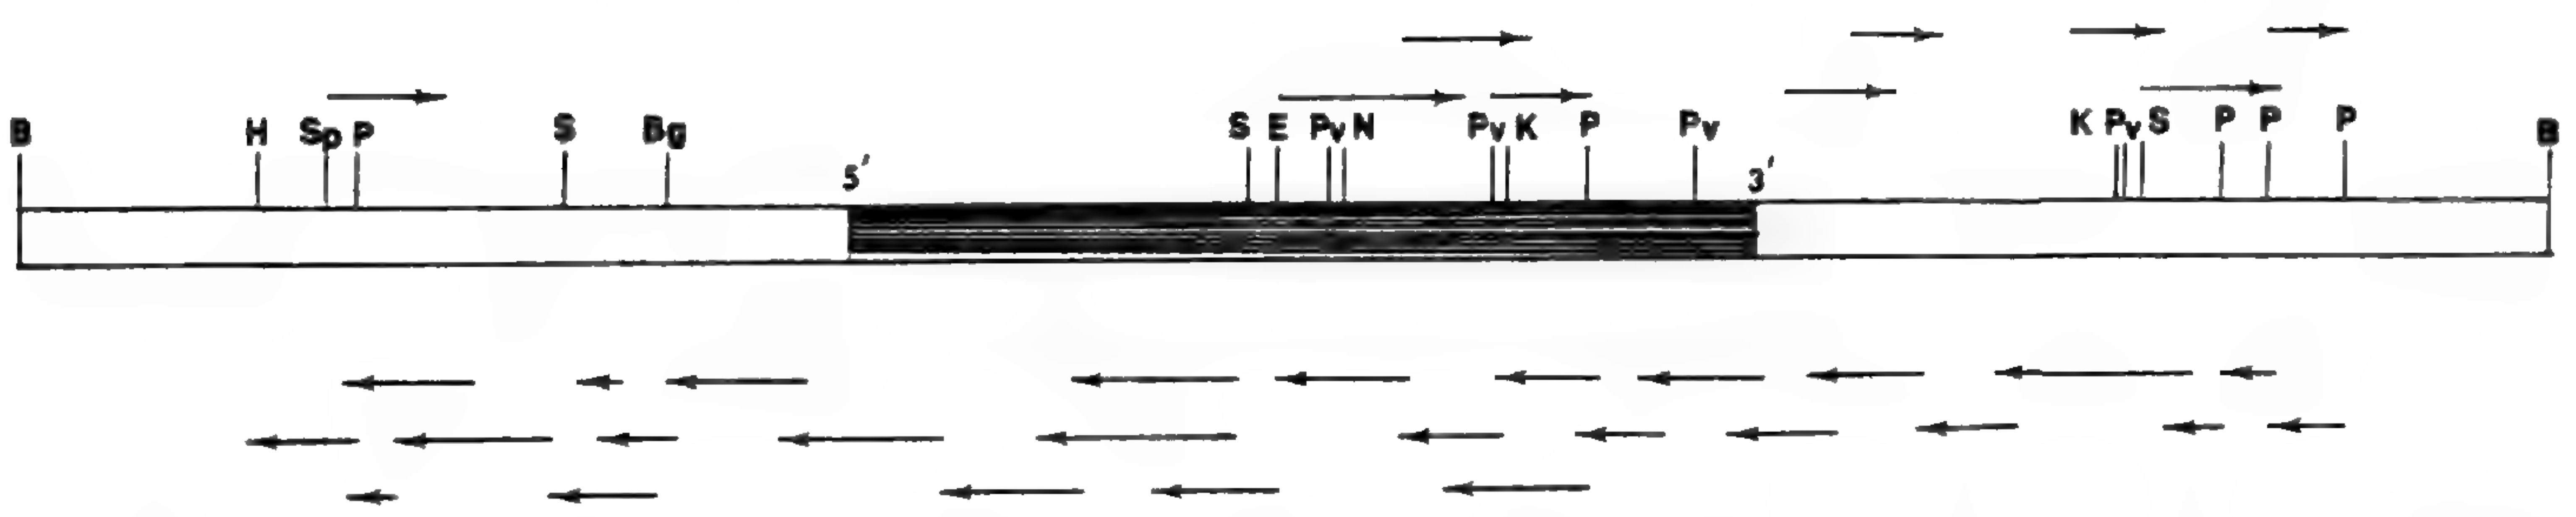

FIGURE 1. *Restriction map and sequencing strategy for the* Clarkia unguiculata *U2 gene which encodes PGI. The gene is present on a 4.45-kb* Bam*H1 fragment. Restriction sites shown are* Bam*H1 (B),* Hpa*I (H),* Sph *(Sp),* Pst*I (P),* Sal*I (S),* Bgl*III (Bg),* Eco*R1 (E),* Pvu*II (Pv),* Nco*I (N), and* Kpn*I (K). The arrows above and below the restriction map show the direction and extent of sequencing for the individual M13 subclones. 3.8 kb including the entire coding region was sequenced on one strand, and 1.6 kb on the complementary strand.*

of *C. unguiculata* (Northrup King "Clarkia Double Mixed Colors"), a species with the PGI duplication. Horticultural material was used because very large amounts of seed could be purchased, permitting us to fine-tune our techniques prior to studying natural populations. The DNA was extracted by a procedure modified from Fischer & Goldberg (1982) that yielded a nuclear pellet that, after lysis, provided high molecular weight DNA fragments (greater than 100 kb). The DNA was partially restricted with *Sau*3a and fragments between 15 and 23 kb obtained by fractionation on a sucrose gradient. After determining optimal ratios of chromosomal DNA and vector arms, the DNA fragments were cloned into the *Bam*H1 site of the lambda replacement vector Charon 35. The resulting library is estimated to contain 1.8 × 10^6 phage with 88% recombinants and represents about seven *Clarkia* genomes.

The library was screened at low stringency (51°C, 5 × SSPE) with an 800-bp DNA fragment of a yeast gene encoding PGI, kindly provided by a biotechnology firm. Since we expected low to very low homology between the yeast and *Clarkia* PGI sequences, the screening conditions were determined in a prior experiment in which the probe was hybridized on a Southern blot to genomic *C. unguiculata* DNA digested with several restriction enzymes. Two positive clones were obtained from the first 30,000 plaques examined. They were purified, and DNA prepared from each was restricted with several enzymes, subjected to agarose gel electrophoresis, and analyzed by Southern blots using the yeast PGI DNA fragment as probe. The two clones had inserts of 13.7 and 15 kb, which proved different. Hybridizing fragments of the former clone, designated U2, were cloned into M13mp10 and partially sequenced. The sequences showed homology to that of the yeast gene. A 4.45-kb *Bam*H1 fragment (Fig. 1) was then subcloned into pUC19 and deletion fragments constructed using the exonuclease III-S1 protocol of Henikoff (1984). One strand of 3.8 kb including the entire coding region was completely sequenced, and 1.6 kb was sequenced on the complementary strand by the dideoxy sequencing protocol (Messing, 1983). The U2 sequence revealed an uninterrupted open reading frame of 1,644 nucleotides encoding a protein of 548 amino acids.

TABLE 2. *Homology between predicted amino acid sequences from nucleotide sequences of U2 and U8, cloned from a genomic library of* Clarkia unguiculata *and amino acid sequences of cyanogen-bromide peptides purified from pig muscle PGI (Achari et al., 1981).*

Sequence	Number Identical Amino Acids / Total Number of Amino Acids	Homology
U2 vs. U8	319/548	58%
U2 vs. Pig	110/166	66%
U8 vs. Pig	108/166	65%
U2 vs. U8 (in sequences covered by Pig peptides)	89/165	54%

The identity of U2 was established by comparing its predicted amino acid sequence with the amino acid sequences of five cyanogen-bromide peptides obtained from pig muscle PGI (Achari et al., 1981). These are the only PGI sequences, protein or DNA, that are published for any organism. The five pig peptides identify a total of 166 amino acids, about 30% of the complete protein. The U2 gene encodes amino acids that are identical to those in pig PGI at 110 of these 166 residues, or 66% of the total (Table 2). A second PGI gene, called U8, also obtained from the *C. unguiculata* genomic library, using U2 as the probe, was found that contains the same sequence present in the 15-kb insert noted above. A similar isolation and sequencing strategy was used to characterize the U8 clone as was used for U2. U8 proved to have a 65% ho-

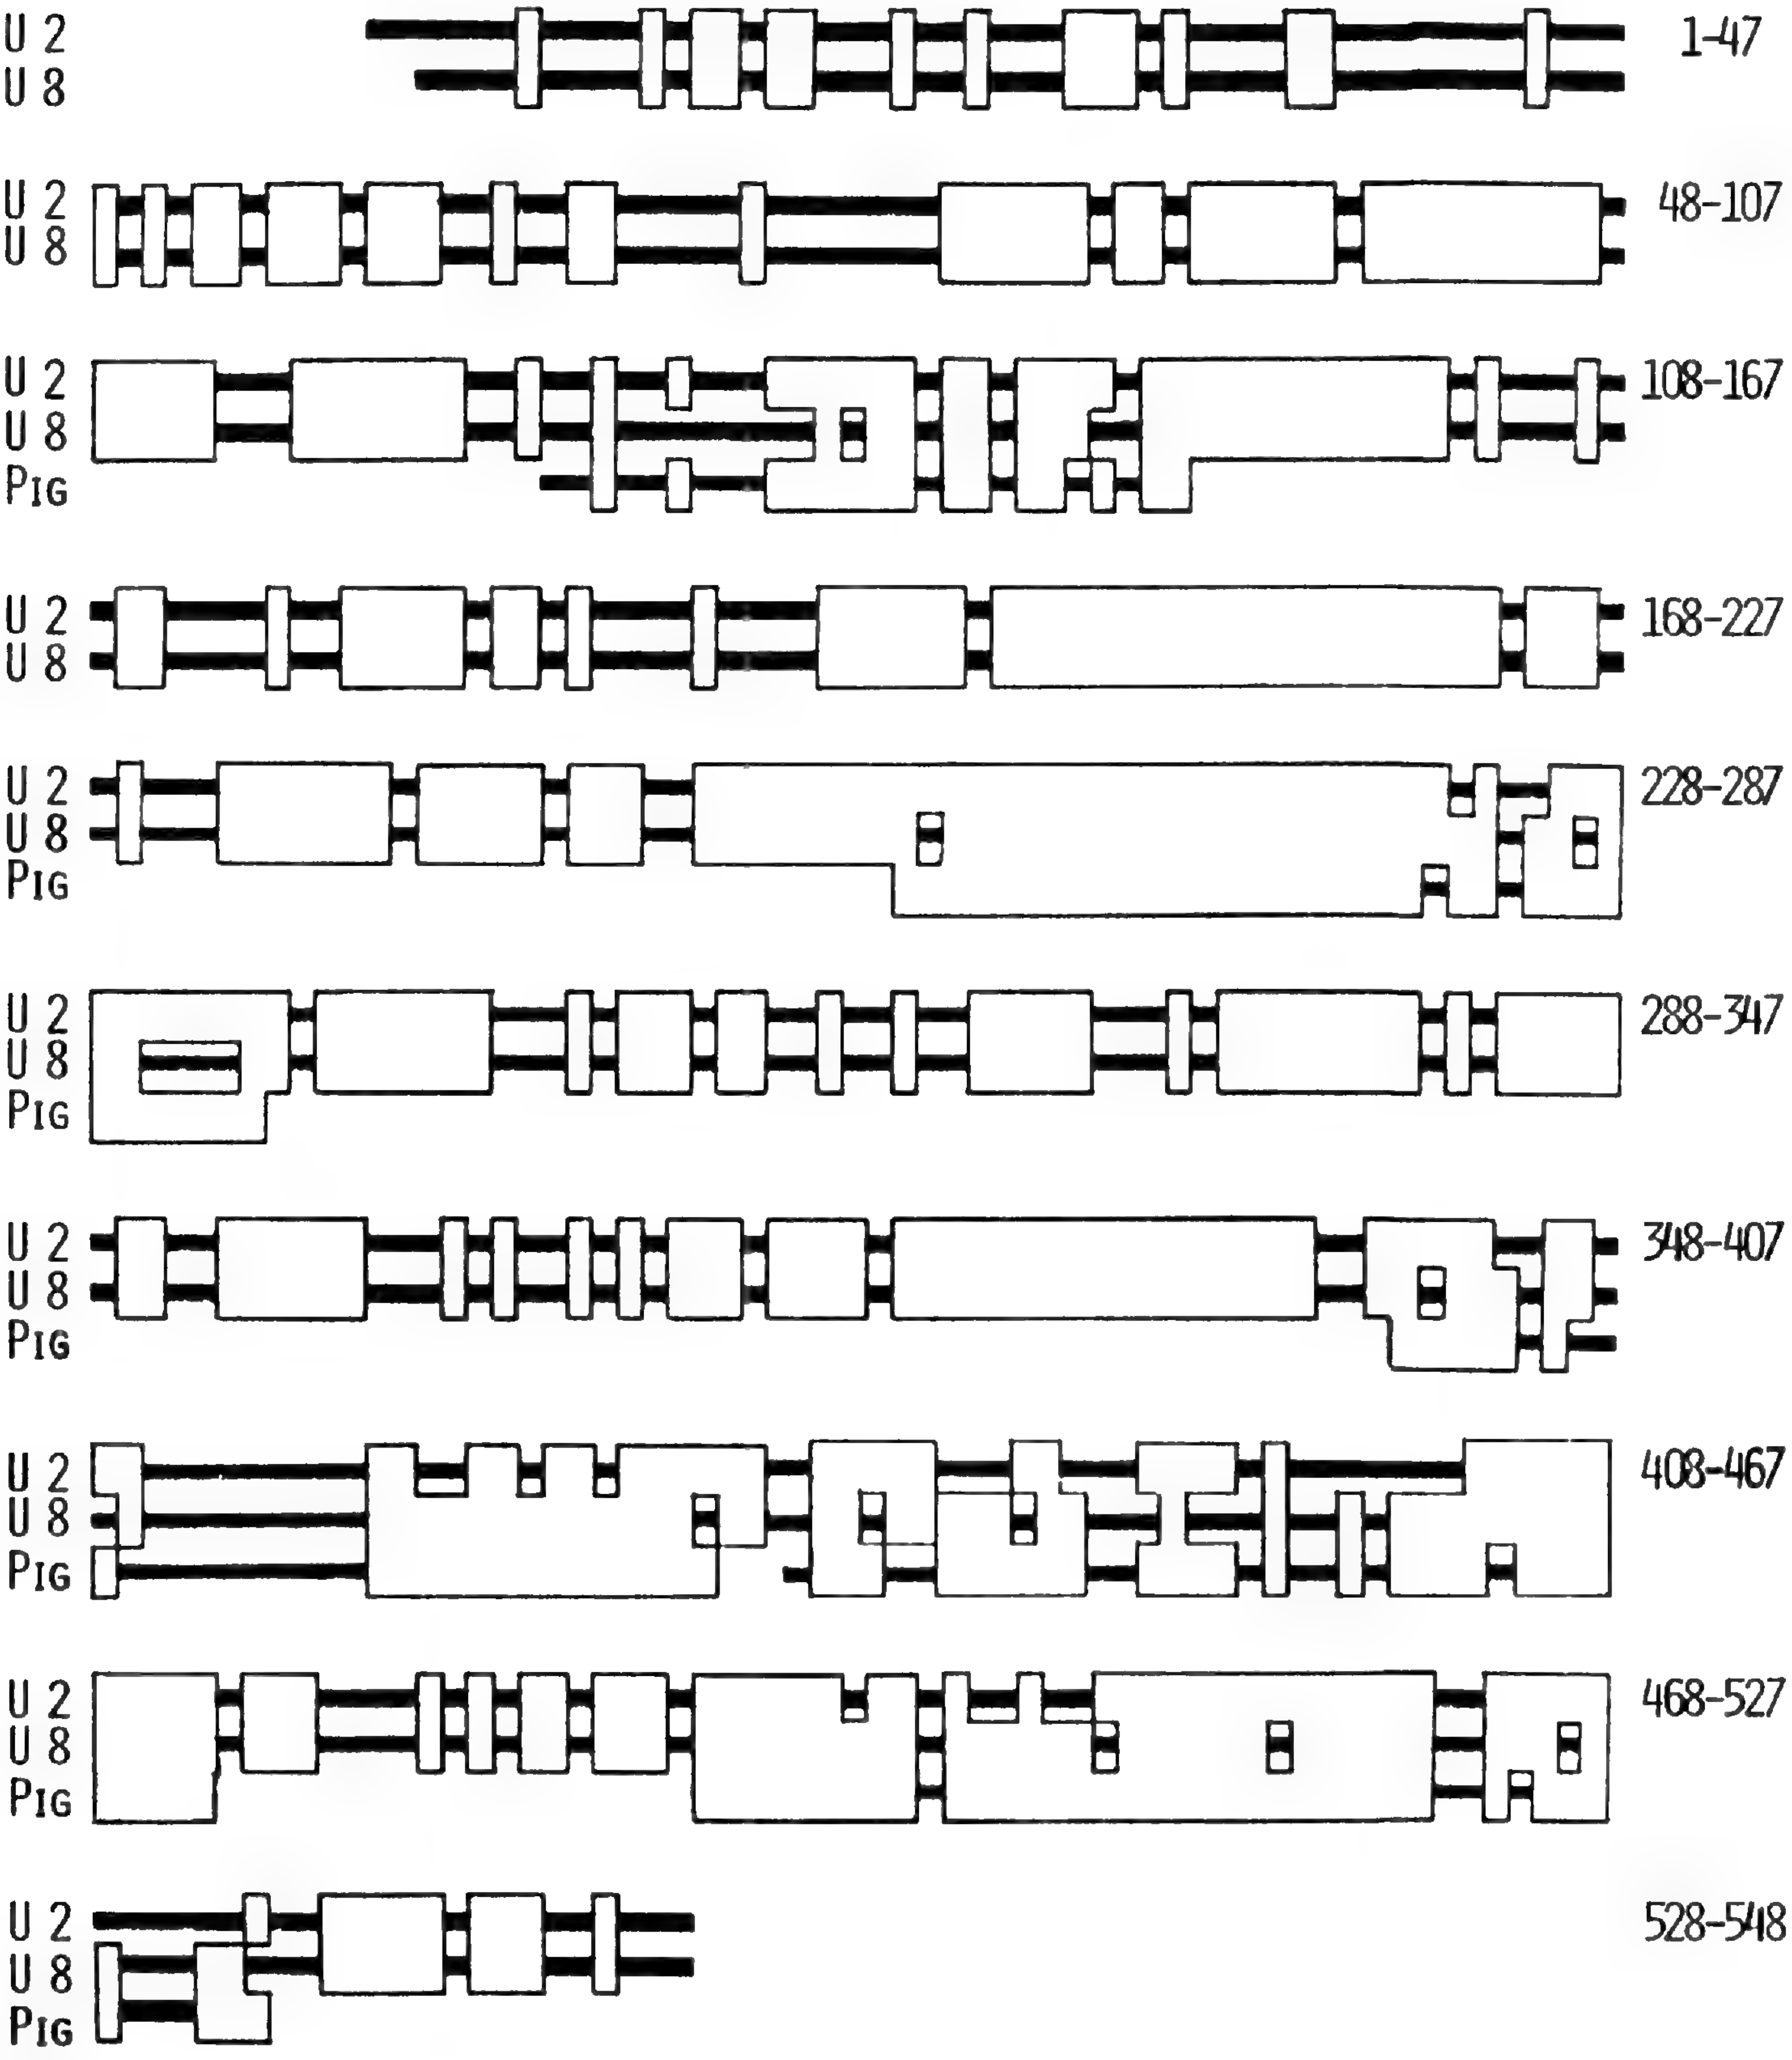

FIGURE 2. *Comparison of the predicted amino acid sequences encoded by* Clarkia unguiculata *U2 and U8 genes with the amino acid sequences from five cyanogen-bromide peptides from pig muscle PGI (Achari et al., 1981). An open box drawn across the black bars indicates the same amino acid appears in the corresponding position on two or three of the sequences. The amino acids are numbered on the right beginning with the first methionine in the U2 sequence. U2 encodes 548 amino acids, U8 encodes 543 amino acids, and the total number of amino acids identified in the pig peptides is 166. The diagram represents the best fit by eye, taking into account several short insertions and deletions in the sequences.*

mology to pig PGI (Table 2), and encodes a protein of 543 amino acids.

The predicted amino acid sequences show that U2 and U8 are 58% homologous over their entire coding regions. Comparing U2 and U8 only in the regions covered by the pig peptides, the two sequences are 54% identical (Table 2). Thus, the two *Clarkia* PGI genes differ more from each other than either does from pig PGI. The homology of the *Clarkia* and pig sequences is diagrammed in Figure 2. The two *Clarkia* proteins exhibit large blocks of very high amino acid identity as well as many shorter regions of nonidentity. Several lengthy portions of the three sequences show complete identity. Overall, the high homology between the pig PGI amino acid sequences and the predicted *Clarkia* amino acid sequences establishes with certainty that both *Clarkia* genes encode PGI.

On the basis of lack of interruption in their open reading frames and the lengths of their sequences, which encode proteins that have closely similar molecular weights to that previously determined for *Clarkia* PGI, neither *Clarkia* gene appears to include introns (and see below). Otherise, both genes have many features expected of eukaryotic genes, including potential TATA boxes and other upstream regions similar to known regulatory sequences. A complete transcriptional characterization of the genes will be reported separately.

Clarkia unguiculata possesses the PGI duplication, and its genome must include two loci encoding cytosolic PGIs and one locus encoding plastid PGI. Since a heterologous probe was used to obtain the U2 and U8 PGI genes, it was necessary to determine which isozyme is encoded by each gene. A priori, the expectation was that sequences encoding the cytosolic PGIs would be more similar to each other than either would be to the plastid PGI. Genes encoding plastid and cytosolic glycolytic isozymes have been cloned and sequenced in plants only for tobacco glyceraldehyde-3-phosphate dehydrogenase (G3PD) (Shih et al., 1986), and the results of that study are closely relevant to our research with PGI. Comparison of predicted amino acid sequences from cDNAs showed that the tobacco cytosolic G3PD was more similar to other eukaryotic G3PD enzymes, with about 65% homology, than it was to the tobacco plastid isozyme, with 45% homology. The homology of U2, U8, and pig PGI are roughly similar to these values, but we were able to compare only a few sequences.

Our initial attempt to identify the isozymes encoded by the *Clarkia* genes centered on the search for correlation between restriction length fragments and allelic segregation. This could be followed by PGI activity staining on starch gels following electrophoresis of leaf extracts and correlated with the RFLP segregation. To date, we have examined a number of DNAs from single *C. unguiculata* plants by restriction analysis followed by electrophoresis and Southern blotting. The DNAs proved highly polymorphic, but we have been able to match restriction fragments to U2. U8 and several other genes cloned from the *C. unguiculata* library have not yet been similarly matched, but this is not unexpected, since the library was made from DNA isolated from a bulk of hundreds of individual seedlings and this commercial strain is highly polymorphic.

However, a different procedure suggests that U8 encodes the slowly migrating allozyme PGI-3B, a cytosolic isozyme. The U8 sequence was inserted in pUC18, downstream from the beta-galactosidase promoter. When the operon was induced by IPTG, the *E. coli* host synthesized very large quantities of PGI protein. The PGI was catalytically active and had a very slightly faster electrophoretic mobility on starch gels than the slow allozyme PGI-3B of *C. unguiculata*, a difference probably caused by different post-translational protein modification between *Clarkia* and *E. coli*. By the same procedure, a large quantity of protein with the molecular weight of PGI was also synthesized from U2, and its electrophoretic mobility was similar to that of *Clarkia* plastid PGI. The expression of these genomic clones in *E. coli*, apparently by virtue of fortuitous promoters in their 5′ noncoding region, provides convincing evidence that introns are not present in these genes. Whether other PGI genes also lack introns remains to be determined. Their absence is surprising, since other genes encoding glycolytic enzymes in plants such as maize *Tpi* has eight introns (Marchionni & Gilbert, 1986) and maize *Adh* has nine introns (Dennis et al., 1984).

To summarize the molecular studies, we have cloned and sequenced two PGI genes from a genomic library of *C. unguiculata*, a species with the PGI duplication. The genes have a homology of 58%; one of them (U8) appears to encode a cytosolic PGI-3 isozyme; the other is thought to encode a plastid PGI. We have also constructed genomic libraries from *Clarkia* species without the PGI duplication and have obtained clones of a number of sequences homologous to the PGI probes from *C. unguiculata*. The molecular genetics studies of PGI in *Clarkia* constitute one of the first analyses of the evolution of a plant nuclear gene. Many additional molecular studies are called for to understand gene evolution and to improve phylogenetic reconstructions.

CHLOROPLAST DNA VARIATION AND PLANT PHYLOGENY[1]

Jeffrey D. Palmer,[2] Robert K. Jansen,[3]
Helen J. Michaels,[2] Mark W. Chase[2,4]
and James R. Manhart[2,5]

ABSTRACT

Several features, foremost its conservative mode of evolution, make chloroplast DNA an extremely valuable molecule for phylogenetic studies. Its conservatism is also its only serious drawback, as this can limit the amount of useful DNA variation at the intraspecific level. Comparative restriction site mapping is currently the preferred molecular method for examining interspecific relationships. At this level, one typically encounters less than 5% homoplasy. Furthermore, the predominantly uniparental inheritance of chloroplast DNA provides unique insights into the origin of hybrid and polyploid complexes, as illustrated by examples from the genus Brassica. *In many families of angiosperms, such as the Asteraceae and Orchidaceae, restriction site mapping can also be used to determine intergeneric relationships. The greater expense of DNA sequencing makes it most appropriate only at those higher taxonomic levels—above the family level—where restriction site mapping fails. Within angiosperms, the* rbcL *gene appears to be the chloroplast gene of choice for phylogenetic studies. Twenty-five* rbcL *sequences have already been accumulated, and several laboratories are making a coordinated effort to sequence this gene widely among angiosperms and gymnosperms. The more conservatively evolving ribosomal RNA genes hold the greatest promise for resolving the deepest branchings of plant evolution and, indeed, have already settled the ultimate question of chloroplast evolution, namely, its endosymbiotic origin. A third approach to extracting phylogenetic information from chloroplast DNA is by analyzing the distribution of major structural rearrangements, such as inversions and the loss or gain of genes and introns. Although such rearrangements are rare relative to point mutations, their great rarity and freedom from homoplasy also make them extremely powerful characters. Examples to be discussed include an inversion defining the most ancient branching in the Asteraceae, rearrangements that mark several major divisions within the Fabaceae, and events that identify the green algal ancestors of land plants.*

The confounding diversity and plasticity of plant morphologies have prompted plant systematists to search for more reliable characters to use in phylogenetic reconstruction. In recent years, these characters often have been chemical ones. A large body of comparative data has been gathered on secondary plant chemicals (reviewed in Harborne & Turner, 1984; Giannasi & Crawford, 1986, in press), yet the ultimate systematic value of these compounds remains unclear, particularly at higher taxonomic levels (Giannasi & Crawford, 1986, in press). The examination of plant protein variation by enzyme electrophoresis continues to be a powerful tool for inferring relationships within species and for studying mechanisms of speciation (Gottlieb, 1981; Crawford, 1983; Harborne & Turner, 1984; Giannasi & Crawford, 1986, in press). However, early attempts to infer broader patterns of plant phylogeny by amino acid sequencing were largely unsuccessful (Boulter, 1980; Harborne & Turner, 1984; Giannasi & Crawford, 1986, in press). While a recent review concluded that plant "amino acid sequencing is an approach whose time has come and gone" (Giannasi & Crawford, 1986), recent studies by Martin and collaborators (e.g., Martin & Dowd, 1986; Martin et al., 1986) demonstrate that this approach does indeed have phylogenetic merit.

---

ANN. MISSOURI BOT. GARD. 75: 1180–1206. 1988.

The tremendous power of modern molecular biology has revolutionized our ability to analyze and compare large stretches of chromosomes and DNA sequences. Literally millions of discrete DNA characters, i.e., base pairs, are present in the genomes of all organisms. Moreover, the underlying basis of changes in the states of these characters can be understood in the most satisfying way possible—as mutations in the genetic material itself. The application of DNA comparisons to systematic questions is now being actively pursued for most life forms. The power and promise of DNA systematics has already been demonstrated in studies whose emphases range from the primary lines of descent of life on Earth (Pace et al., 1986) to population dynamics and the speciation process in higher animals (Avise et al., 1987; Moritz et al., 1987).

Although the field of chloroplast DNA (cpDNA) systematics is only 12 years old (Atchison et al., 1976; Vedel et al., 1976), it has already provided significant insights into a number of phylogenetic problems, and, together with parallel studies of nuclear DNA variation, offers the best hope of producing an accurate phylogeny of the major lines of plant descent. Several reviews of the field have appeared recently (Cattolico, 1985; Palmer, 1985a, 1986a, 1987; Giannasi & Crawford, 1986, in press). This article will review approaches for extracting useful phylogenetic information from chloroplast DNA comparisons as practiced in this laboratory and also results obtained from such studies.

THE CHLOROPLAST CHROMOSOME

An understanding of certain basic properties of the cpDNA molecule is critical to a proper appreciation of its utility in systematic studies. The following overview is based primarily on several review articles (Sears, 1980; Gillham et al., 1985; Palmer, 1985b, c, 1987; Rochaix, 1985; Ritland & Clegg, 1987; Zurawski & Clegg, 1987; Wolfe et al., 1987), which should be consulted for details beyond this brief synopsis and for relevant references. In addition, the recently completed sequences of the entire chloroplast genomes of an angiosperm (*Nicotiana tabacum*; Shinozaki et al., 1986) and a liverwort (*Marchantia polymorpha*; Ohyama et al., 1986) provide a wealth of specific information on chloroplast gene content and organization.

STRUCTURE AND GENE CONTENT

Figure 1 shows the structure and gene arrangement of a representative and well-understood chloroplast genome, that of tobacco. This circular chromosome is 156 kilobase (kb) pairs in size (155,844 base pairs, to be exact) and is arranged in four parts; there are two identical 25-kb segments that form an inverted repeat separating the rest of the molecule into single-copy regions of 87 kb and 18 kb. The typical chloroplast genome of land plants is densely packed with approximately 120 genes, some of which are shown in Figure 1. These genes encode four ribosomal RNAs, 30–31 transfer RNAs, approximately 55 proteins of known function, and about 30 unidentified proteins. Chloroplast gene products function primarily in photosynthesis and in transcription-translation. The former category includes many of the critical polypeptides of the major thylakoid protein complexes (see legend to Fig. 1) and also the large subunit of the primary CO_2 fixing enzyme, ribulose-1,5-bisphosphate carboxylase. Gene products involved in transcription-translation include the ribosomal and transfer RNAs, approximately a third of the chloroplast ribosomal proteins, four subunits of RNA polymerase, and initiation factor 1. Surprisingly, tobacco and *Marchantia* cpDNAs contain six genes similar in sequence to those encoding subunits of *mitochondrial* NADH dehydrogenase, although their function in the chloroplast remains a mystery.

Both strands of the chloroplast genome are actively expressed, indeed transcription switches strands over 30 times. Many chloroplast genes are grouped functionally into polycistronic operons, such as those containing the four ribosomal RNA genes, *atp*I-H-F-A, *atp*B-E, and a cluster of eight ribosomal proteins extending from *rpl*23 through *rps*8 (Fig. 1). The order and mode of expression of genes in these operons are highly similar to those found in prokaryotes. A major structural difference between certain chloroplast genes and those of prokaryotes is the presence of introns, which in tobacco occur in six tRNA genes and ten protein genes, but which are absent from eubacterial genes.

EVOLUTION AND INHERITANCE

Land plant cpDNAs evolve quite slowly in all respects. They vary in size less than two-fold (120–217 kb), with most of this variation resulting from a few major expansions or contractions of the large inverted repeat, so that the range of sequence complexities is only 110–150 kb. Most length mutations are quite short (1–10 bp), although larger ones on the order of 50–1,200 bp occur frequently enough to be a major component of the variation encountered in restriction fragment and map comparisons (see below). Gene content is highly con-

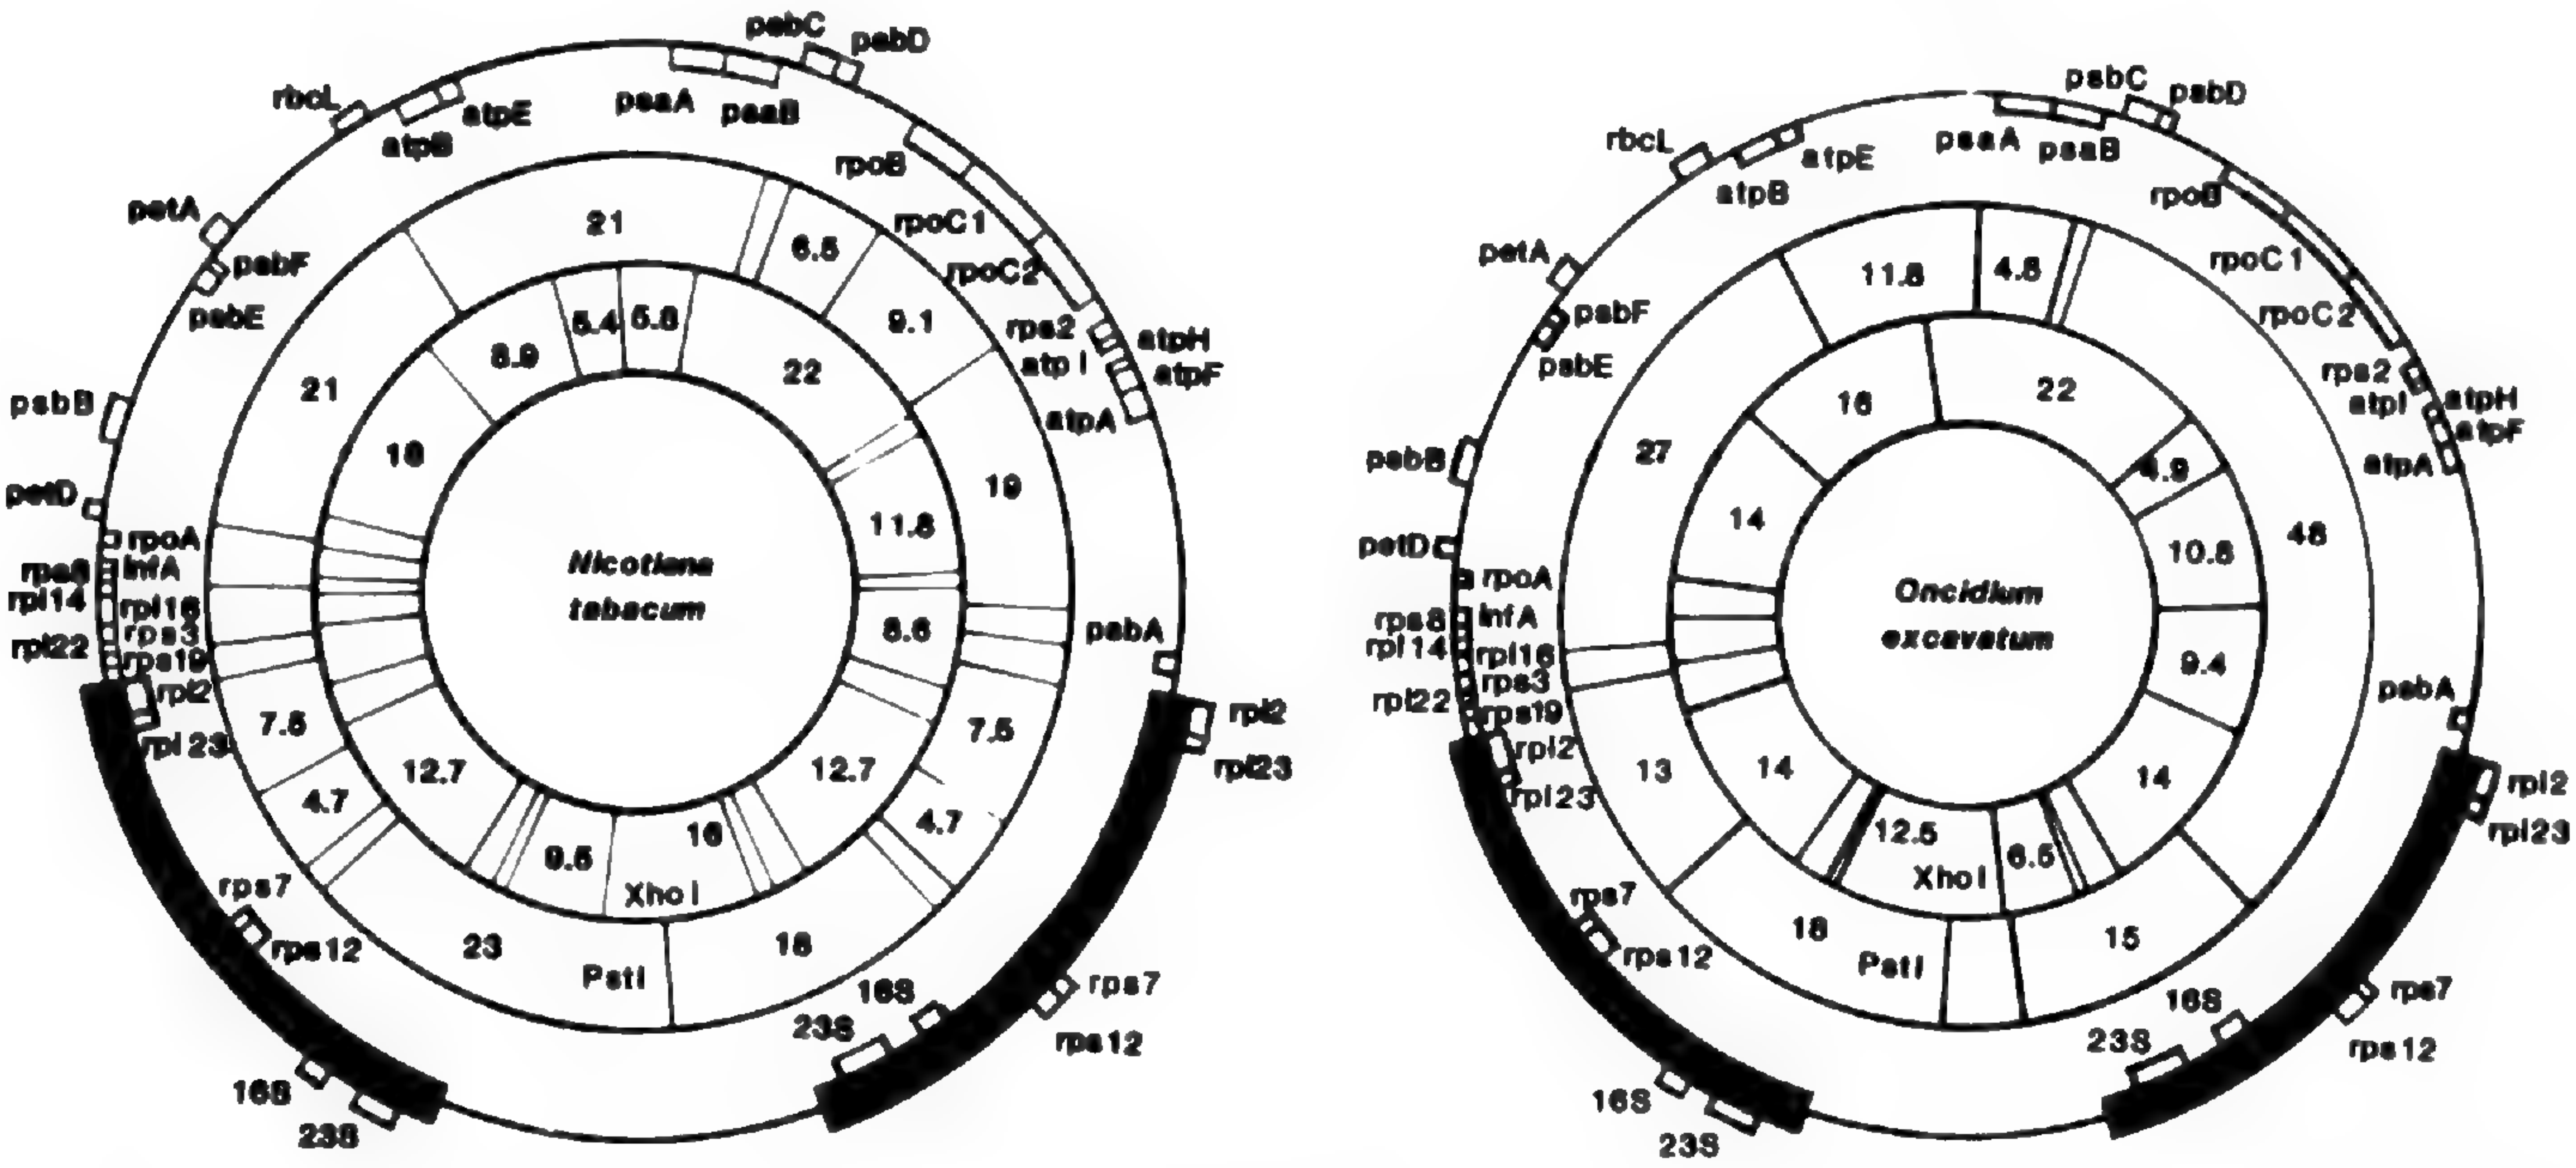

FIGURE 1. *Physical and gene maps of typical cpDNAs from a dicot (*Nicotiana tabacum; *Solanaceae) and monocot (*Oncidium excavatum; *Orchidaceae). Heavy black lines centered on the circles indicate large inverted repeats. Ribosomal RNA genes are indicated by 16S and 23S. Genes for the 50S and 30S ribosomal proteins are given as* rpl *and* rps, *respectively, followed by the number of the corresponding* E. coli *protein. Genes for RNA polymerase subunits are indicated by* rpo, *followed by a subunit-specific letter.* Inf*A encodes initiation factor 1.* Rbc*L encodes the large subunit of ribulose-1,5-bisphosphate carboxylase. Subunits of the thylakoid membrane complexes ATP synthase, photosystem I, photosystem II, and cytochrome b_6/f complex are encoded by* atp, psa, psb, *and* pet, *respectively, followed by a subunit-specific letter. Only selected genes are shown for the completely sequenced cpDNA of tobacco; see Shinozaki et al. (1986) for a more complete map. Orchid data are from M. Chase & J. Palmer (unpublished data).*

served; only two differences are known among the 120 genes present in the cpDNAs of tobacco and *Marchantia*, which diverged some 400 million years ago. The order of chloroplast genes is also highly conserved. The tobacco gene order is found in most other angiosperms (e.g., an orchid, Fig. 1) and in at least one fern and one gymnosperm, and differs by only one inversion from the *Marchantia* order. With the exceptions so far of only two groups of plants (some legumes and *Pelargonium*), most of the changes in gene order found among angiosperm cpDNAs can be accounted for by one or two simple inversions.

Sequence comparisons of several kinds reveal a low rate of nucleotide substitution in land plant cpDNA as a whole, although direct sequence studies reveal rate differences among specific chloroplast genes. On average, the rate of silent substitution in chloroplast genes is two to three times lower than in nuclear genes and 20 times lower than in animal mitochondrial genes, but three to four times higher than in plant mitochondrial genes. Transitions outnumber transversions in chloroplast genes by a factor of somewhat less than two relative to random expectations, a much smaller bias than that found in animal mtDNA.

A critical feature of cpDNA from the standpoint of phylogenetic studies at lower taxonomic levels is its mode of inheritance. In all land plants examined thus far, it is inherited clonally, through the maternal parent in most angiosperms and the paternal parent in gymnosperms. In those plants where both parents contribute chloroplasts to their offspring, the chloroplasts and their genomes have never been seen to recombine, but simply sort out somatically.

APPROACHES TO DETECTING AND ANALYZING CHLOROPLAST DNA VARIATION

Mutations in cpDNA are fundamentally of two types—point mutations (single nucleotide pair substitutions) and rearrangements, with several kinds of rearrangements recognized. By far the most frequent mutations are point mutations and deletions/insertions in noncoding regions. Whereas point mutations can profitably be used for phylogenetic studies at all taxonomic levels, the systematic use of noncoding deletions/insertions is often inappropriate, as will be discussed in the section on restriction site mapping. Other classes of rearrangements (inversions and deletions/insertions of genes, introns, and one copy of the large inverted repeat) occur rarely during cpDNA evolution. Because of their rarity, these changes are often extremely useful in phylogenetic reconstruction.

In the following sections, we discuss the kinds of approaches available for comparing cpDNAs and revealing phylogenetically informative mutations. The three major approaches will be discussed in terms of the methodologies involved, the kinds of mutations detected, and the taxonomic levels at which they are most appropriate. Before discussing these approaches, we first review methods for preparing cpDNA and total DNA for use in phylogenetic studies.

ISOLATION OF CHLOROPLAST AND TOTAL DNA

The most generally applicable procedure for preparing purified cpDNA is the sucrose gradient procedure described in Palmer (1986b). For some plants, such as members of the Geraniaceae, substantially higher yields are obtained by substituting for the aqueous blending used in Palmer (1986b) a two-step homogenization procedure, consisting of powdering of liquid nitrogen-frozen tissue in a coffee mill (Calie & Hughes, 1987a), followed by Polytron-grinding of the powder in aqueous buffer. A large number of alternative procedures for preparing cpDNA are reviewed in Palmer (1986b). We particularly call the reader's attention to a NaCl-isolation technique (Bookjans et al., 1984) that works extremely well with many recalcitrant legumes and Malpighiaceae, to recently developed techniques for extracting cpDNA from conifers (White, 1986) and mosses (Calie & Hughes, 1987a), and to a promising modification (Dally & Second, submitted) of the nonaqueous procedure of Bowman & Dyer (1982), which eliminates the use of highly dangerous organic chemicals.

In many cases it may be convenient, if not preferable, to analyze cpDNA variation in preparations of total cellular DNA, rather than purified cpDNA. The major advantages of using total DNA are *yield* (total DNA extraction efficiencies are nearly quantitative and provide 5–100 times higher yields of cpDNA than cpDNA extraction procedures; 1–2 grams of fresh leaf tissue will usually provide sufficient total DNA for 10–30 restriction enzyme digests, enough for most comparisons of cpDNA variation), *flexibility* (total DNA preparations can obviously be used to study variation in all three plant genomes), and *adaptability* (total DNA has been extracted from several groups of plants in which common methods of cpDNA extraction did not work). The small amount of starting material needed for total DNA extractions has proved critical in our studies on orchids, many of which are rare or minute plants that at maturity may weigh only 0.3–0.6 grams.

Since cpDNA is present in several thousand copies in the typical leaf cell (Bendich, 1987), it is easy to visualize and map cpDNA fragments by hybridizing cloned cpDNA fragments to filter blots containing restriction enzyme digests of total DNA. Indeed, most current studies of cpDNA restriction site variation have employed total DNA (e.g., Sytsma & Gottlieb, 1986a, b; Coates & Cullis, 1987; Jansen & Palmer, 1988). The use of purified cpDNA is of somewhat greater advantage in DNA sequencing and rearrangement studies, as described in the relevant sections below.

An extremely effective procedure for preparing total cell DNA is Doyle & Doyle's (1987) modification of the CTAB isolation method of Saghai-Maroof et al. (1984). This method typically yields 20–100 micrograms of high molecular weight DNA from 0.5–2 grams of fresh (or fresh frozen) leaves. We find that higher yields of total cellular DNA are often obtained from species, particularly orchids, with succulent tissues by increasing the CTAB buffer from 2× (Doyle & Doyle, 1987) to 3× concentration. Also, fibrous leaves are often homogenized more efficiently by grinding in liquid nitrogen (either with mortar and pestle or in a coffee mill), followed by addition of CTAB buffer, rather than directly in the buffer. The CTAB method sometimes gives an enrichment of cpDNA (relative to nuclear) if the alcohol-precipitated DNA is spun down rather than spooled out of the aqueous solution. The CTAB method has also proven successful in the extraction of usable DNA from recently dried herbarium specimens (Doyle & Dickson, 1987). A variation on this CTAB procedure was reported by Rogers & Bendich (1985) to give good results with fresh tissues from a wide variety of plants, but to yield only degraded DNA from older herbarium specimens and mummified tissues.

RESTRICTION SITE MAPPING

The cpDNAs of closely related species (from the same or related genera) are most easily compared by examining the pattern of fragments produced upon digestion of the DNAs with restriction endonucleases and subsequent electrophoresis in agarose gels. The restriction fragment phenotypes that are diagnostic for three types of mutations—base substitutions (point mutations), deletions/insertions (length mutations), and inversions—have been described in earlier papers (Upholt, 1977; Palmer et al., 1985; Palmer, 1986a). Point mutations (detected as the gain or loss of restriction enzyme cleavage sites) and length mutations (detected as fragment size differences) are common, whereas inversions are rare. The length mutations detected

FIGURE 2. *Hypervariation in cpDNA resulting from length mutations. DNAs from 1–4 populations of each of four species in the genus* Pisum *(*P. sativum, *lane S;* P. elatius, *lanes E;* P. humile, *lanes H;* P. fulvum, *lanes F) were digested with the restriction enzymes XhoI, and fragments were separated by electrophoresis in a 0.7% agarose gel. Fragments were transferred from the gel to a nitrocellulose filter and hybridized with a ^{32}P-labeled XhoI fragment of 3.2 kb from pea cpDNA. Sizes indicated at left are in kb. Modified from Palmer et al. (1985).*

in restriction enzyme studies usually occur in spacers between genes and pose problems for phylogenetic analysis because they tend to cluster in "hotspot" regions having high levels of variability and because the assignment of exact homology is often difficult (e.g., Fig. 2). In combination, these two factors can result in high degrees of homoplasy (i.e., parallelism and convergence). Therefore, spacer length mutations are usually not included in a formal phylogenetic analysis (Perl-Treves & Galun, 1985; Palmer et al., 1985; Sytsma & Gottlieb, 1986a), although it is critical that they be properly recognized and distinguished from restriction site mutations.

In early studies cpDNA restriction site mutations were inferred indirectly by the inspection of restriction fragment profiles of total, purified cpDNA (e.g., Palmer & Zamir, 1982; Erickson et al., 1983; Clegg et al., 1984). This approach is limited to situations in which 1) cpDNA can be readily prepared (requiring both large amounts of tissue, 10–100 g fresh weight, and amenability of the tissue to cpDNA purification techniques) and 2) levels of base sequence divergence are low enough (less than 0.5–1.0%) to permit the critical interpretation of fragment pattern differences in terms of specific mutations. Currently, most researchers in the field analyze cpDNA variation by a filter hybridization approach, in which cloned fragments of one chloroplast genome are hybridized to filter blots containing digests of all the DNAs under study (e.g., Sytsma & Gottlieb, 1986a, b; Coates & Cullis, 1987; Jansen & Palmer, 1988). The hybridization approach enables the direct ordering, or mapping, of restriction enzyme cleavage sites and permits a more critical analysis of mutations and discrimination between site mutations and length mutations. In addition, it allows one to use total DNA, which offers several advantages over the use of purified cpDNA (see previous section).

The choice of cpDNA clones to use as hybridization probes in mapping studies depends on several factors (reviewed in Palmer, 1986b). "Homologous" clones, i.e., those from one of the taxa under study, give the best results but can be a lot of work to make if not already available. The use of "heterologous" clones requires sufficient conservation of 1) base sequence to ensure a significant level of cross-hybridization and 2) linear arrangement of the chromosome to permit alignment of the cross-hybridizing fragments and interpretation of the hybridization signals. Fortunately, the great majority of cpDNAs are highly conserved in sequence and arrangement (Palmer, 1985b, c; Zurawski & Clegg, 1987), and heterologous probes have been shown to work effectively across subclasses of angiosperms (e.g., Perl-Treves & Galun, 1985; Sytsma & Gottlieb, 1986a). The relevant properties of 15 angiosperm cpDNA clone banks were tabulated in Palmer (1986b). Additional clone banks have been developed for a number of other angiosperms (tobacco, Sugiura et al., 1986; tomato, Phillips, 1985; potato, Heinhorst et al., 1988; soybean, Singh et al., 1984; lettuce, Jansen & Palmer, 1987a; a poplar, *Populus nigra,* R. Smith & K. Sytsma, unpublished data; sorghum, Dang & Pring, 1986; an orchid, *Oncidium excavatum,* M. Chase & J. Palmer, unpublished data), two ferns (Stein et al., 1986; D. Stein, unpublished data), a conifer (C.-H. Tsai & S. Strauss, unpublished data), and the liverwort *Marchantia polymorpha* (Ohyama et al., 1986). Most of these clone banks are freely available for use.

An outline of the approach we currently use for comparative mapping of cpDNA restriction site mutations is as follows: 1) Total DNAs are prepared from 1–2-g leaf samples by the procedure of Doyle & Doyle (1987) or by one of the modifications of this procedure described in the preceding section. 2) The DNAs are digested with each of 10–20 different restriction enzymes that cut the genome 20–100 times. 3) The digests are separated electrophoretically in 1.0% agarose gels in which the bromophenol blue dye marker is run 10 cm. (Most of the details of the electrophoresis and hybridization conditions are given in Palmer, 1986b; plans for the gel rigs we use are available upon request of the senior author.) The use of narrow tooth gel combs permits 35 samples (e.g., 33 plant DNAs and two lanes of size markers) to be run across a 20 cm width corresponding to the width of standard 8″ × 10″ X-ray film. The DNAs are arranged on the gel (or gels) according to presumed relatedness. By running the gels no farther than 10 cm, we accommodate two gel-sized filters (each 20 cm × 12.5 cm), or 66 experimental lanes, on each X-ray film exposure. 4) Two replica filters of each gel are made using the bidirectional blotting procedure of Smith & Summers (1980) as modified for greater sensitivity by the alkaline transfer procedure (Reed & Mann, 1985). We use durable nylon filters (Zetabind; manufactured by AMF Cuno), which in our experience can be readily reused 15 or more times. 5) The two identical sets of 8–12 filters (one filter per enzyme in the case of a 33-DNA study) are hybridized in plastic buckets using the BLOTTO (nonfat dry milk) hybridization buffer of Johnson et al. (1984). Hybridization probes consist of cloned fragments of an appropriate chloroplast genome (see above). Using two probes at a time, and taking a week for each cycle of hybridization and autoradiographic exposure, we require about two to three months to perform the entire set of hybridizations once all the gels have been run and blotted (each hybridization cycle requires only about two person-days of work per week).

The most time-consuming and difficult part of such studies, particularly those in which levels of divergence are on average greater than 1%, can be the interpretation in terms of individual mutations of the fragment pattern differences revealed by the autoradiographs. We recommend the construction of complete restriction site maps for each enzyme for one of the taxa under study. This comprehensive mapping is aided by including on each enzyme gel a double digest of the reference DNA with the enzyme specific to that gel and an enzyme used in common in all the double digests. The double digest hybridizations allow one to place the single enzyme maps in register with one another and thereby to construct a single unified restriction map. Mutations relative to this basic map can then be recognized by comparing the patterns across the autoradiographs and then identifying and localizing on the map fragment changes consistent with the loss/gain of specific cleavage sites (i.e., the presence in one taxon of two adjacent fragments which are replaced in a second taxon by a single fragment equal in size to the two missing ones). Restriction site mutations are studied by grouping the X-ray films by enzyme and "walking" along the chloroplast chromosome from cloned hybridization probe to adjacent probe fragment. Resorting the films according to probe fragment facilitates detection and confirmation of length mutations, as well as the resolution of most ambiguities noted in the first level of analysis.

The phylogenetic analysis of restriction site mutations is easily accomplished within the framework of parsimony-based cladistic analysis. Each site can be treated as a single two-state character, whose polarity can be assessed by outgroup comparisons (Watrous & Wheeler, 1981). Algorithms based on both Wagner parsimony (PAUP, developed by D. Swofford) and Dollo parsimony (PHYLIP, developed by J. Felsenstein) can be employed to analyze cpDNA data. Wagner parsimony gives equal weight to parallel gains and losses, whereas Dollo parsimony prohibits the former class of events. The justification for the use of Dollo parsimony is that parallel site losses are in fact much more probable than parallel site gains (DeBry & Slade, 1985). The bootstrap algorithm of Felsenstein (1985) is useful for evaluating the statistical significance of the monophyletic groups defined by parsimony analysis. The application of parsimony and bootstrap programs to large sets of cpDNA site mutations is best exemplified by the studies of Sytsma & Gottlieb (1986a) and Jansen & Palmer (1988).

DNA SEQUENCING

DNA sequence analysis allows one to compare bases individually and results in much lower levels of homoplasy than site mapping, where changes at any of six positions can cause a site loss. By sequencing a gene, one effectively avoids the problem of length mutations and also gains resolution at greater phylogenetic distance, since many genes are more conserved than the genome as a whole. The trade-off relative to restriction site mapping is that sequencing is currently a significantly slower and more expensive way of gathering phylogenetic information. Therefore, sequencing is presently most appropriate at the family level and above, where restriction site mapping is plagued by excessive homoplasy and length mutation.

No major studies on chloroplast gene sequences and plant phylogeny have been published. However, one chloroplast gene (*rbc*L, encoding the large, catalytic subunit of ribulose-1,5-bisphosphate carboxylase) has, because of its fundamental importance in photosynthesis, been sequenced widely enough to demonstrate the phylogenetic utility of this approach. Members of each of the four angiosperm families for which multiple *rbc*L genes have been sequenced cluster as natural groups, while representatives of three subclasses of dicots group together at an appreciable molecular dis-

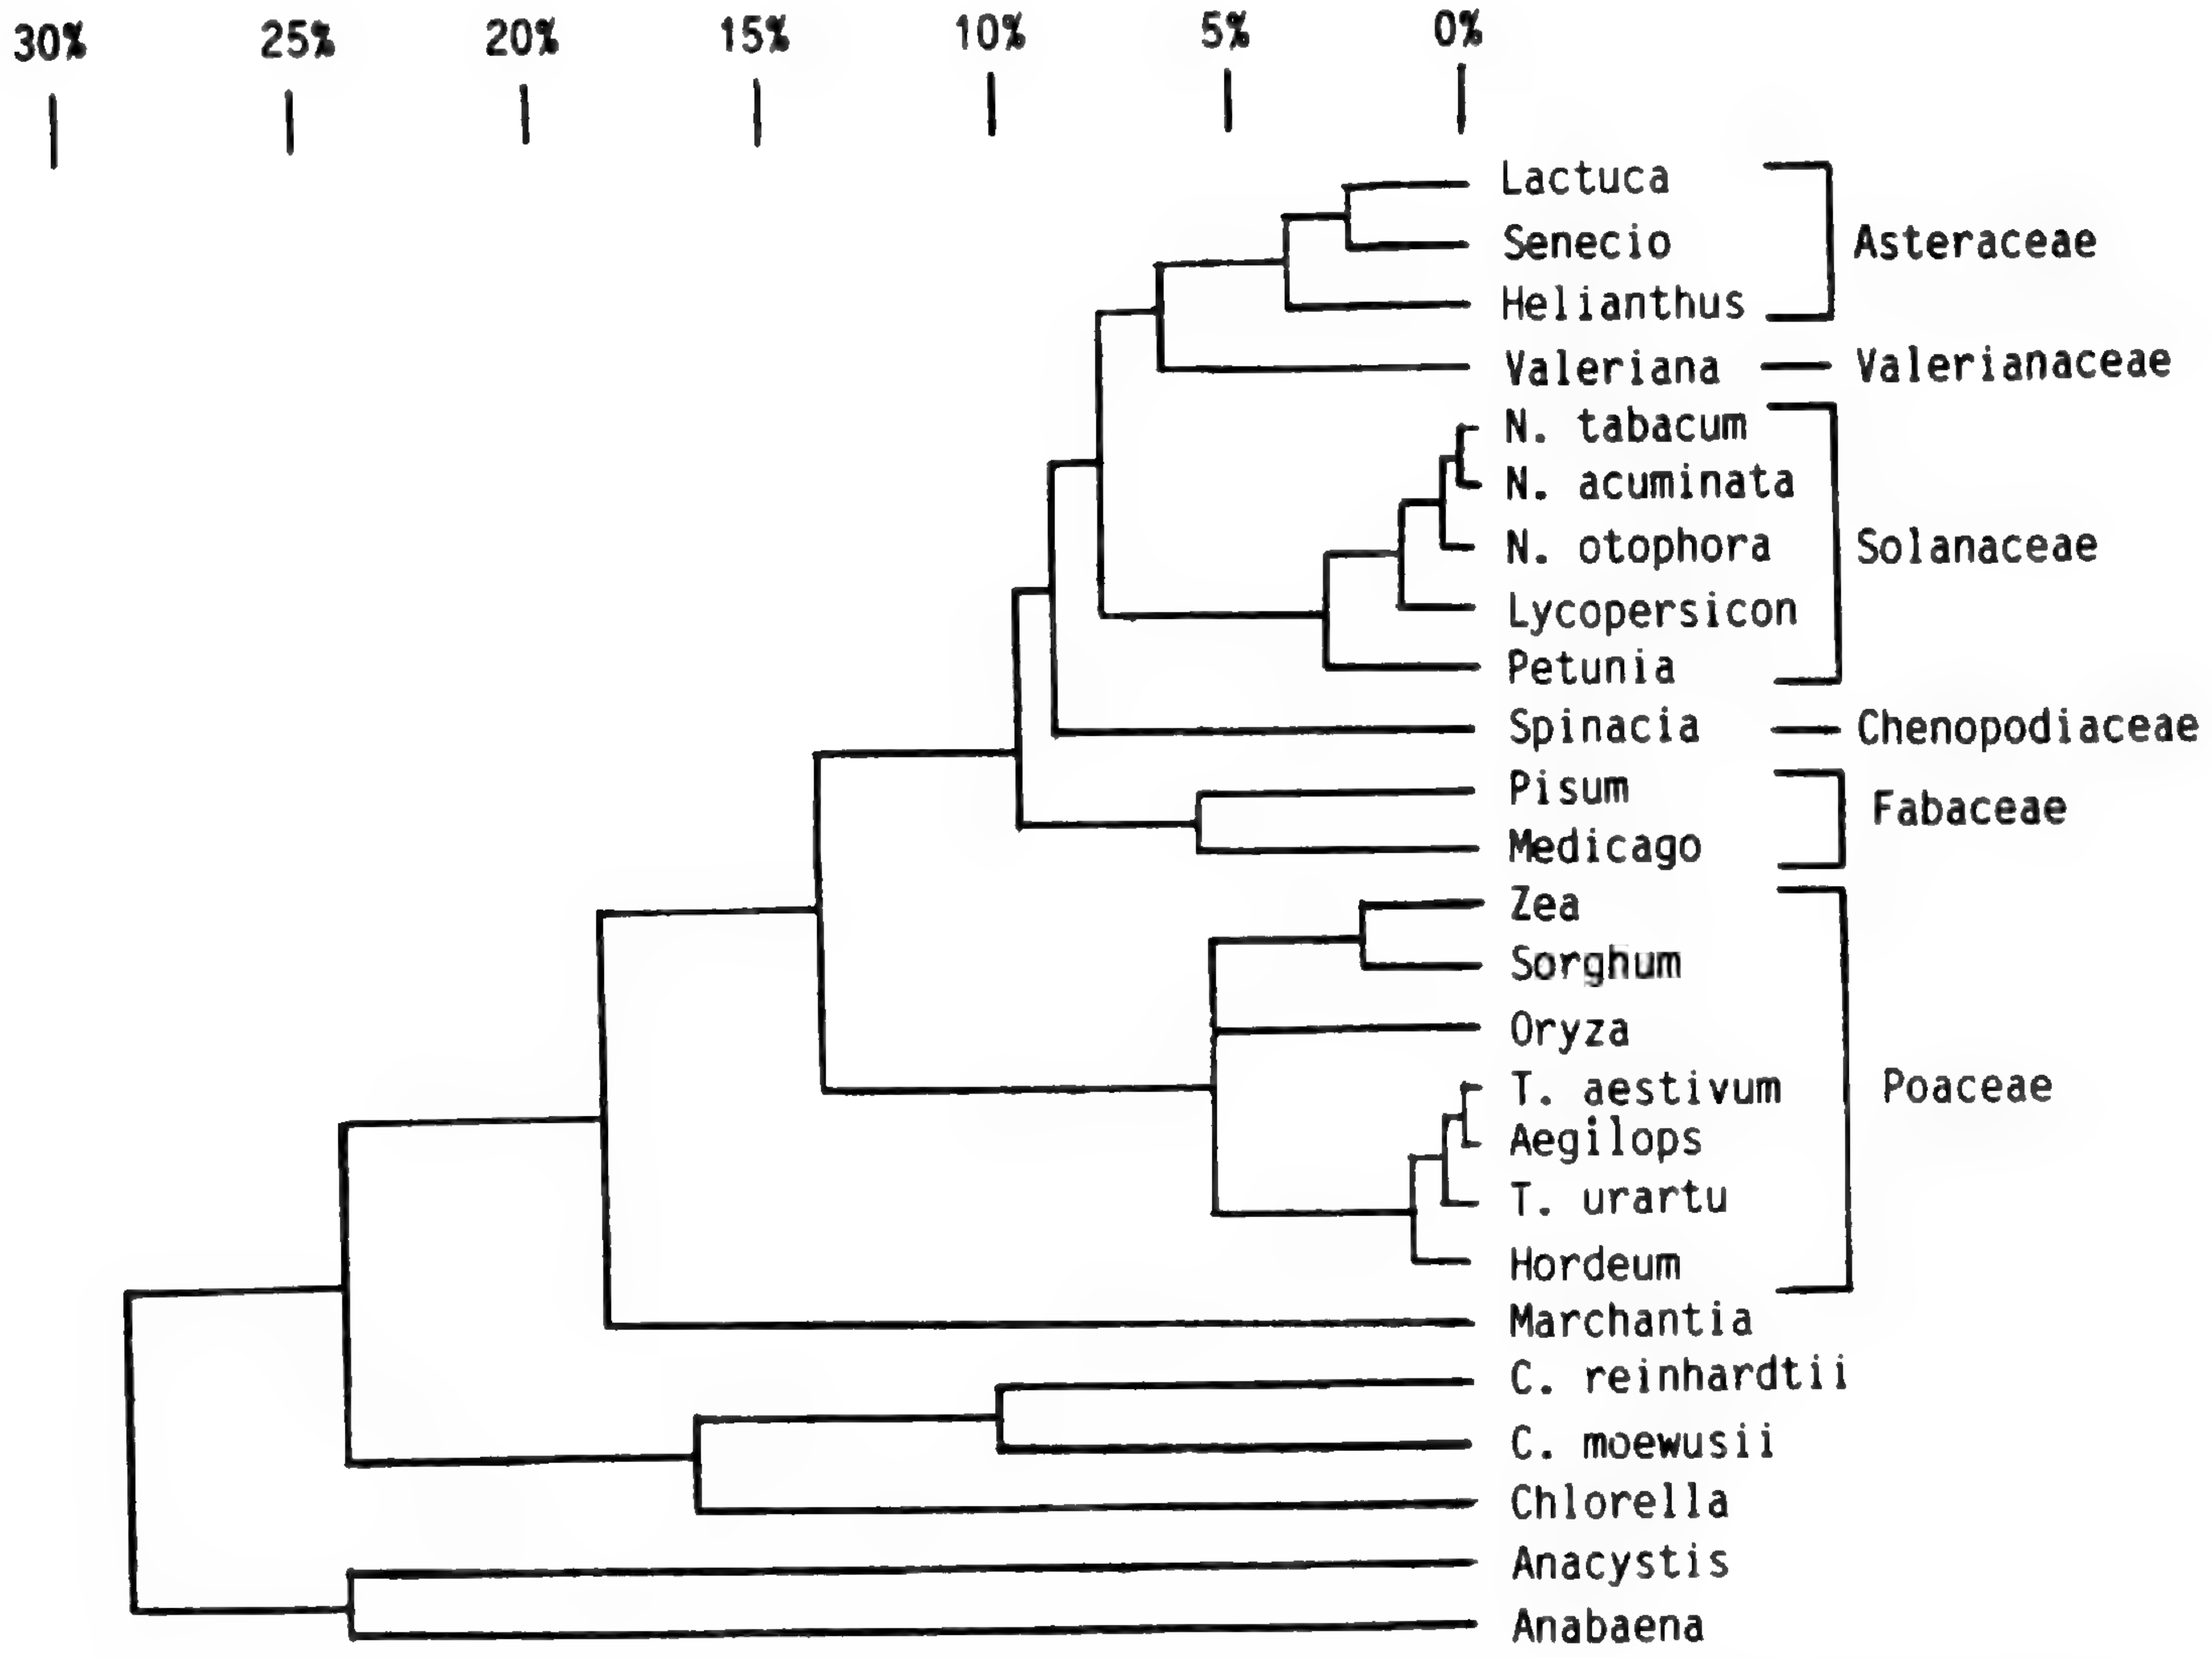

FIGURE 3. *Phenogram of* rbcL *sequence relationships. The diagram is based solely on the percent nucleotide sequence divergence (top scale) between* rbcL *genes of the indicated taxa. No corrections have been applied for multiple substitutions at a position. As yet, no phenetic or cladistic algorithms have been applied to this data set. References for eight of the sequences are given in Ritland & Clegg (1987); the others are* Nicotiana acuminata *and* N. otophora *(Lin et al., 1986)*, Lycopersicon *(W. Gruissem, pers. comm.)*; Petunia *and* Medicago *(Aldrich et al., 1986a, b)*; Lactuca, Senecio, Helianthus, *and* Valeriana *(H. Michaels, R. Jansen & J. Palmer, unpublished data)*; Oryza *(Nishizawa & Hirai, 1987)*; Sorghum *(J. Doebley pers. comm.)*; Aegilops *(Terachi et al., 1987)*; Triticum aestivum *and* T. urartu *(T. Dyer, unpublished data)*; Marchantia *(Ohyama et al., 1986)*; Chlamydomonas moewusii *(Yang et al., 1986); and* Chlorella *(Yoshinaga et al., 1988)*.

tance from the grasses (Fig. 3). A liverwort, three green algae, and two cyanobacteria appear as successive outliers to the angiosperms. With certain minor exceptions, discussed below in "Familial Relationships," all of the relationships expressed in Figure 3 are consistent with widely accepted concepts of plant phylogeny. Such correspondence is encouraging relative to the problematic early history of protein sequencing and plant phylogeny (see introductory paragraphs).

For a variety of reasons, we feel that *rbc*L is the chloroplast gene of choice for examining phylogenetic relationships within vascular plants: 1) The *rbc*L gene is by far the most widely sequenced chloroplast gene. This provides not only a reservoir of data that can be compared with data from future studies but also confidence that the gene is a reliable one for phylogenetic purposes (Fig. 3). 2) A number of plant molecular systematists have started to or are planning on using *rbc*L (we are sequencing *rbc*L in the Asteridae and other subclasses of dicots; M. Clegg, D. Giannasi, D. Soltis, and P. Soltis are conducting a broad survey of *rbc*L in several subclasses of angiosperms; M. Chase in Rosidae and Liliidae; K. Sytsma in Myrtales; R. Jansen in Asteraceae; G. Furnier in gymnosperms). In a few years, accumulated *rbc*L data should permit the construction of a broad framework of phylogenetic relationships among angiosperms and gymnosperms. 3) The *rbc*L gene is large enough (1,431 bp; only eight of the 120 chloroplast genes are significantly larger) to provide a sufficient number of characters (i.e., base pairs) for phylogenetic studies. 4) Its rate of evolution appears appropriate for questions of angiosperm phylogeny, whereas other obvious candidates such as the 16S and 23S ribosomal RNA genes change too slowly (the 16S gene is only 4% divergent between monocots and dicots, compared with 3–6% *rbc*L divergence within each of three angiosperm families in Fig. 3).

Our current *rbc*L sequence studies rely on three technical factors to enable collection of large amounts of sequence data in a rapid and efficient manner. First, rather than screen large shotgun clone banks of total cellular DNA or total cpDNA for *rbc*L-containing clones, we isolate directly a *rbc*L-containing fragment (first identifying it by blot hybridization) from a cpDNA digest separated in a low-melting-temperature agarose gel and then ligate the fragment directly in the melted agarose to a suitable cloning vector. In the case of most taxa examined in the Asteridae and Rosidae, digestion with EcoRI, BamHI, SacI, XhoI, or various double-digest combinations of these enzymes produces a conveniently sized fragment (1.5–5 kb) containing the entire *rbc*L gene. The use of purified cpDNA considerably simplifies this cloning step as compared with total DNA. The second savings results from our use of the plasmid-phage cloning vector BLUESCRIPT M-13 (Strategene Inc.). This allows us to clone the gel-isolated *rbc*L-containing fragment in a double-stranded form and then obtain single-stranded DNA for dideoxy chain termination sequencing without the need for recloning into a single-stranded phage vector. Third, we use synthetic oligonucleotides (20–25 bases in length) complementary to conserved regions of *rbc*L as primers in dideoxy sequencing reactions. These primers were synthesized by G. Zurawski, who generously has made them widely available to molecular systematists. By using synthetic primers of this nature, we avoid perhaps the most time-consuming aspect of sequencing, i.e., preparing multiple subclones from each primary clone.

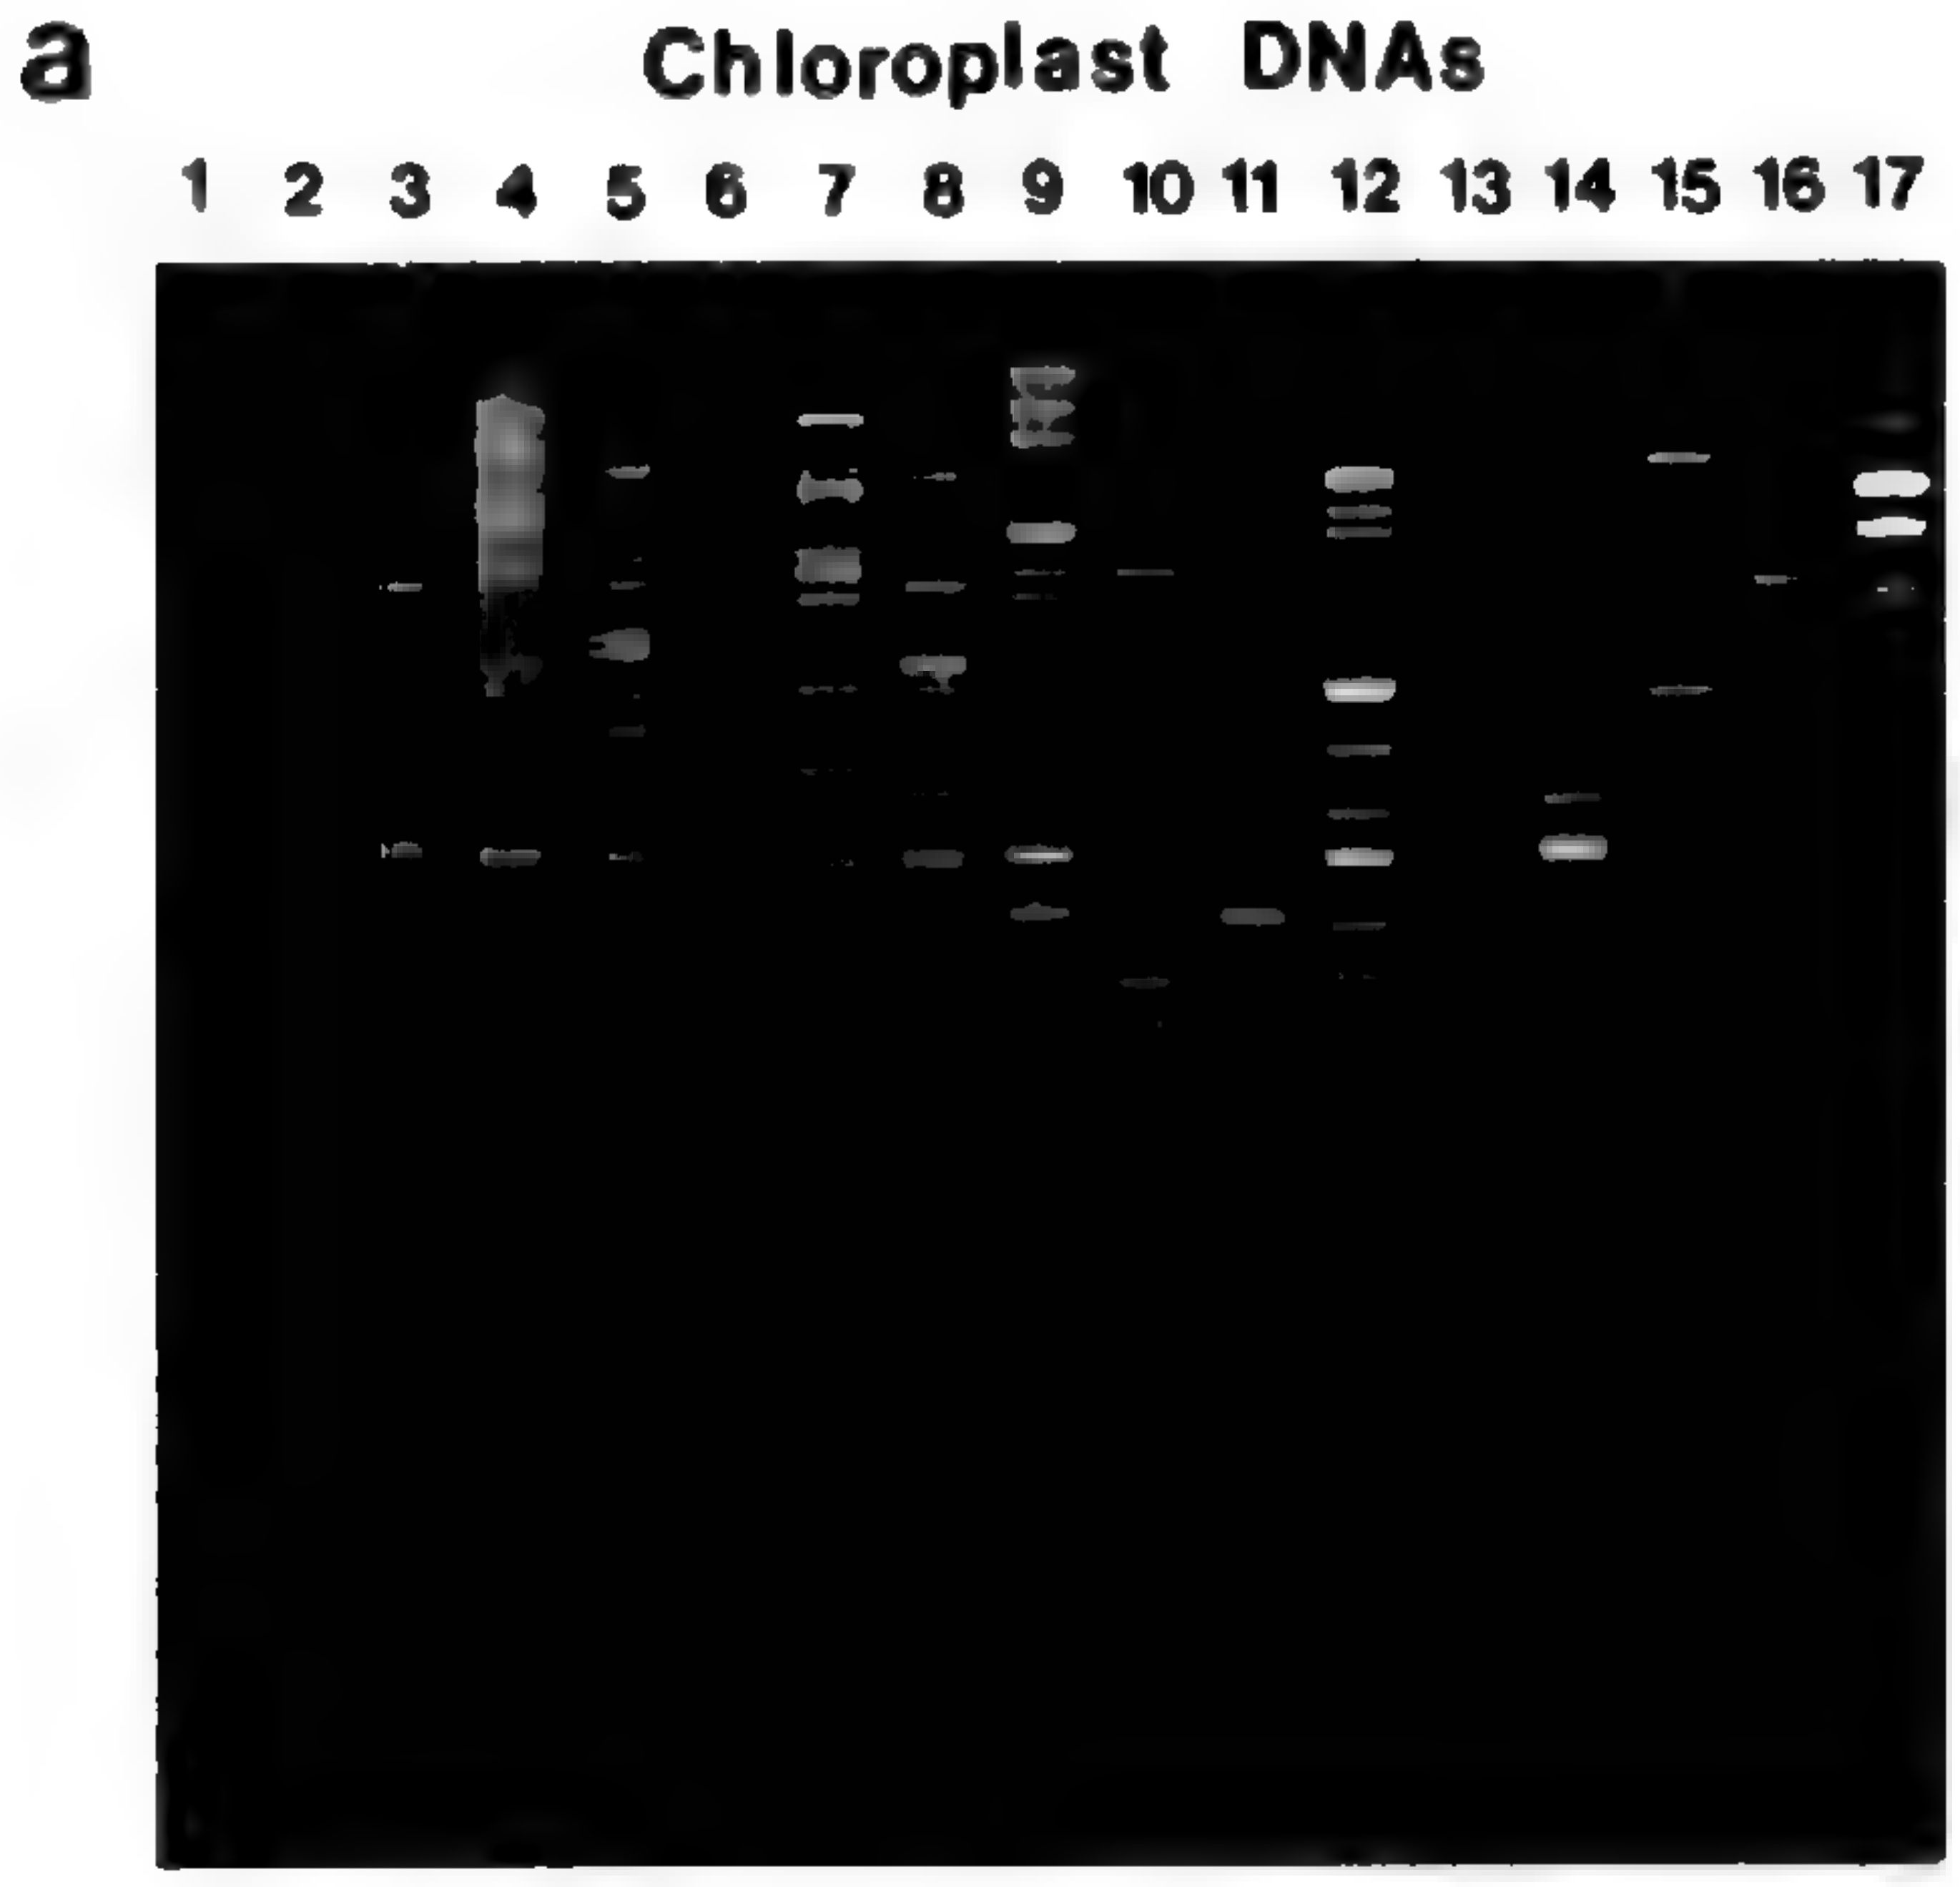
The technology for DNA sequencing is rapidly advancing at present. Significant future savings in time should derive from the use of 1) double-stranded dideoxy sequencing protocols (Korneluk et al., 1985; Zhang et al., 1988); 2) optimized sequencing reactions permitting sequence reading up to 1 kb from a priming site (Johnston-Dow et al., 1987); 3) the polymerase chain reaction to amplify a DNA fragment many thousands of times in vitro, which either facilitates the cloning step or obviates it altogether (Erlich et al., 1988; Oste, 1988); and 4) automated DNA sequencing machines (Connell et al., 1987; Prober et al., 1987).

Once obtained, DNA sequence data are aligned and compared using standard DNA sequence analysis software programs, a large number of which are now commercially available. Cladistic analysis of the sequence data (each nucleotide position is treated as a single four-state character) can be performed using the same parsimony programs and statistical tests as described for restriction site data. In addition, maximum likelihood programs have been developed specifically for nucleotide sequence data (Felsenstein, 1981, 1983), and Nei (1987) reviewed a number of tree-building algorithms that use sequence data.

REARRANGEMENT ANALYSIS

A second class of DNA mutations useful for phylogenetic inference is major rearrangements (the first class being the base substitutions detected by sequencing and site mapping). Major rearrangements are defined here as inversions and deletions/insertions of introns, of the coding region of genes, and of one segment of the large inverted repeat characteristic of most chloroplast genomes. The analysis of major cpDNA rearrangements is in several ways a complementary approach to comparative sequencing for studying higher levels of plant phylogeny. An advantage of sequencing is that large numbers of characters (1,431 in the case of *rbc*L) can be surveyed with reasonably predictable expectations as to the number of differences that will be found (Fig. 3). Many fewer DNA rearrangements can be expected and a preliminary survey is needed to find them. However, once found, they are often easy to survey widely (Fig. 4). The extreme rarity and lack of homoplasy of major rearrangements (Fig. 5) makes each one a signal character in a way that nucleotide substitutions, which inevitably will be afflicted with certain levels of homoplasy, can never be. Each rearrangement is therefore a much more powerful character, one that in our opinion should be weighted much more heavily than a single nucleotide substitution or restriction site mutation. Large amounts of sequence data may not suffice to resolve relatively ancient and compressed evolutionary radiations, whereas each rearrangement generally resolves with confidence a particular branching point in a phylogeny.

The existence of inversions and deletions of the cpDNA inverted repeat has been known for several years (Palmer, 1985c; Palmer et al., 1987). However, it is only with the recent acquisition of the complete sequences of the chloroplast genomes of the angiosperm *Nicotiana tabacum* (Shinozaki et al., 1986) and the liverwort *Marchantia polymorpha* (Ohyama et al., 1986) that it became possible to uncover and exploit significant numbers of the two other major classes of rearrangements,



Lane Number	Species	Family	Subclass
1	Zea mays	Poaceae	Commelinidae
2	Narcissus tazetta	Amaryllidaceae	Liliidae
3	Aristolochia durior	Aristolochiaceae	Magnoliidae
4	Delphinium grandiflorum	Ranunculaceae	Magnoliidae
5	Eschscholtzia californica	Papaveraceae	Magnoliidae
6	Pilea microphylla	Urticaceae	Hamamelidae
7	Spinacia oleracea	Chenopodiaceae	Caryophyllidae
8	Rumex obtusifolius	Polygonaceae	Caryophyllidae

namely gene and intron losses/gains. All four of these rearrangement classes are usually detected by Southern hybridization experiments using defined segments of chloroplast genes as probes. In some cases, follow-up DNA sequencing analysis may be called for if the results of the hybridization experiments are ambiguous.

As illustrated in Figure 4, gene and intron losses/gains are easily detected by a simple presence/absence test. For example, a cloned fragment internal to the intron of the gene *rpl*2 hybridizes to all angiosperm cpDNAs tested except to that of spinach (Fig. 4d). This result and similar hybridizations to other cpDNAs have led to the conclusion that this intron was lost in the common ancestor of the order Caryophyllales (J. Palmer & G. Zurawski, unpublished data). Similarly, hybridization studies reveal that the gene *rpo*A is absent from the chloroplast genome of *Pelargonium* × *hortorum* (Fig. 4d) and all other species of *Pelargonium* (P. Calie & J. Palmer, unpublished data), while the *rpl*22 gene is absent from the chloroplast genomes of all legumes (Fig. 4e; J. Palmer, B. Milligan, J. Doyle, unpublished data). It should be noted that all three of these intron/gene absences have been confirmed by sequencing the region of the suspected absence in at least one of the relevant taxa (Zurawski et al., 1984; B. Milligan, P. Calie, J. Palmer, unpublished data). The "gene losses" should, in the larger biological context, be viewed as "gene transfers," since genes that are missing from the chloroplast genome appear to have been transferred to the nucleus (S. Baldauf, S. Gantt, J. Palmer, unpublished data).

The detection of inversions and inverted repeat loss/gains is somewhat more complicated than for gene or intron loss/gains. Inversions can be diagnosed in two ways. Two nearby fragments in an uninverted genome that have become separated by virtue of inversion will consistently hybridize to different fragments in the inverted genome. Conversely, two fragments that are widely separated in a genome lacking an inversion will each hybridize to the same two fragments in a genome containing a derived inversion, indicating a new linkage relationship (e.g., see figs. 2 and 3 of Jansen & Palmer, 1987a). The presence or absence of the large inverted repeat shown in Figure 1 is diagnosed as follows (Palmer et al., 1987; Lavin et al., 1988). In digests produced by enzymes that cut rarely (10–20 times per genome), short, single copy fragments flanking a deleted repeat will normally hybridize to different fragments in genomes retaining the repeat, but to the same fragment in genomes lacking the repeat. Also, with most rarely cutting enzymes, short fragments near the end of the repeat will hybridize to two fragments in genomes retaining the repeat, but to only one fragment in those lacking it.

In a typical survey for rearrangements, we digest each cpDNA with four enzymes only (compared with the 10–20 used for restriction site studies), each cutting on the order of 40–100 times. This provides resolution sufficient to detect small inversions without unduly increasing the size of the study. In contrast to restriction site studies, where it is most useful to arrange all the digests for a given enzyme on a single gel or set of gels, all four digests for a given DNA are placed together on the same gel. This facilitates rapid diagnosis of rearrangements. Eight DNAs can be analyzed conveniently on a single gel with 35 lanes, including three for size markers. Double-sided blotting (Smith & Summers, 1980) allows one to make two filter replicas for each gel, which then can be probed sequentially over a period of weeks, months, and even years.

For hybridization probes, we use small cloned fragments 0.2–3.0 kb in size that we have prepared from several angiosperm chloroplast genomes (Jansen & Palmer, 1987a). These clones are available upon request of J. Palmer for use in molecular systematic studies. In addition, we currently are making probes specific for many of the genes from the completely sequenced tobacco chloroplast genome (Shinozaki et al., 1986), using a starting set of large cloned fragments provided by M. Sugiura (Sugiura et al., 1986). Smaller probes (0.2–1.0 kb) are most useful as internal, gene- and intron-specific markers to detect gene and intron losses. These smaller probes, plus somewhat larger ones (1–3 kb) containing spacer and tRNA genes, are useful to detect inversions because many cpDNA inversions have their endpoints in tRNA-spacer-rich regions of the genome (Palmer, 1985c; Jansen & Palmer, 1987a).

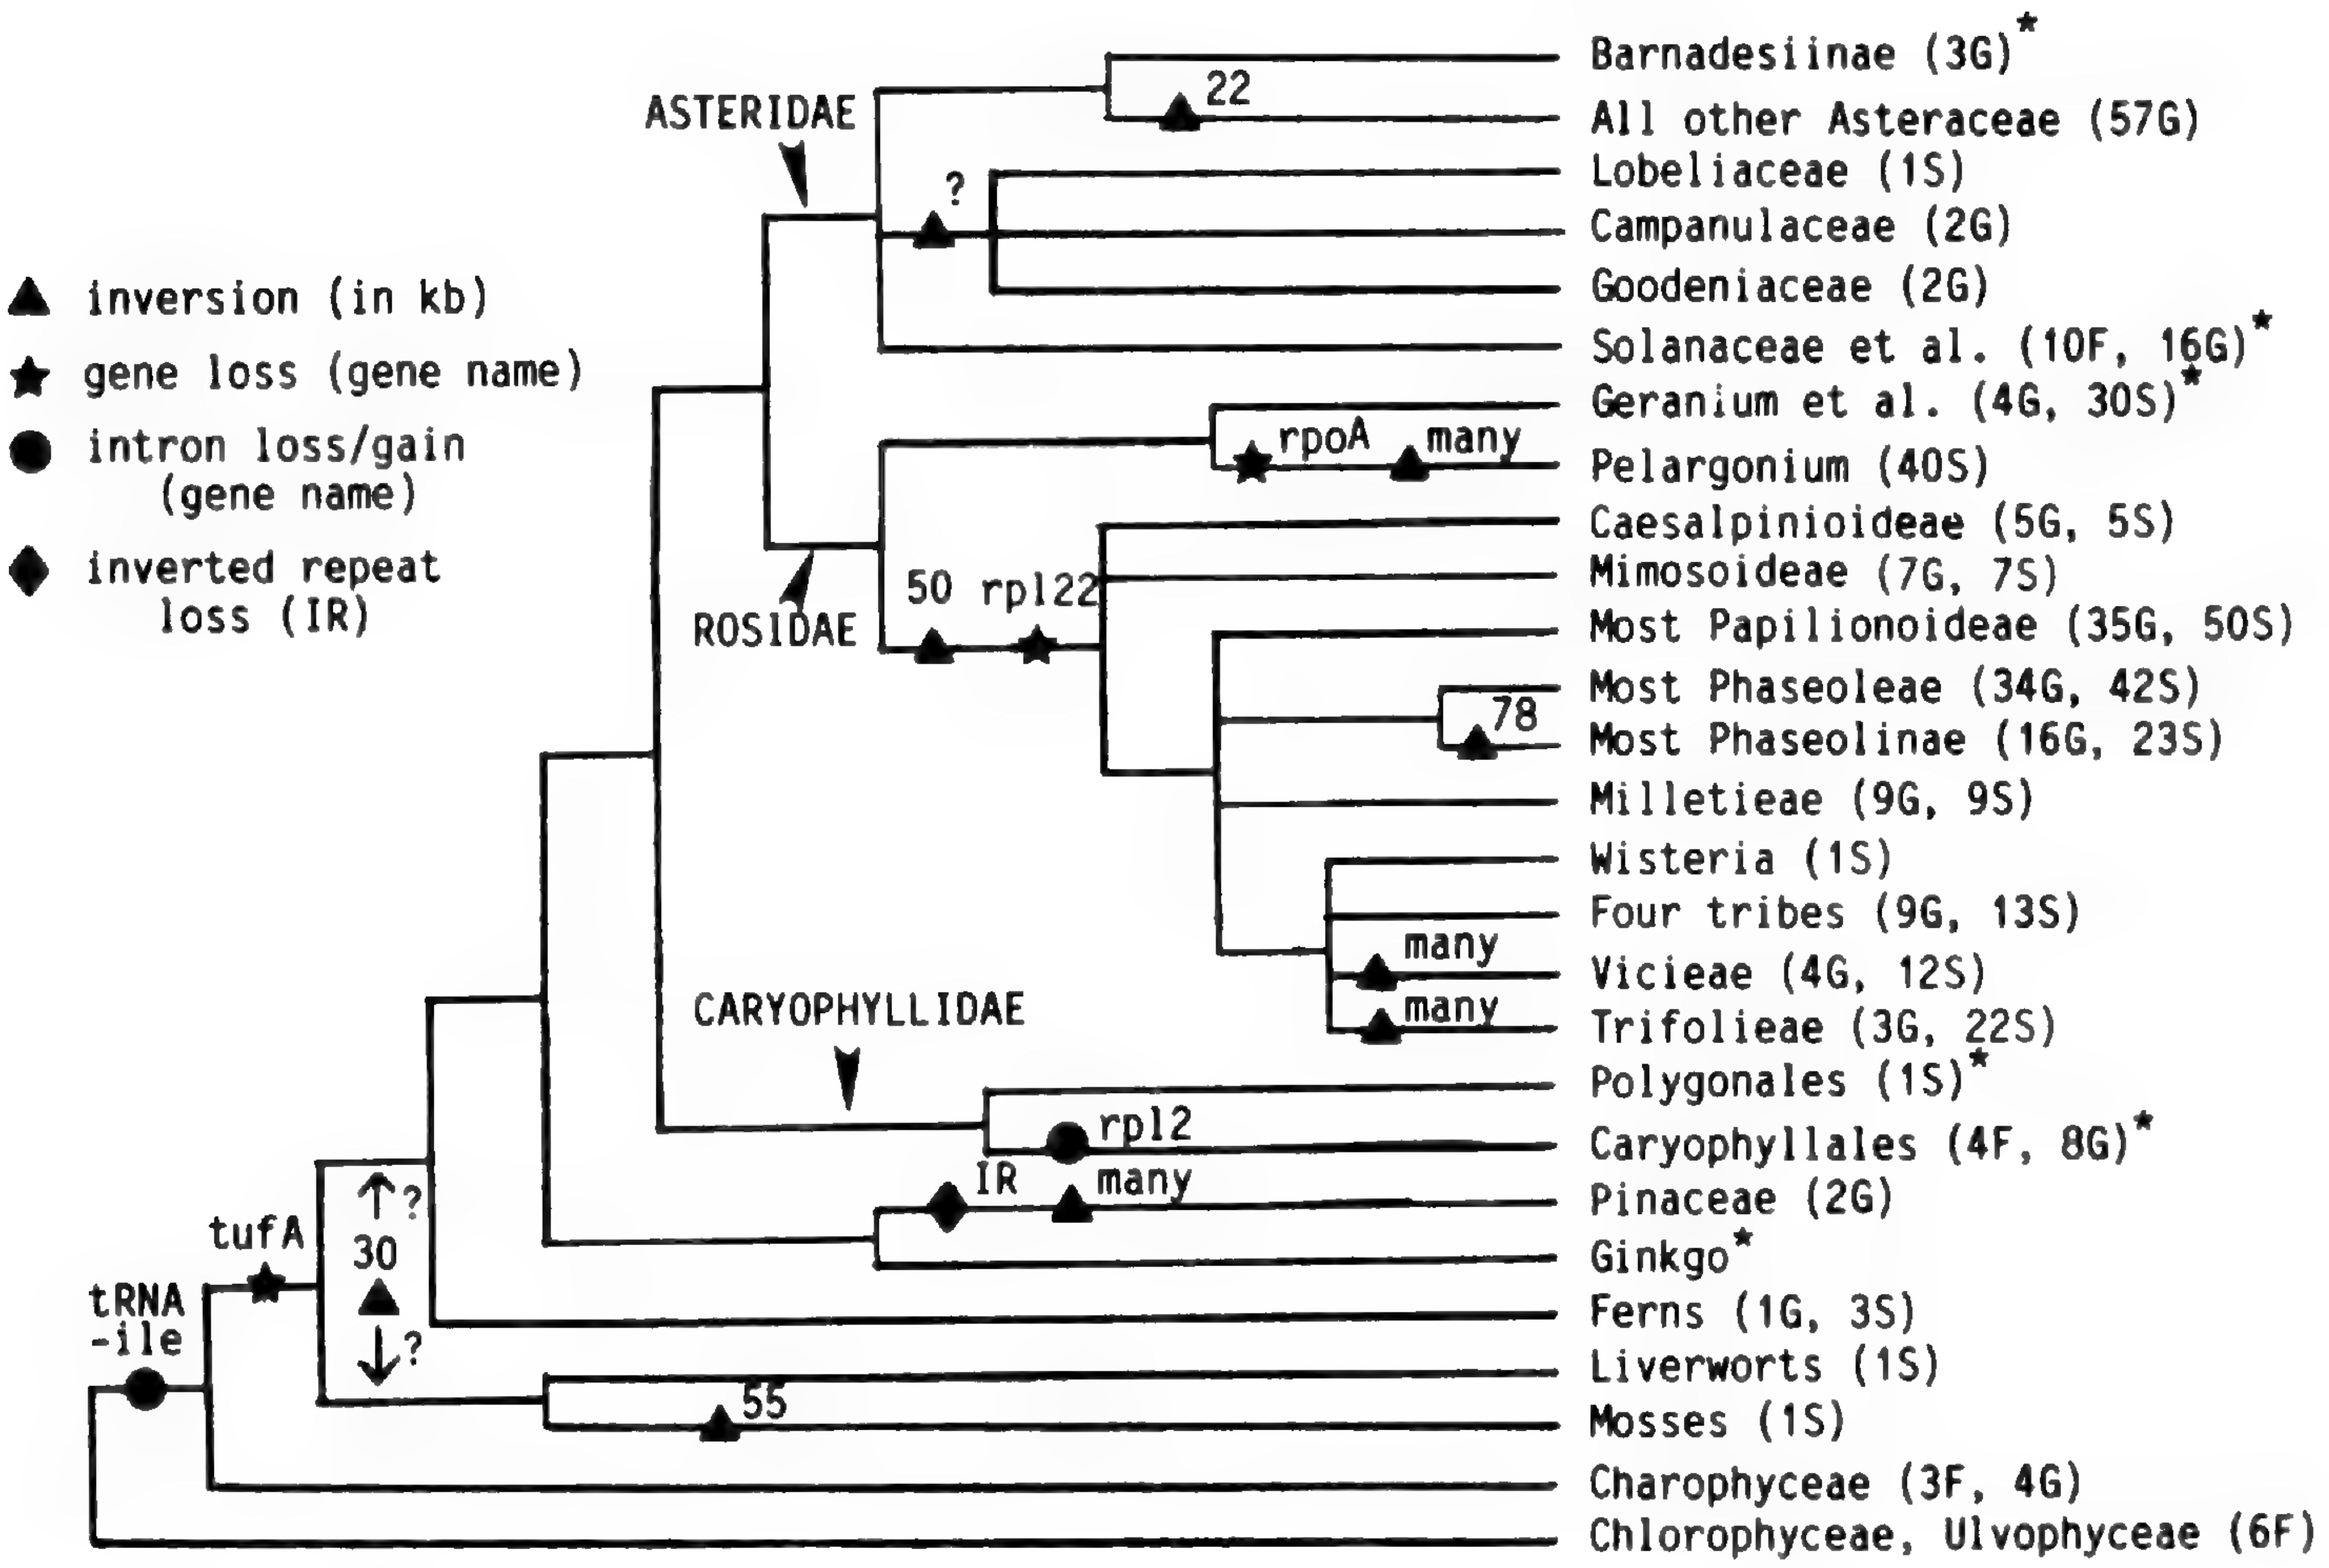

FIGURE 5. *Evolutionary tree based on the distribution of selected cpDNA rearrangements. Not all known rearrangements are shown (see text and Palmer, 1985c, 1987, for more complete listing and for references). Asterisks denote genomes with the consensus vascular plant gene order. Numbers in parentheses indicate numbers of taxa examined (F = family; G = genus; S = species). Question marks denote rearrangements of uncertain nature and/or phylogenetic distribution and direction. Four charophytes have been examined for the* tufA *gene loss, but only one for the tRNA-ile intron gain.*

APPLICATIONS OF CHLOROPLAST DNA DATA TO SYSTEMATIC QUESTIONS

Most cpDNA comparisons have been made within and between congeneric species using the approach of restriction site analysis. The utility of this approach at these levels has already been well documented in a number of papers and reviews (for reviews, see Palmer, 1985a, 1986a, 1987; Giannasi & Crawford, 1986, in press). Consequently, the following discussion will emphasize recent developments and results obtained in studies at higher taxonomic levels.

INTRASPECIFIC RELATIONSHIPS

The ultimate utility of cpDNA as a marker within and among populations of a species remains unclear. Relatively little cpDNA differentiation was obtained in the two most extensive intraspecific studies (of 371 individuals and 147 populations of two pine species (Wagner et al., 1987) and 100 individuals and 21 populations of *Lupinus texensis* (Banks & Birky, 1985)). In a number of more limited studies (reviewed in Palmer, 1987; Giannasi & Crawford, in press), multiple populations from the same species often had indistinguishable cpDNAs. However, when found, intraspecific differences have been quite informative, particularly regarding the origins of several crop plants (Palmer et al., 1983; Clegg et al., 1984; Palmer et al., 1985; Doebley et al., 1987). A recent study demonstrated extensive intraspecific variation within *Heuchera micranthra* sufficient to document multiple origins of autopolyploidy (Soltis et al., in press). In this case, cpDNA variation actually provided greater resolution at the populational level than nuclear isozyme markers.

It is not surprising that intraspecific variation in cpDNA is often limited, given the overall conservatism of the chloroplast molecule (Palmer, 1985b, c; Zurawski & Clegg, 1987). By pushing the molecular approaches to their extreme in terms of the number of nucleotides sampled, it may be possible to address many microevolutionary questions using cpDNA. By using more enzymes, especially ones that cut frequently, the sample size could readily have been increased by a factor of ten or more in many of the studies in which little or no variation was found. It is unlikely, however, that the cpDNA molecule will ever be as useful for populational studies as the rapidly evolving mitochondrial genome of animals (Avise et al., 1987; Moritz et al., 1987), although the *Heuchera* case (Soltis et al., in press) begins to approach the animal mitochondrial situation.

INTERSPECIFIC RELATIONSHIPS

Over 40 studies have now been published in which cpDNA restriction site variation has been used to assess phylogenetic relationships at the interspecific level (many of these are reviewed in Palmer, 1986a; Giannasi & Crawford, 1986, in press), and at least 30 laboratories are now engaged in such pursuits. The molecular phylogenies constructed using cpDNA data have been remarkably untroubled by homoplasy, which ranged from 0% in *Pisum* (Palmer et al., 1985) and *Lisianthius* (Sytsma & Schaal, 1985), to 2.5% in *Lycopersicon-Solanum* (Palmer & Zamir, 1982), 3.3% in *Zea* (Doebley et al., 1987), 3.8% in *Brassica* (Palmer et al., 1983), 4.8% in *Clarkia* sect. *Peripetasma* (Sytsma & Gottlieb, 1986a), and 4.9% in *Cucumis* (Perl-Treves & Galun, 1985). The overall level of homoplasy in these seven studies is 3.9%, i.e., only 12 convergences and parallelisms were necessary to account for the observed distribution of 299 variant cpDNA restriction sites.

To illustrate the kinds of insights cpDNA analysis can provide, we briefly review results obtained in the genus *Brassica*. This is an excellent group to examine in this context for a number of reasons. First, relationships within the genus have already been studied using a wide variety of morphological, genetical, and biochemical approaches (reviewed in Vaughan, 1977; Prakash & Hinata, 1980), and therefore an excellent opportunity exists to evaluate the merits of a cpDNA analysis. Second, *Brassica* features one of the classic cases of a polyploid, hybrid species complex, one that was already well understood at the nuclear level, but where additional, sometimes surprising, findings emerged from the cpDNA analysis. Finally, the *Brassica* work exemplifies the reproducibility of most molecular analyses. Two different groups independently studied cpDNA restriction site variation in *Brassica* (and coincidentally published their results in the same issue of the same journal) and reached largely similar conclusions (Erickson et al., 1983; Palmer et al., 1983).

Figure 6 is a cladogram based on the analysis of cpDNAs from eight species and 21 populations of *Brassica* and *Raphanus sativus* (Palmer et al., 1983). Six of the eight species (those whose genome designations are given in Fig. 6) comprise the three diploids and three tetraploids whose nuclear relationships were first expressed in the famous triangle diagram of U (1935). One unexpected finding is the placement of *Raphanus sativus* (radish) within one of the two major sections of *Brassica*. This placement was first made (Palmer et al., 1983) without the use of an outgroup by invoking the molecular clock assumption (Wilson et al., 1977), which now appears to not hold for cpDNA (see Fig. 8 and "Directions and Prospects") but has since been validated by outgroup comparison (J. Palmer, unpublished data). A similar contrast between molecular and morphological data, suggesting the need for reassessment of generic boundaries, has recently been made in the case of *Clarkia* and the monotypic genus *Heterogaura*. *Heterogaura heterandra* is clearly a derivative of *Clarkia* at the molecular level but features a very divergent morphology from all *Clarkia* species (Sytsma & Gottlieb, 1986b; also see papers in this volume by K. Sytsma & J. Smith and L. Gottlieb).

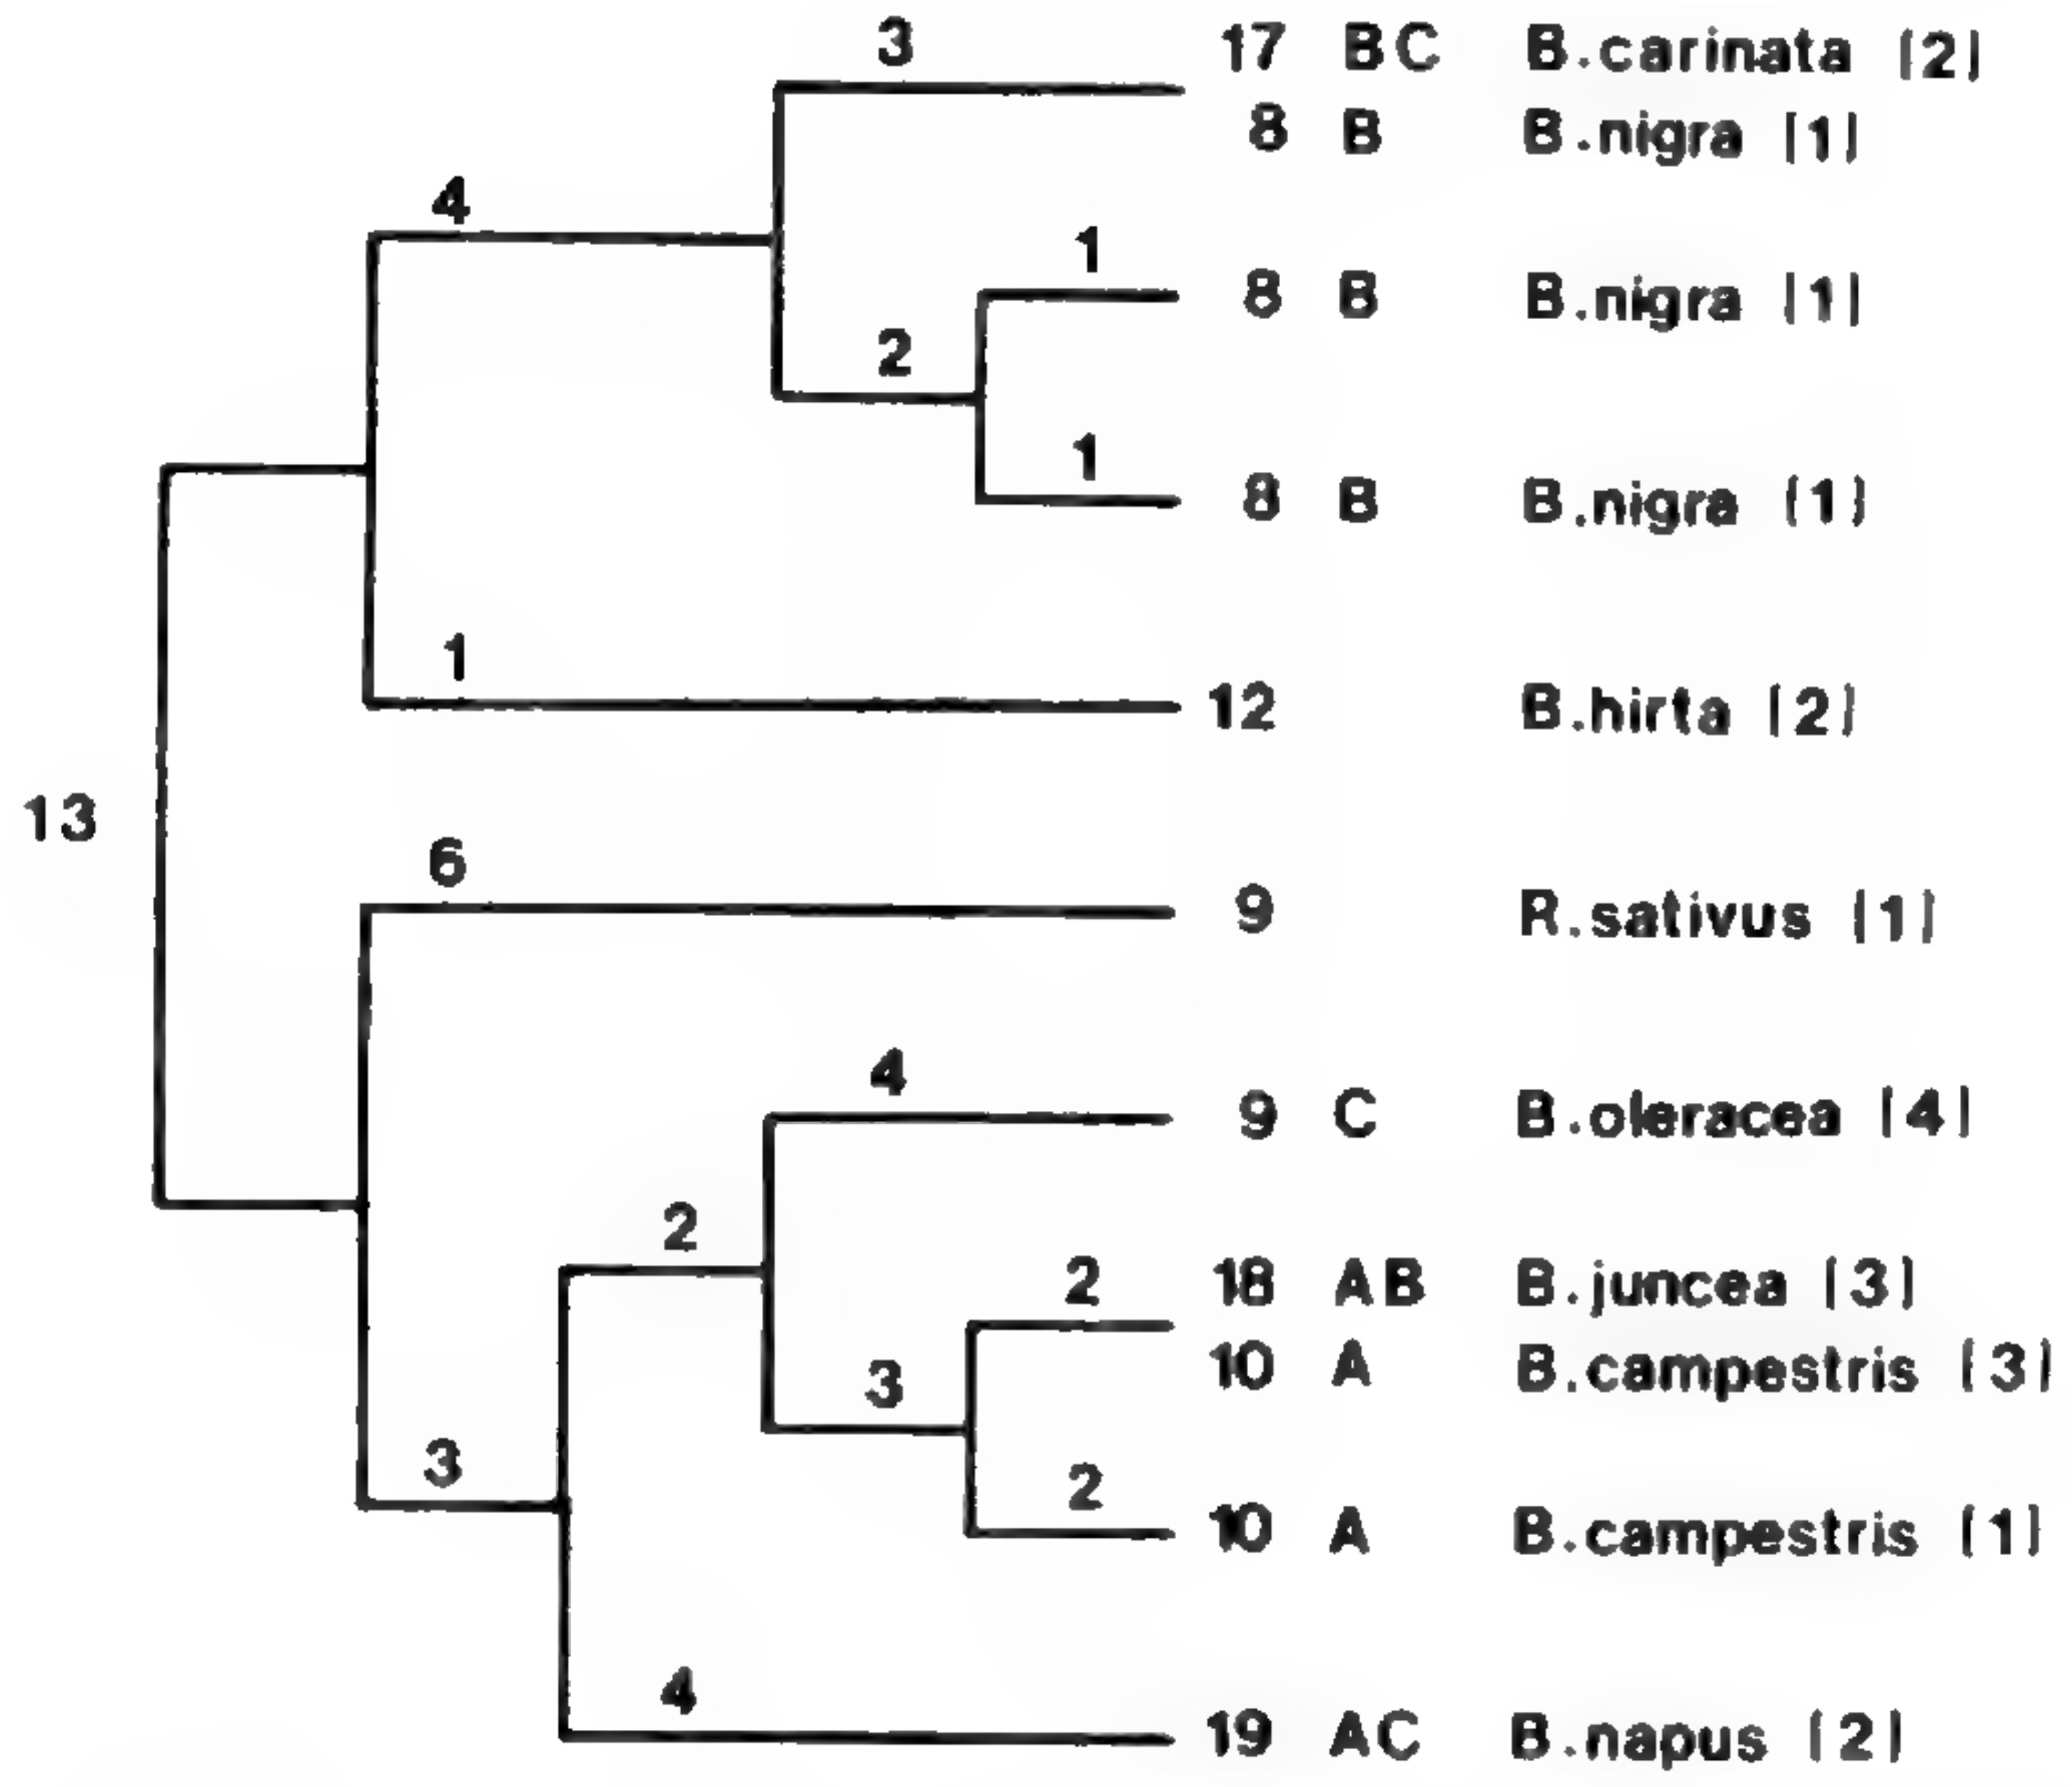

FIGURE 6. *Evolutionary tree of eight cultivated species of* Brassica *and* Raphanus *based on a parsimony analysis of cpDNA restriction site mutations. Numbers on branches indicate number of derived mutations. Numbers at termination of branches indicate nuclear chromosome number, followed by genome designation. Numbers in parentheses indicate number of accessions examined. Redrawn from Palmer et al. (1983).*

Both Erickson et al. (1983) and Palmer et al. (1983) obtained considerable insight into the origins of the amphidiploid species *B. carinata*, *B. juncea*, and *B. napus*. The cpDNAs of *B. carinata* and *B. juncea* were essentially identical to those of the diploids *B. nigra* and *B. campestris*, respectively (Fig. 6). Since cpDNA is maternally inherited in

Brassica (Erickson et al., 1983), one can conclude that these latter two species served as the maternal parents in the interspecific hybridizations that gave rise to the two amphidiploids. By subtraction, *B. oleracea* and *B. nigra* must have served as the paternal parents in these crosses. The cpDNA data permitted two quantitative conclusions regarding the timing of hybridization, although it should be kept in mind that these conclusions rest on an implicit assumption of rate constancy. *Brassica carinata* and *B. juncea* were judged to result from recent hybridization events since their cpDNAs were identical at all 3,000 base pairs compared with those of specific parental lines (Fig. 6; Palmer et al., 1983). However, these recent hybridizations must have taken place after a substantial period of separation and diversification of the parents, since the two pairs of parental cpDNAs were substantially diverged (29–30 mutations distinguish the *B. nigra* genome from those of *B. oleracea* and *B. campestris*; Fig. 6).

Surprisingly, the chloroplast genome of the third amphidiploid, *B. napus*, is less closely related to those of its uncontested nuclear parents, *B. campestris* and *B. oleracea*, than they are to each other (Fig. 6). To resolve this conflict between nuclear and cytoplasmic phylogenies, Palmer et al. (1983) hypothesized that *B. napus* gained its cytoplasm by introgression from some unidentified species. In contrast, in *Helianthus* concordant results obtained using both cpDNA and nuclear DNA do not support a morphologically based hypothesis of introgression (Rieseberg et al., 1988).

FAMILIAL RELATIONSHIPS

A great challenge to plant sytematists is to reconstruct phylogeny among genera and at higher levels, where relationships are in general much more poorly understood than among congeneric species. Although little has yet been published on higher level cpDNA systematics, results are encouraging from several studies in progress, and therefore we feel it important to discuss these in some detail. In addition, the reader should consult the article in this volume by Sytsma & Smith, which discusses their ongoing work on the Onagraceae (also see Sytsma & Gottlieb, 1986a, b).

Asteraceae. The Asteraceae make up one of the largest and most successful flowering plant families, consisting of 12–17 tribes, approximately 1,100 genera, and 20,000 species (Cronquist, 1981). A combination of specialized floral characters (capitula, reduced and modified floral parts, inferior ovaries, basal and erect ovules, and syngenesious anthers) support the monophyly of the family. Recent classifications (Thorne, 1983; Dahlgren, 1980; Takhtajan, 1980; Cronquist, 1981) emphasized the distinctness of the family by placing it in a monotypic order at the most advanced position in the Dicotyledonae. Although there is some controversy concerning the age of the family (Turner, 1977), fossil evidence (Cronquist, 1977; Muller, 1981) and biogeographical considerations (Raven & Axelrod, 1974) suggest that the Asteraceae originated in the middle to upper Oligocene (30 million years ago) and subsequently underwent rapid and extensive diversification.

During the past 30 years, six different schemes of phylogenetic relationships among the subfamilies and tribes have been proposed (Cronquist, 1955, 1977; Carlquist, 1976; Wagenitz, 1976; Jeffrey, 1978; Thorne, 1983; Bremer, 1987). Most of these recent classifications agree that two distinct subfamilies (Asteroideae and Cichorioideae) should be recognized; however, there is no consensus concerning the circumscription of the subfamilies, the number of monophyletic tribes, and the relationships among tribes. Two reasons account for the lack of agreement on intrafamilial relationships in the Asteraceae. First, previous studies have relied almost completely on morphological characters, which have undergone repeated parallel and convergent evolution. Second, only the most recent reassessment of relationships (Bremer, 1987) has applied cladistic approaches to phylogenetic reconstruction, and even that study is limited by high levels of homoplasy and a lack of statistical testing of alternative trees.

To provide new characters to aid in clarifying relationships in this complex family, we have analyzed cpDNA variation within the Asteraceae and putatively related families. We have completed studies using two approaches to the study of cpDNA evolution, the assessment of genome arrangement and comparative restriction site mapping, and recently initiated a comparative study of *rbc*L sequences.

Our studies have revealed two genome arrangements in the Asteraceae that differ by a single inversion (Jansen & Palmer, 1987a, b). Chloroplast DNAs from the subtribe Barnadesiinae (tribe Mutisieae) are colinear with those of most other land plants, including ten families putatively related to the Asteraceae. All other Asteraceae examined (57 genera from 16 tribes) share a derived 22-kb inversion. This rearrangement defines a basal evolutionary dichotomy within the family and has two important phylogenetic implications. First, the Mutisieae are paraphyletic, as previously hypothesized on the basis of morphological evidence (Small, 1918; Wodehouse, 1928; Cabrera, 1977; Bremer, 1987). Second, the Barnadesiinae represent the sister group to the rest of the family, which resolves one of the most controversial systematic issues within the Asteraceae. Five different tribes—Cardueae, Heliantheae, Mutisieae, Senecioneae, and Vernonieae—have previously been suggested as the most primitive lineage (Cronquist, 1955, 1977; Carlquist, 1976; Wagenitz, 1976; Jeffrey, 1977). The identification of the earliest lineage provides indirect support for previous hypotheses concerning the origin of the Asteraceae in the Andes of northern South America (Raven & Axelrod, 1974; Turner, 1977) and the primitive woody habit and bilabiate flowers of the ancestors of the family (Carlquist, 1976; Jeffrey, 1977).

Our restriction mapping study has been carried out in two stages. We first examined taxa primarily from the tribe Mutisieae (Jansen & Palmer, 1988) and then studied representatives of the entire family (R. Jansen, H. Michaels, J. Palmer, unpublished data). Initially, cpDNAs from 13 genera of the Mutisieae, one genus from each of three other tribes, and two genera from two outgroup families were analyzed with ten restriction enzymes. A total of 211 restriction site mutations were detected, 55 of which were phylogenetically informative. Wagner and Dollo parsimony trees constructed with these data were very similar; only the Wagner tree is discussed here. The Wagner parsimony analysis resulted in a single most parsimonious tree (Fig. 7, top) with 247 steps and 15% homoplasy. Four major phylogenetic relationships are depicted in this tree. The most significant is the initial dichotomy separating the subtribe Barnadesiinae (Mutisieae) from the rest of the Asteraceae, including the three other subtribes of the Mutisieae. This is the same dichotomy defined by the inversion described above. The robustness of this initial dichotomy has strong statistical support (98% confidence interval) by the bootstrap analysis of Felsenstein (1985). Furthermore, a recent cladistic analysis (Bremer, 1987) based primarily on morphological data, but also including the 22-kb cpDNA inversion (Jansen & Palmer, 1987b), placed the Barnadesiinae at a basal position within the Asteraceae. Also in accord with the inversion result, the restriction site data indicate the Mutisieae as paraphyletic, since three of the four subtribes are more closely related to the three other examined tribes of the Asteraceae than to subtribe Barnadesiinae. The molecular phylogeny (Fig. 7, top) also provides support for the monophyly of three of the four currently recognized subtribes of the Mutisieae (sensu Cabrera, 1977). Only the morphologically diverse and geographically widespread subtribe Gochnatiinae is shown to be paraphyletic, a conclusion also reached by Bremer (1987).

To clarify further relationships within the Mutisieae, a more extensive analysis was performed in which 12 of the 16 genera of Asteraceae examined above were analyzed using 19 restriction enzymes (Jansen & Palmer, 1988). A total of 390 restriction site mutations were detected, 117 of which were phylogenetically informative. Wagner and Dollo parsimony analyses again gave similar results. The Wagner analysis (Fig. 7, bottom) resulted in a single most parsimonious tree of 454 steps and 14% homoplasy. The tree provides further support for the relationships indicated by the ten-enzyme tree (Fig. 7, top). This is reflected in the higher confidence intervals for a number of monophyletic groups, including all taxa that share the cpDNA inversion, the three subtribes of the Mutisieae with the inversion, and the subtribes Mutisiinae and Nassauviinae. The 19-enzyme tree also indicates that subtribe Gochnatiinae is paraphyletic.

More detailed phylogenetic comparisons were performed using 11 enzymes and 57 genera of the Asteraceae, representing all currently recognized tribes. A total of 926 restriction site mutations were mapped, 328 of which were phylogenetically informative. Wagner parsimony analyses using the global swapping option of PAUP generated 12 equally parsimonious trees of 1,315 steps, all of which support the monophyly of the subfamily Asteroideae (sensu Thorne, 1983). Phylogenetic analyses of the data using the same options in PHYLIP gave six equally parsimonious trees of 1,316 steps, all of which support two monophyletic subfamilies (Asteroideae and Cichorioideae sensu Thorne, 1983). A bootstrap analysis (Felsenstein, 1985) produced a majority rule consensus tree (Fig. 8) with 1,318 steps and 30% homoplasy. Although this tree is three steps longer than the most parsimonious tree, it is presented here because it shows the groups that are best supported statistically.

The most significant implications of the cpDNA phylogeny for the Asteraceae (Fig. 8) concern the circumscription of tribes and subfamilies and phylogenetic relationships among tribes. There is strong support for the monophyly of the subfamily Asteroideae, which includes the eight tribes Tageteae, Heliantheae, Eupatorieae, Calenduleae, Senecioneae, Inuleae, Anthemideae, and Astereae. This group occurs in all most parsimonious trees generated by both PAUP and PHYLIP and has a confidence interval of 86%. The remaining tribes

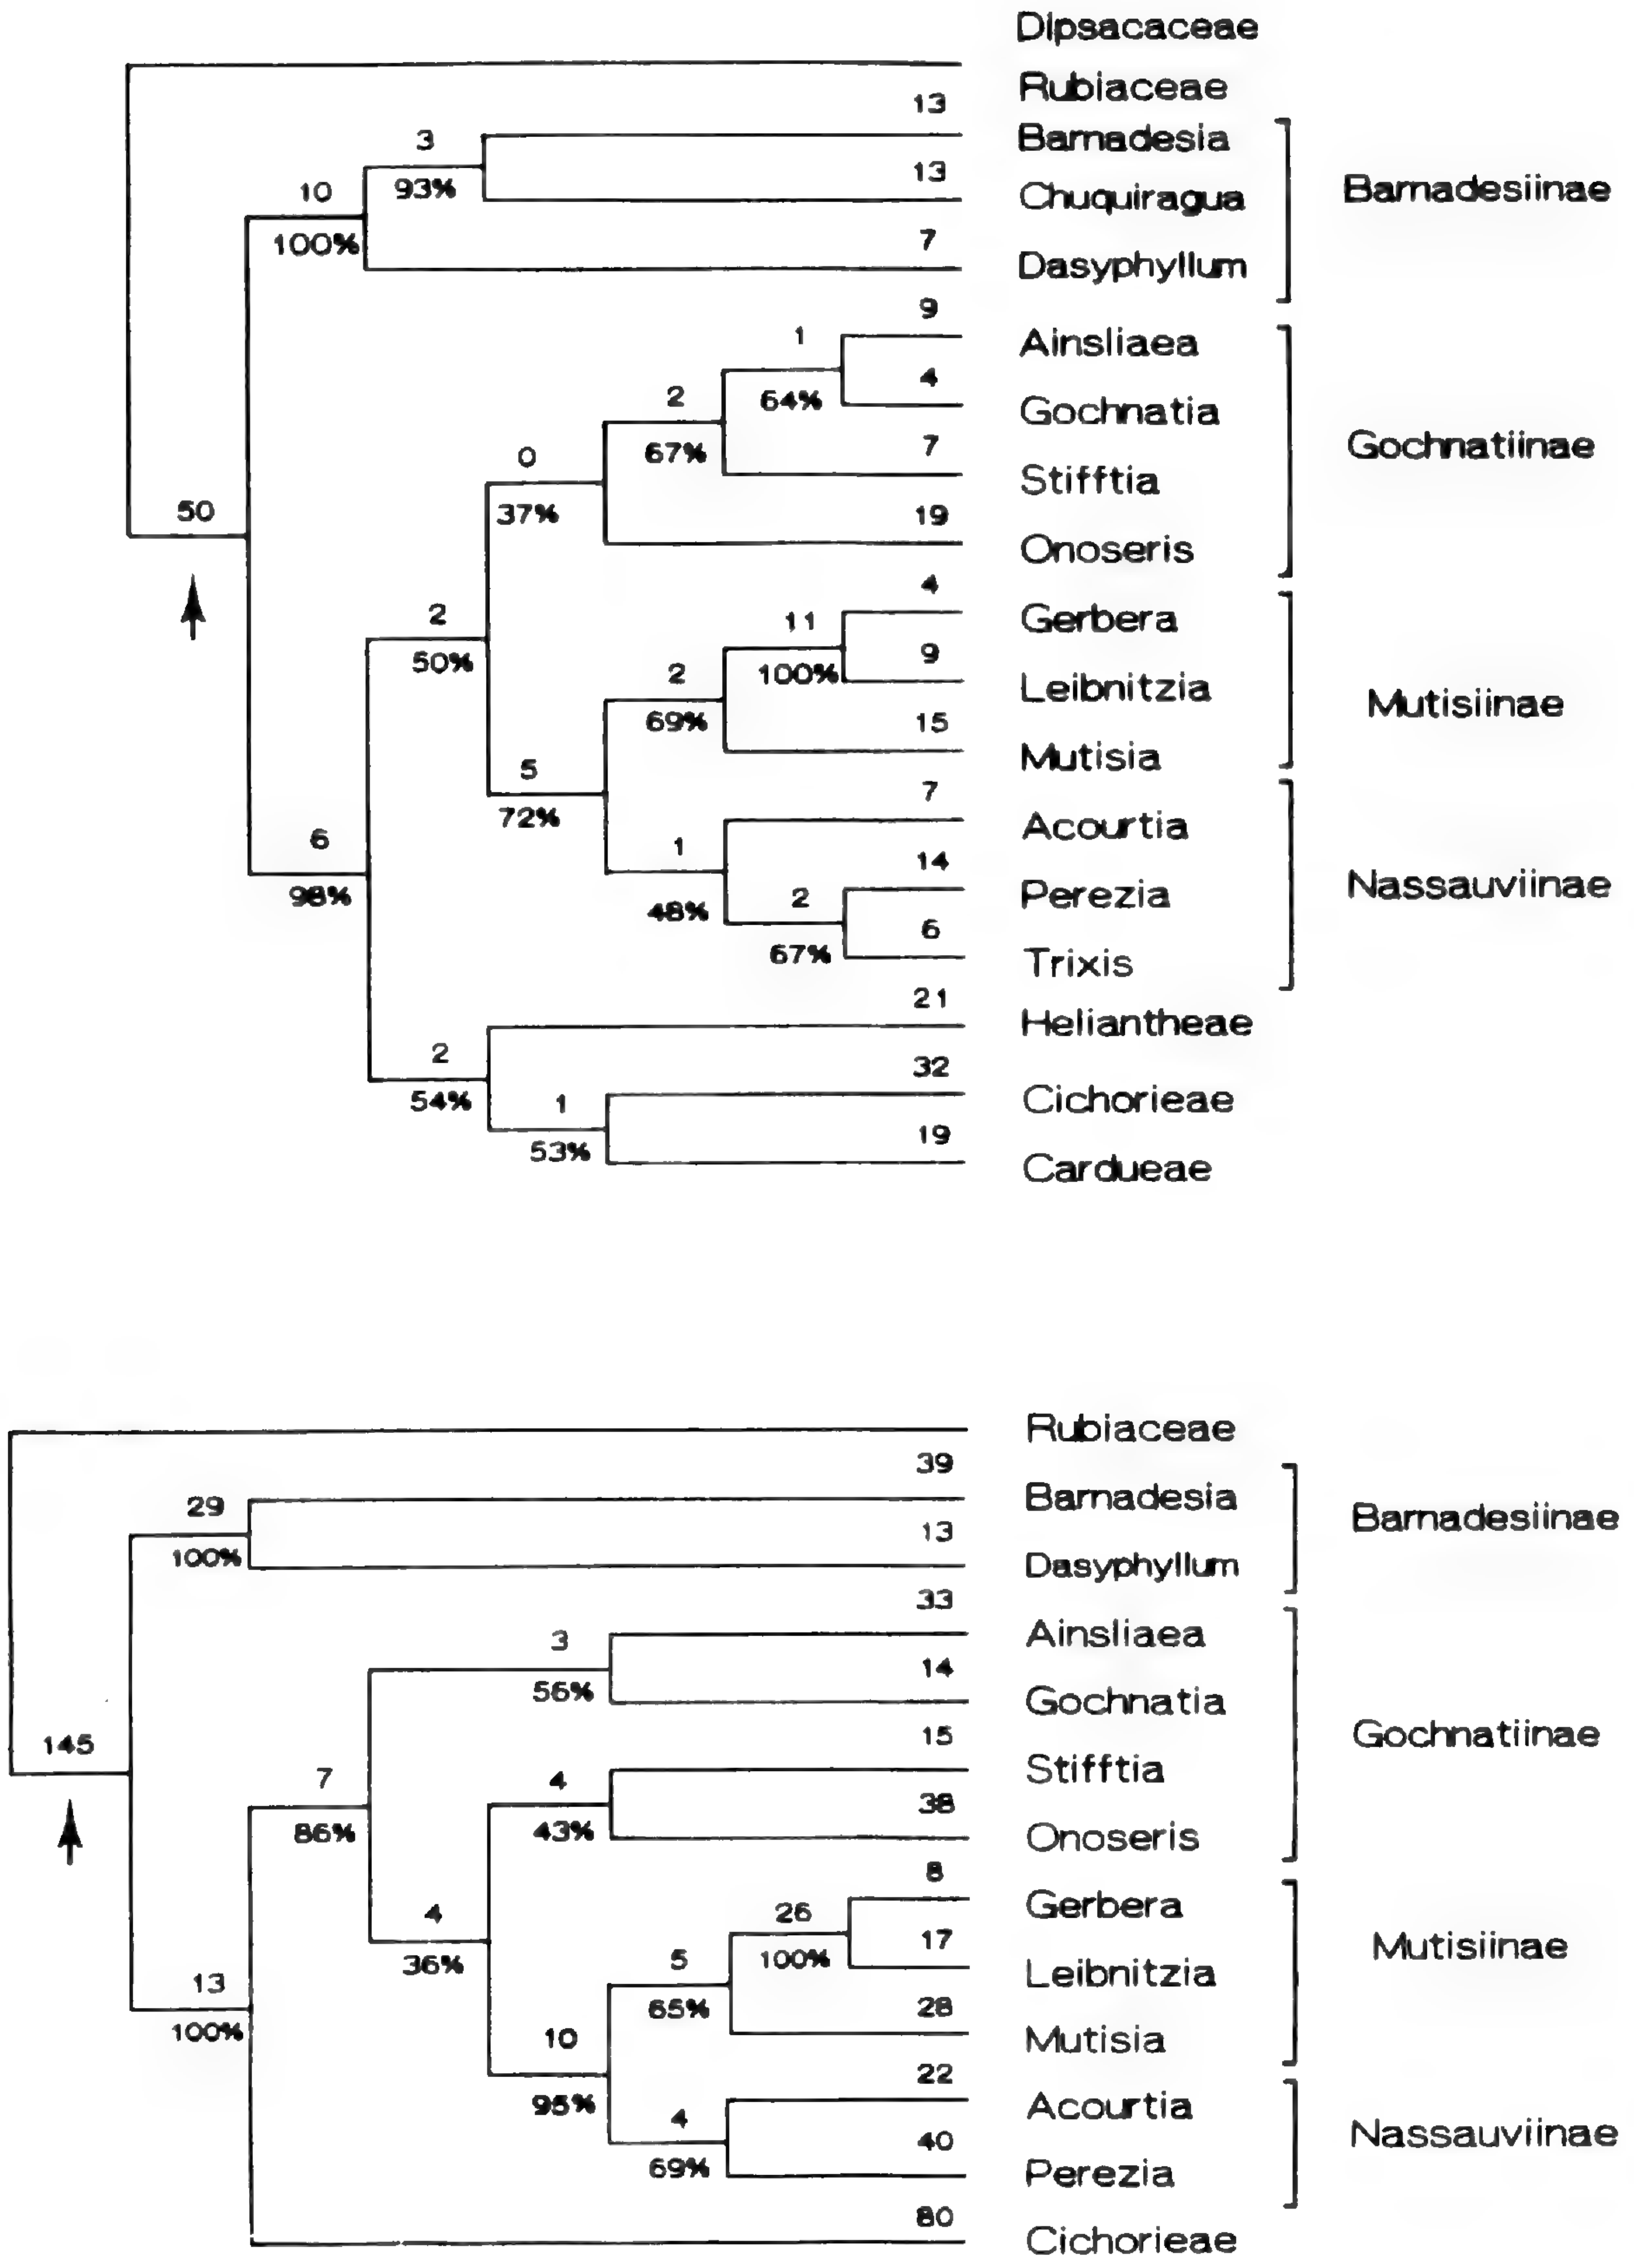

FIGURE 7. *Wagner parsimony trees of genera in the Mutisieae and other Asteraceae. The numbers at each node and along each lineage indicate the number of site mutations. The percentages indicate the number of times that a monophyletic group occurred in 100 bootstrap samples (Felsenstein, 1985). The arrows indicate the occurrence of a 22-kb cpDNA inversion (Jansen & Palmer, 1987b). A single species was examined from each genus, which are as shown for the Mutisieae, and for the other taxa are: Dipsacaceae,* Cephalaria *and* Dipsacus; *Rubiaceae,* Pentas *and* Psychotria; *Heliantheae,* Helianthus; *Cichorieae,* Lactuca; *Cardueae,* Carthamnus. *(Top) Single most parsimonious tree for 16 species of Asteraceae using 211 cpDNA restriction site mutations identified with 10 enzymes. The tree has 247 steps and 15% homoplasy, including 27 parallel losses, two parallel gains, five gains/losses, and two losses/gains. (Bottom) Single most parsimonious tree for 12 species of Asteraceae using 390 cpDNA restriction site mutations identified with 19 enzymes. The tree has 454 steps and 14% homoplasy, including 41 parallel losses, six parallel gains, nine gains/losses, and eight losses/gains. Reprinted with permission from Jansen & Palmer (1988).*

form a paraphyletic group, indicating that the Cichorioideae as circumscribed by most recent workers (Carlquist, 1976; Wagenitz, 1976; Jeffrey, 1978; Thorne, 1983) may not be a strictly natural group. This conclusion is consistent with the recent morphologically based cladistic study of Bremer (1987). The molecular phylogeny indicates that 11 of 14 currently recognized tribes are monophyletic, with the Heliantheae, Mutisieae, and Tageteae being paraphyletic. The cpDNA data (Fig. 8) reveal that the Liabeae and Vernonieae are monophyletic, in agreement with the finding of Bremer (1987). Relationships among the eight tribes in subfamily Asteroideae are clearly resolved in some instances. The previously recognized tribes Cotuleae and Ursinieae (sensu Jeffrey, 1978; Robinson & Brettell, 1973) are closely allied to the Anthemideae, which agrees with their placement in this tribe by Bremer & Humphries (in press). The Tageteae are paraphyletic with respect to the Heliantheae and both tribes are paraphyletic with respect to the Eupatorieae. The very close relationship between the Eupatorieae and Heliantheae does not agree with Bremer's (1987) placement of the former tribe close to the Astereae. Except for the close relationship of the Calenduleae and Senecioneae, there is little resolution of tribal affinities for the remaining members of the Asteroideae. Further phylogenetic analyses using Dollo parsimony and a careful reassessment of character homology are under way to resolve more fully the relatedness of these tribes. For example, an analysis in which statistical approaches were used to eliminate the six most homoplasious characters produced a single most parsimonious tree which again strongly supported the Asteroideae as monophyletic but also weakly supported the monophyly of the Cichorioideae.

The substitution rate in cpDNA (as measured indirectly by the number of restriction site mutations) is markedly faster in the derived subfamily Asteroideae than in the basal, paraphyletic Cichorioideae (Fig. 8). At the extremes, tracing back to the node defined by the 22-kb inversion, only 14 site mutations are derived in the lineage leading to *Stifftia* (Gochnatiinae), compared with 116 in *Santolina* (Anthemideae). This greater than eight-fold discrepancy is not in accord with the molecular clock hypothesis (Wilson et al., 1977) but is consistent with recent findings of rate inequities in the evolution of nuclear DNA (Britten, 1986) and mitochondrial DNA (Wolfe et al., 1987; Palmer & Herbon, in press).

The existence of significant rate differences in cpDNA evolution within the Asteraceae means that a phenetic (distance) analysis may produce a tree that conflicts substantially with the true phylogeny, particularly if the proper algorithm is not used (Nei, 1987). Many lineages within the Asteroideae are phenetically more closely related to members of the Cichorioideae than to other members of the Asteroideae. Such a relationship is also apparent upon a phenetic analysis of the limited *rbc*L sequences (only three) for the Asteraceae (Fig. 3), which shows *Helianthus* (Asteroideae) as an outlier with respect to *Lactuca* (Cichorioideae) and *Senecio* (Asteroideae). This phenetic analysis of sequence data (Fig. 3) is at odds with cladistic analyses of both the same data (H. Michaels, R. Jansen, J. Palmer, unpublished) and also restriction site data (Fig. 8; note the high confidence interval, 86%, of the Asteroideae lineage).

Orchidaceae. The focus of our molecular studies in the Orchidaceae has been the neotropical orchid subtribe Oncidiinae. This large subtribe (1,500 species; 75 genera) is one of the most diverse orchid subtribes in terms of floral and vegetative morphology and chromosome number and has long been viewed as "natural" and isolated relative to other orchid subtribes in the New World. The taxonomic circumscriptions of the two largest genera, *Oncidium* (450 species) and *Odontoglossum* (250 species), have been considered problematic since the 1840s. We hoped that a cpDNA-based study of phylogenetic relationships among the groupings identified as natural units (genera and various subgeneric categories) would aid in taxonomic realignment. We (M. Chase & J. Palmer, unpublished) used ten restriction enzymes to analyze cpDNA variation in 99 species that represent most of the currently recognized generic and subgeneric groupings in the Oncidiinae and an additional 33 species from other subtribes in the Epidendroideae sensu lato.

One problem we hoped to address with a phylogeny reconstructed from molecular data was the evolution of chromosome number in the Oncidiinae, which ranges from $n = 5$–30 among species that are not obvious polyploids. Prior hypotheses postulated that this range results from hybridization among species of lower numbers followed by episodes of chromosome doubling (Garay, 1963; Charanasri & Kamemoto, 1975). Chase (1986) studied morphological trends and concluded that hybridization and polyploidy were not involved and that taxa with lower numbers were the results of several independent lineages experiencing reduction from primitively high numbers. The number of loci coding for soluble enzymes was found to be

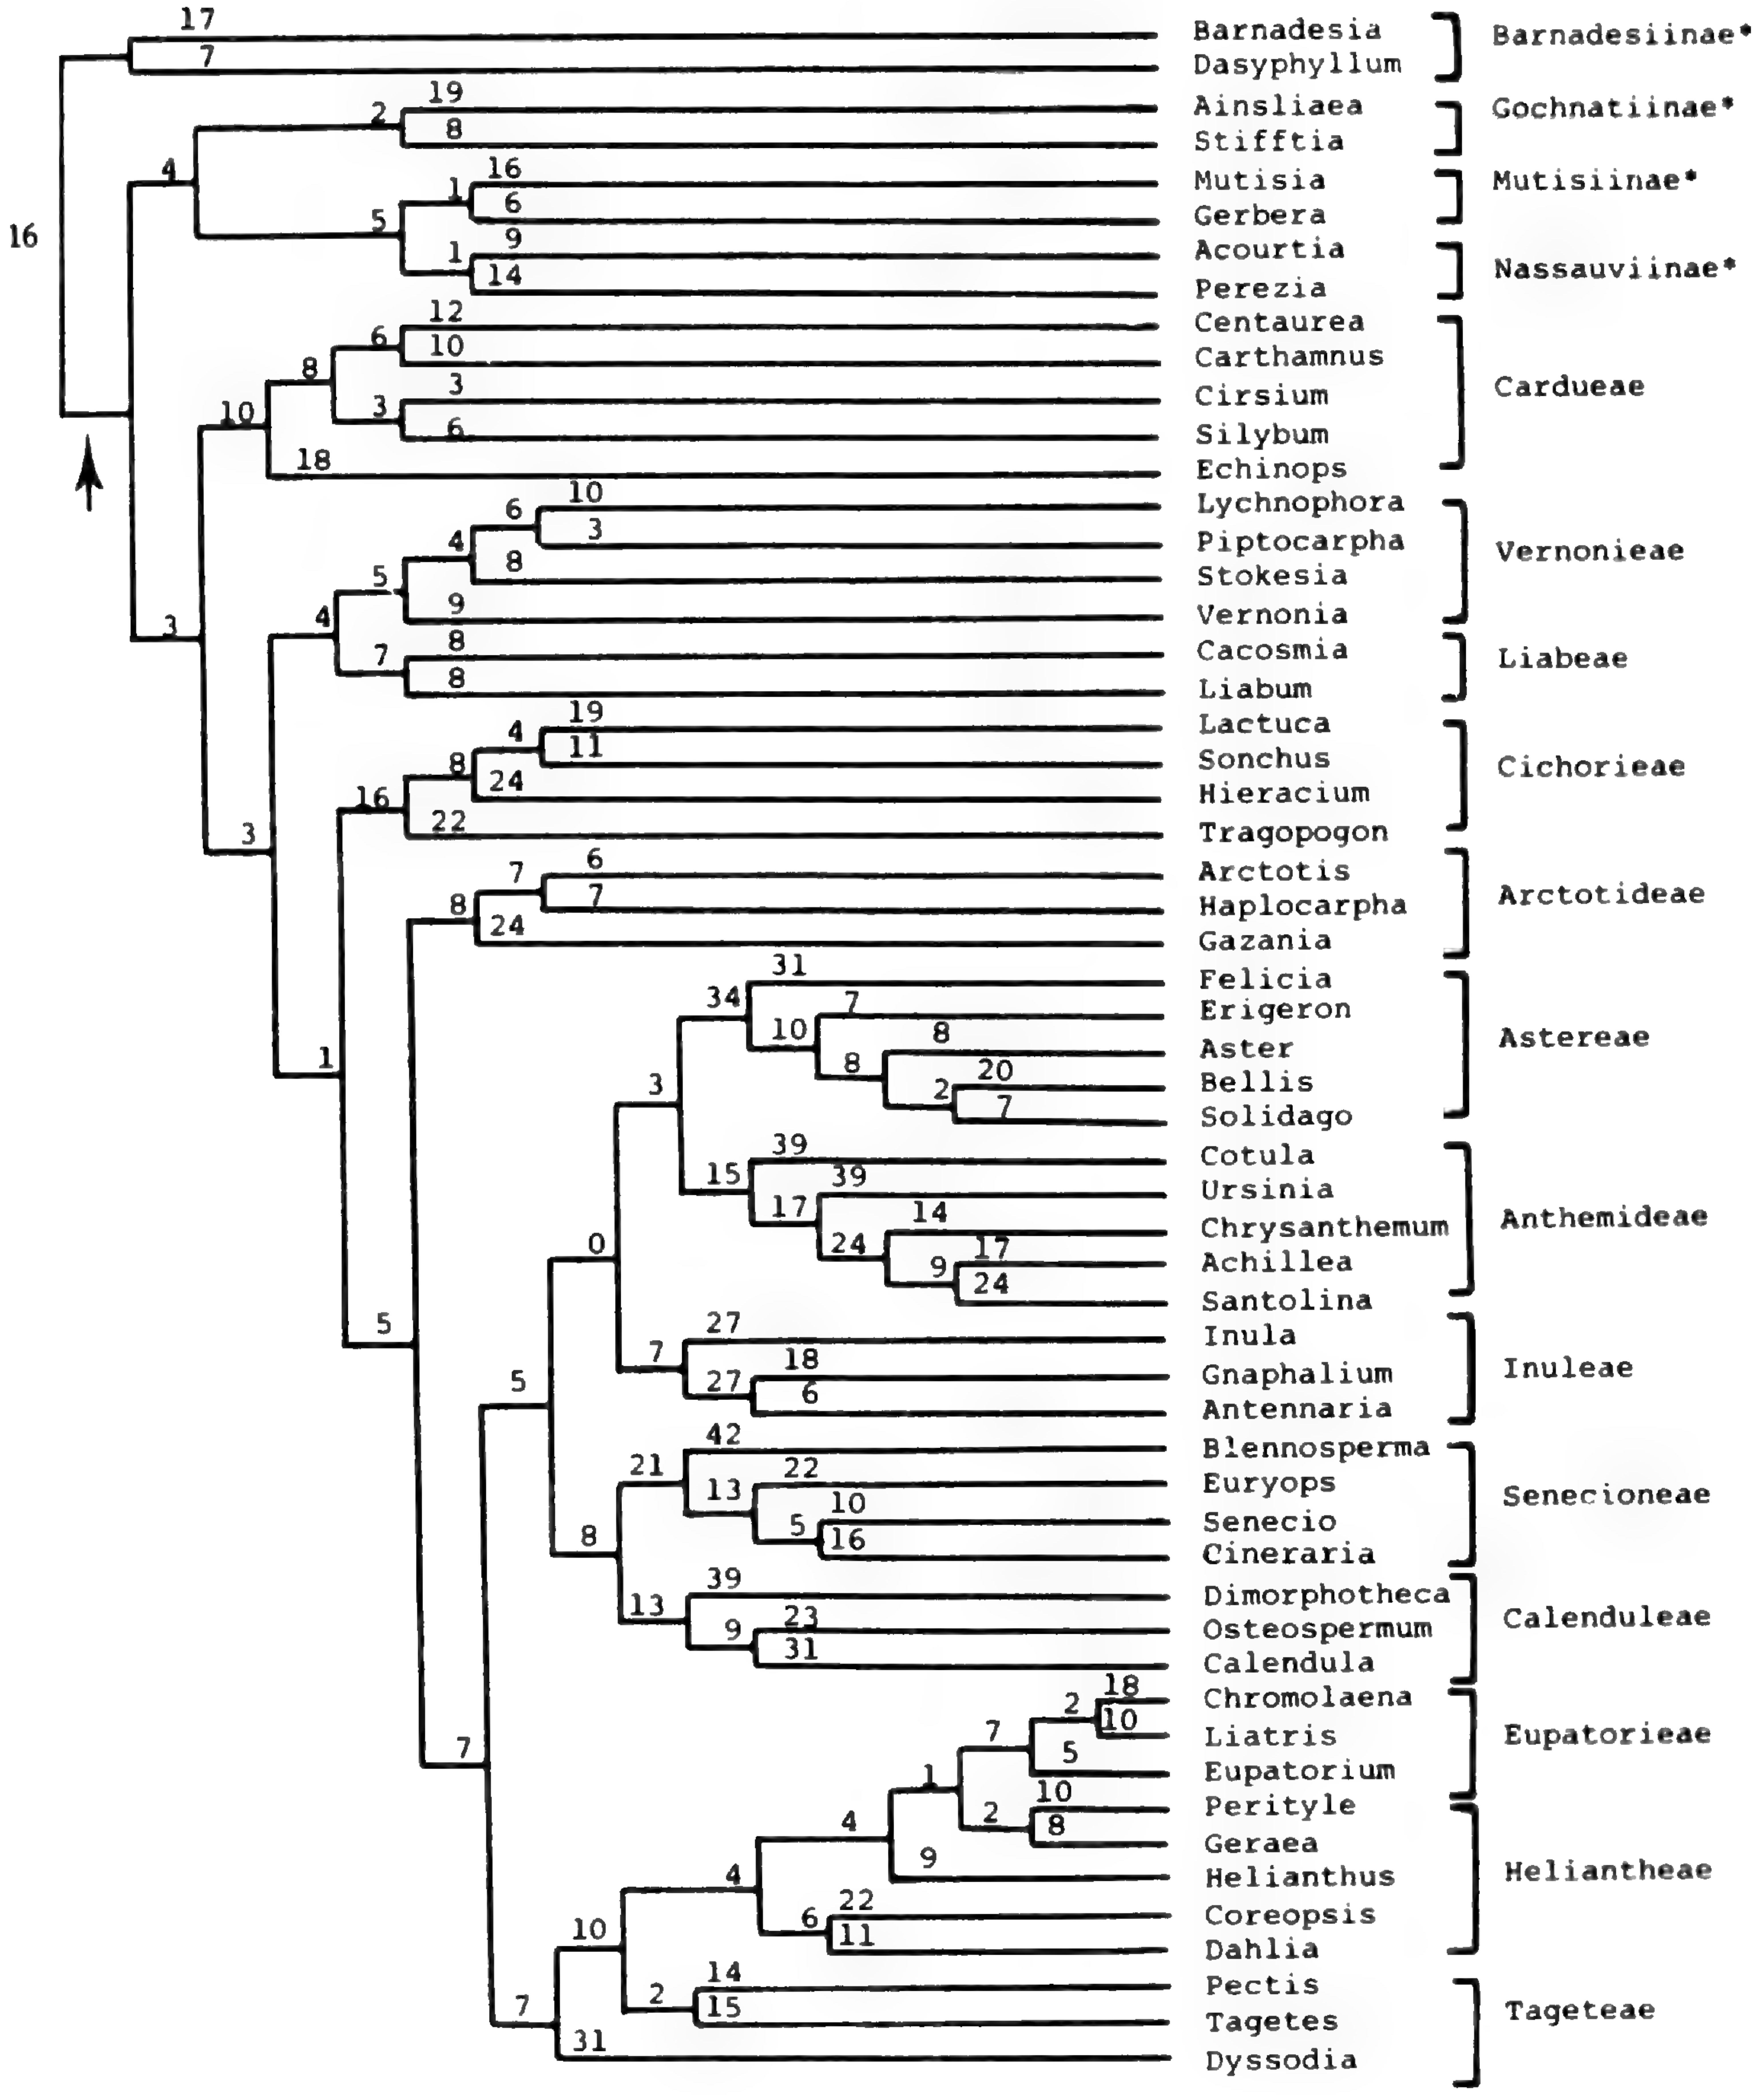

FIGURE 8. *Molecular phylogeny of the Asteraceae. Shown is a majority rule consensus tree generated by the bootstrap option of PHYLIP using 926 restriction site mutations. The numbers at each node and along each lineage indicate the number of restriction site mutations. The tree has a total of 1,318 steps and 30% homoplasy and is rooted relative to the Barnadesiinae. Brackets show the current circumscription of 13 of the tribes, while the four subtribes of the Mutisieae are indicated with asterisks. The arrow indicates the occurrence of a 22-kb cpDNA inversion (Jansen & Palmer, 1987b). Unpublished data of R. Jansen, H. Michaels, and J. Palmer.*

the same among species exhibiting the complete range of chromosome number (Chase & Olmstead, 1988), making allopolyploidy an unlikely explanation to account for these differences. The cpDNA phylogeny (M. Chase & J. Palmer, unpublished) strongly supports the idea that members of several lineages have undergone parallel reduction in chromosome number.

The traditional idea that the Oncidiinae comprise an isolated subtribe was shown by a study of seed morphology (Chase & Pippen, in press) to be fallacious (i.e., a number of other subtribes have the same seed morphology). The molecular phylogeny has identified as close relatives many of the same subtribes as did the study of seed morphology. Among these other subtribes are the Bifrenariinae, Lycastinae, Maxillariinae, Xylobiinae, and, in particular, the Lockhartiinae and Ornithocephalinae. Most systems of orchid classification have used pollinium number to place all but the Lockhartiinae in another tribe from that of the Oncidiinae. Pollinium number appears not to be a reliable indicator of relationships in these orchids (Chase & Pippen, in press; M. Chase & J. Palmer, unpublished).

The cpDNA phylogeny is concordant with the evidence from morphology that *Oncidium* and *Odontoglossum* are not monophyletic genera. *Oncidium* in particular is paraphyletic rather than a genus held together by synapomorphies. The morphologically distinct derivatives of this assemblage have been recognized as different genera. The apparent phylogenetic radiation that produced this large species complex has a strong geographic component. Members of several sections of *Oncidium* endemic to the mountains of southeastern Brazil are more closely related to genera, such as *Gomesa*, endemic to this same region, than to morphologically similar sections of *Oncidium* from other geographical areas.

We failed to find cpDNA mutations that could establish relationships among several well-defined (both by molecular and morphological data) lineages of the Oncidiinae. One explanation for this result is a slowed rate of molecular change during the period when these lineages arose. This explanation also requires a corresponding decrease in the rate of morphological change followed by increases in molecular and morphological rates during subsequent evolution in several now-separate lineages. A more likely explanation we feel is that a large number of lineages diverged in a short period of evolutionary time from a polymorphic ancestral stock. This process must have happened so rapidly that either no mutations exist at this level or the few mutations that do exist convey conflicting ideas of relationships because of homoplasy. The implications of such a phylogenetic radiation are significant in evolutionary and taxonomic terms. Radiations of this type have long been suspected to be responsible for the large numbers of closely related, taxonomically difficult species and genera found in most large families of vascular plants, but this is the first time molecular evidence documenting such a phenomenon has been uncovered (for a similar case in *Clarkia*, see symposium paper by K. Sytsma in this volume).

Fabaceae. Chloroplast DNA variation has been used to explore interspecific relationships in several legume genera (reviewed in Doyle, 1987), and studies using restriction site mapping are currently in progress to address relationships in several tribes of legumes (J. Doyle, pers. comm.). However, the high level of cpDNA sequence divergence in certain legumes (Palmer & Thompson, 1982) suggests that such efforts would be largely fruitless in these groups. Several cpDNA rearrangements have been well characterized in legumes and appear to be useful phylogenetically.

Two rearrangements, a 50-kb inversion and the loss of the *rpl*22 gene from the chloroplast genome (and its concomitant transfer to the nucleus), are shared by all members examined of the three subfamilies of legumes (Figs. 4, 5; Palmer et al., 1987; J. Palmer & J. Doyle, unpublished data). These two events may constitute legume-specific markers, as they are absent from the cpDNAs of such putatively related families as Rosaceae and Sapindaceae. However, other close relatives, such as the Connaraceae and Chrysobalanaceae, remain to be examined.

A 78-kb inversion that includes most of the large single copy region of the chloroplast genome (Palmer et al., in press) has been surveyed in 50 genera of papilionoid legumes, principally in the tribe Phaseoleae (Bruneau et al., 1988). This inversion is shared by all members examined of the subtribe Phaseolinae sensu Lackey (1981), and its distribution also helps elucidate the placement of several problematic genera. For example, *Clitoria* and *Centrosema* lack the inversion and therefore ought to be excluded from a narrowly defined Phaseolinae for which this character is a synapomorphy. In contrast, *Macrotyloma*, whose subtribal placement has been disputed, has the inversion and on this basis is best placed in the Phaseolinae.

The most intriguing legume rearrangment, both from the standpoint of cpDNA evolution and legume phylogeny, is the loss of the large cpDNA inverted repeat. This inverted duplication, which typically is on the order of 25 kb in size (Fig. 1), is a hallmark of land plant cpDNAs (reviewed in Palmer, 1985b, c). The repeat structure has been lost (one of the two repeat elements has been deleted, without the loss of genetic information) only twice among all of the nearly 1,000 species of land plants whose cpDNAs have been investigated. One of these absences characterizes at least two genera of Pinaceae (Fig. 5; Strauss et al., 1988) and the other several tribes of legumes (Palmer et al., 1987).

A total of 136 species of legumes have now been surveyed for the presence of the inverted repeat, including 124 species representing 76 genera and 24 of the 30 tribes of subfamily Papilionoideae (Lavin et al., 1988). The inverted repeat is present in most legumes, including members of all three subfamilies and a taxonomically diverse group of papilionoid tribes (Fig. 5). It is absent in all members examined from the Galegeae, Vicieae, Cicereae, Trifolieae, Carmichaelieae, and Hedysareae, a group of temperate herbaceous papilionoid tribes characterized by a combination of features, such as reduction or loss of the pulvinus and a base chromosome number of $n = 7$ or 8. In this respect our results are consistent with phylogenetic hypotheses based on traditional characters. However, two areas of apparent disagreement exist. First, *Wisteria* is the only member of the tropical tribe Milletieae that lacks the inverted repeat. *Wisteria* is also unusual within the Milletieae in its entirely temperate distribution and its base chromosome number of $n = 8$, both characters that link it with the Galegeae, which also lack the inverted repeat. Secondly, Loteae and Coronilleae, which have the inverted repeat, are commonly grouped on the basis of morphology with temperate herbaceous tribes that lack it. The distinction between these two groups of tribes is, however, also supported by some nonmolecular characters, such as root nodule morphology.

Circumstantial evidence and theoretical speculation suggest that the absence of the inverted repeat leads to an unstable chloroplast genome prone to more frequent rearrangement (Palmer & Thompson, 1982; Palmer, 1985b; Strauss et al., 1988). In some legumes, other factors, such as the presence of large dispersed repeats, also contribute to an unstable, actively rearranging chloroplast genome (Palmer et al., 1987). This acceleration in rearrangement rate can be dramatic; for example, genomes in *Pisum* and *Trifolium* differ from those of other genera in the same tribes by eight or more inversions (Fig. 5). Contrast this with the colinearity of cpDNAs of major groups of vascular plants (Fig. 1; Palmer & Stein, 1986) and with the single inversion that distinguishes cpDNAs of vascular plants and some bryophytes (Fig. 5). While interesting from the standpoint of mechanisms of molecular evolution, extensive rearrangement makes it impossible to align much or all the chloroplast chromosomes of different taxa, thus largely precluding comparative cleavage site analysis. In addition, the use of the rearrangements as characters is usually not justified owing to the enormous amount of work required to define each rearrangement as an individual, polarizable mutation.

Solanaceae. The chloroplast genomes of species in the Solanaceae are among the best known at the molecular level thanks to the complete sequencing of cpDNA from tobacco (*Nicotiana tabacum*; Shinozaki et al., 1986). A number of studies have utilized cpDNA restriction fragment variation to examine interspecific relationships in *Lycopersicon*, *Solanum*, and *Nicotiana* (Palmer & Zamir, 1982; Hosaka, 1986, and references therein), but none have addressed higher level issues in the family. The limited divergence observed in *rbc*L sequences of three disparate genera of Solanaceae bodes well for such an approach (Fig. 3; this level corresponds to that seen in the Asteraceae, where site mapping has proven successful), and we have recently initiated a comparative mapping study of 100 representative species and genera of Solanaceae.

The *rbc*L sequence data, limited as they may be, are tantalizing in placing *Nicotiana* and *Lycopersicon* closer to each other than either is to *Petunia* (Fig. 3). Although in conflict with standard schemes (D'Arcy, 1979), which place *Nicotiana* and *Petunia* in the same tribe (Nicotianeae) and *Lycopersicon* in a different subfamily (Solanoideae), this relationship is supported by sequence data for several nuclear genes (Pichersky et al., 1986) and by chromosome numbers ($n = 12$ for tobacco and tomato and $n = 7$ for petunia). It will be important to see whether the controversial relationships suggested by the phenetic treatment of *rbc*L sequence data (Fig. 3) are supported by the large-scale mapping study in progress, as well as by a cladistic analysis and a more sophisticated phenetic analysis (Nei, 1987) of the same sequence data.

Poaceae. Chloroplast DNA has been used extensively to investigate interspecific relationships in grasses (particularly in cereals), more so than in any other plant family (reviewed in Hilu, 1987). However, with few exceptions (e.g., Doebley et al., 1987), these studies have yielded limited phylogenetic insights owing to insufficient sampling of taxa and cpDNA sequences and also to nonrigorous methods of phylogenetic analysis. Similar problems exist for two studies of intergeneric and intertribal relationships of grasses (Lehvaslaiho et al., 1987; Enomoto et al., 1985). Despite these problems, a surprisingly reasonable phylogeny was derived for ten grass genera from an analysis of cpDNA restriction fragment patterns (Enomoto et al., 1985).

The *rbc*L gene has been sequenced more extensively in grasses than in any other plant family. The resulting phenogram (Fig. 3) shows good agreement with previously held concepts (Watson et al., 1985) and with a cladogram based on nuclear ribosomal RNA sequences (Hamby & Zimmer, 1988). This latter congruence is comforting, given the possibility for reticulate evolution to produce different phylogenies for maternally inherited chloroplast genes and biparentally inherited nuclear ones. The closer molecular relationship of *Triticum aestivum* to *Aegilops crassa* than to *T. urartu* (Fig. 3) is not surprising, since *Triticum* is an unnatural group with strong affinities to *Aegilops* and to several other genera in subtribe Triticinae (Kerby & Kuspira, 1987).

Several cpDNA inversions have been characterized in one or a few grasses, and at least one of these is shared by members of different subfamilies (Palmer & Thompson, 1982; Quigley & Weil, 1985; Hirai et al., 1985). These inversions are lacking in the four other families of monocots whose cpDNAs have been mapped (Fig. 1; de Heij et al., 1983; J. Palmer, unpublished). Careful exploration of the phylogenetic distribution of these inversions should, therefore, define several major branchings of grass evolution.

HIGHER-ORDER RELATIONSHIPS

The major avenue for exploring relationships among families and at higher levels is DNA sequencing. Supplementary information will also come from the rare and powerful rearrangements that lead to alterations in chloroplast genome structure and gene content.

Land plants. As discussed in the section on DNA sequencing, *rbc*L is the chloroplast gene of choice for comparative sequencing among angiosperms and gymnosperms. While the *rbc*L phenogram in Figure 3 offers little revelation concerning higher-level questions of angiosperm phylogeny, this situation will soon change owing to the coordinated *rbc*L sequencing efforts under way in several laboratories. The correspondence of the *rbc*L phenogram and also those based on more limited sampling of the genes *atp*B (Ritland & Clegg, 1987) and *psb*A (Wu et al., 1987) with generally held concepts of angiosperm phylogeny is encouraging. In contrast, a phylogenetic analysis based on sequences of the chloroplast *rpl*2 gene conflicts with generally accepted classification schemes and with other molecular data (Zurawski & Clegg, 1987). The explanation for this discrepancy appears to lie in the unusual evolutionary properties of *rpl*2, which is subject to a substantial selective constraint on third-position substitutions, perhaps owing to the presence of a gene on the strand opposite to that encoding *rpl*2 (Zurawski & Clegg, 1987). It is important to emphasize that this anomalous evolutionary behavior of *rpl*2, which makes it such a poor choice for phylogenetic study, was observed directly from consideration of the dynamics of nucleotide substitutions (Zurawski & Clegg, 1987), an observation *independent* of the realization that the gene is a poor phylogenetic marker.

Despite the lack of any systematic effort to identify and survey major rearrangements among land plant cpDNAs, several already have turned up that promise to mark dichotomies among major plant groups. The best documented is the aforementioned loss of the *rpl*2 intron (Figs. 4, 5), an event that unites the Caryophyllales (Centrospermae) in a manner consistent with the analysis of Rodman et al. (1984). Other rearrangements for which further study promises to illuminate specific branchings include the loss of the large inverted repeat in two genera of Pinaceae (Strauss et al., 1988) and a 30-kb inversion of unknown evolutionary polarity that distinguishes vascular plants from the single liverwort and moss examined thus far (Fig. 5; Ohyama et al., 1986; Calie & Hughes, 1987b).

Algae. Our knowledge of the structure and sequence of algal chloroplast genomes is quite limited compared with those of land plants. No significant comparative sequence study or data base yet exists for algal chloroplast genes, although several laboratories are now engaged in sequencing chloroplast ribosomal RNA genes in major algal groups (pers. comm. from S. Giovannoni & K. Field, R. Chapman & E. Zimmer, R. Cattolico, and J. Manhart & J. Palmer). Rates of structural rearrangement and size change in cpDNA appear to be substantially higher in algae, particularly green algae, than in land plants (e.g., Lemieux & Lemieux, 1985; reviewed in Palmer, 1987). These high rates probably preclude the use of inversions as phylogenetic characters at higher levels among algae, although they may be useful within genera. Other organizational features, in particular the content of genes and introns, hold promise for defining major events of algal evolution. The use of two such markers for defining the green algal origins of land plants is described in the next two paragraphs.

The gene *tuf*A, encoding the chloroplast protein synthesis factor EF-Tu, has previously been shown to be encoded by cpDNA in the phytoflagellate *Euglena gracilis* (Montandon & Stutz, 1983) and suggested to be cpDNA-encoded in the green alga *Chlamydomonas reinhardtii* (Watson & Surzycki, 1982). However, this gene is absent from the cpDNAs of an angiosperm and a bryophyte, as demonstrated by complete sequencing of the two genomes (Ohyama et al., 1986; Shinozaki et al., 1986). Recent studies (Fig. 5; J. Manhart, S. Baldauf & J. Palmer, unpublished data) reveal that *tuf*A is indeed encoded by cpDNA in *Chlamydomonas* and all other green algae examined, with the possible exception of *Coleochaete*, the presumed closest relative to land plants (Graham, 1985). In contrast, we find *tuf*A to be a nuclear gene in land plants. The transfer of *tuf*A from the chloroplast to the nucleus thus defines land plants as a natural, monophyletic group, with the disposition of *Coleochaete* with respect to this character in need of further study.

The chloroplast gene for tRNA-isoleucine contains a large intron in all land plants examined (Ohyama et al., 1986; reviewed in Palmer, 1985c) but lacks introns in all eukaryotic algae, including the green algae *Chlamydomonas* (Schneider & Rochaix, 1986) and *Chlorella* (Yamada & Shimaji, 1986). We find this intron to be present in *Nitella* cpDNA and are examining other charophytes and other classes of green algae (Fig. 5; J. Manhart & J. Palmer, unpublished data). This intron gain thus has the potential to define a specific lineage of charophytes as the sister group of land plants, consistent with ultrastructural and other evidence (Mattox & Stewart, 1984).

A signal accomplishment of molecular systematics is the unambiguous resolution of the longstanding controversy regarding the very origin of the chloroplasts. Findings from numerous molecular approaches, including the analysis of rRNA gene sequences (Fig. 9) and of gene organization (e.g., Cozens & Walker, 1987), have established unequivocally that chloroplasts are derived, endosymbiotic, photosynthetic bacteria (most likely cyanobacteria; reviewed in Gray, 1983). The challenges that remain for molecular systematists are to elaborate the full history of chloroplast endosymbiosis. Have different chloroplast lineages been derived from just one or from multiple independent and/or serial endosymbioses, and what are the sources of the plastid and nucleus in each of these associations (Whatley, 1983; Palmer, 1985b)? Analysis of ribosomal RNA sequences (Giovannoni et al., 1988) and consideration of chloroplast genome size and gene content (Palmer, 1985c) favor the idea of a single initiating endosymbiosis (i.e., one between a photosynthetic *prokaryote* and a nonphotosynthetic eukaryote), followed by several strictly eukaryotic symbioses.

DIRECTIONS AND PROSPECTS

Chloroplast DNA is now routinely used to investigate interspecific relationships among angiosperms and other plants. Its popularity at this level reflects both the general preoccupation of plant systematists with interspecific questions and also a set of factors that make cpDNA analysis especially appropriate at this level. These include the special utility of cpDNA for providing insights into the *directionality* of the hybridization events that are so common in plants, the relative ease of comparing cpDNA molecules at this level, the sufficiency of readily detectable mutations, and the low levels of homoplasy associated with the cladistic analysis of these mutations.

With current practices, the value of cpDNA analyses to reveal patterns of intraspecific variation and processes of speciation is marginal owing to the slow rate of cpDNA evolution. A concentrated effort is necessary to develop technical strategies that will allow the routine accumulation of sufficient numbers of cpDNA mutations to make the molecule predictably useful below the species level. In the short term such an enlargement of the cpDNA data base will involve increasing the number of restriction sites scored in a typical survey. This will mean using more retriction enzymes, particularly ones that cut frequently (100–400 times per genome), utilizing electrophoretic techniques (e.g., acrylamide gels of the type normally used for DNA sequencing) adequate to the task of resolving multiple small fragments, and hybridizing blots made from these gels repeatedly with cloned fragments spanning the genome. In the long term, it is conceivable that sufficient advances in the technology of DNA sequencing (e.g., of the type presently being sought to allow the sequencing of the three billion base pair genome of humans) will occur to permit efficient intraspecific study by this approach.

The analysis of phylogenetic relationships among genera and tribes is currently a nexus for the various approaches used to compare cpDNA molecules. Restriction site mapping, the easiest approach, is of demonstrated utility within families showing moderate levels of cpDNA divergence, such as the enormous family Asteraceae. In families of greater molecular diversity, such as the Fabaceae and Onagraceae (see symposium paper

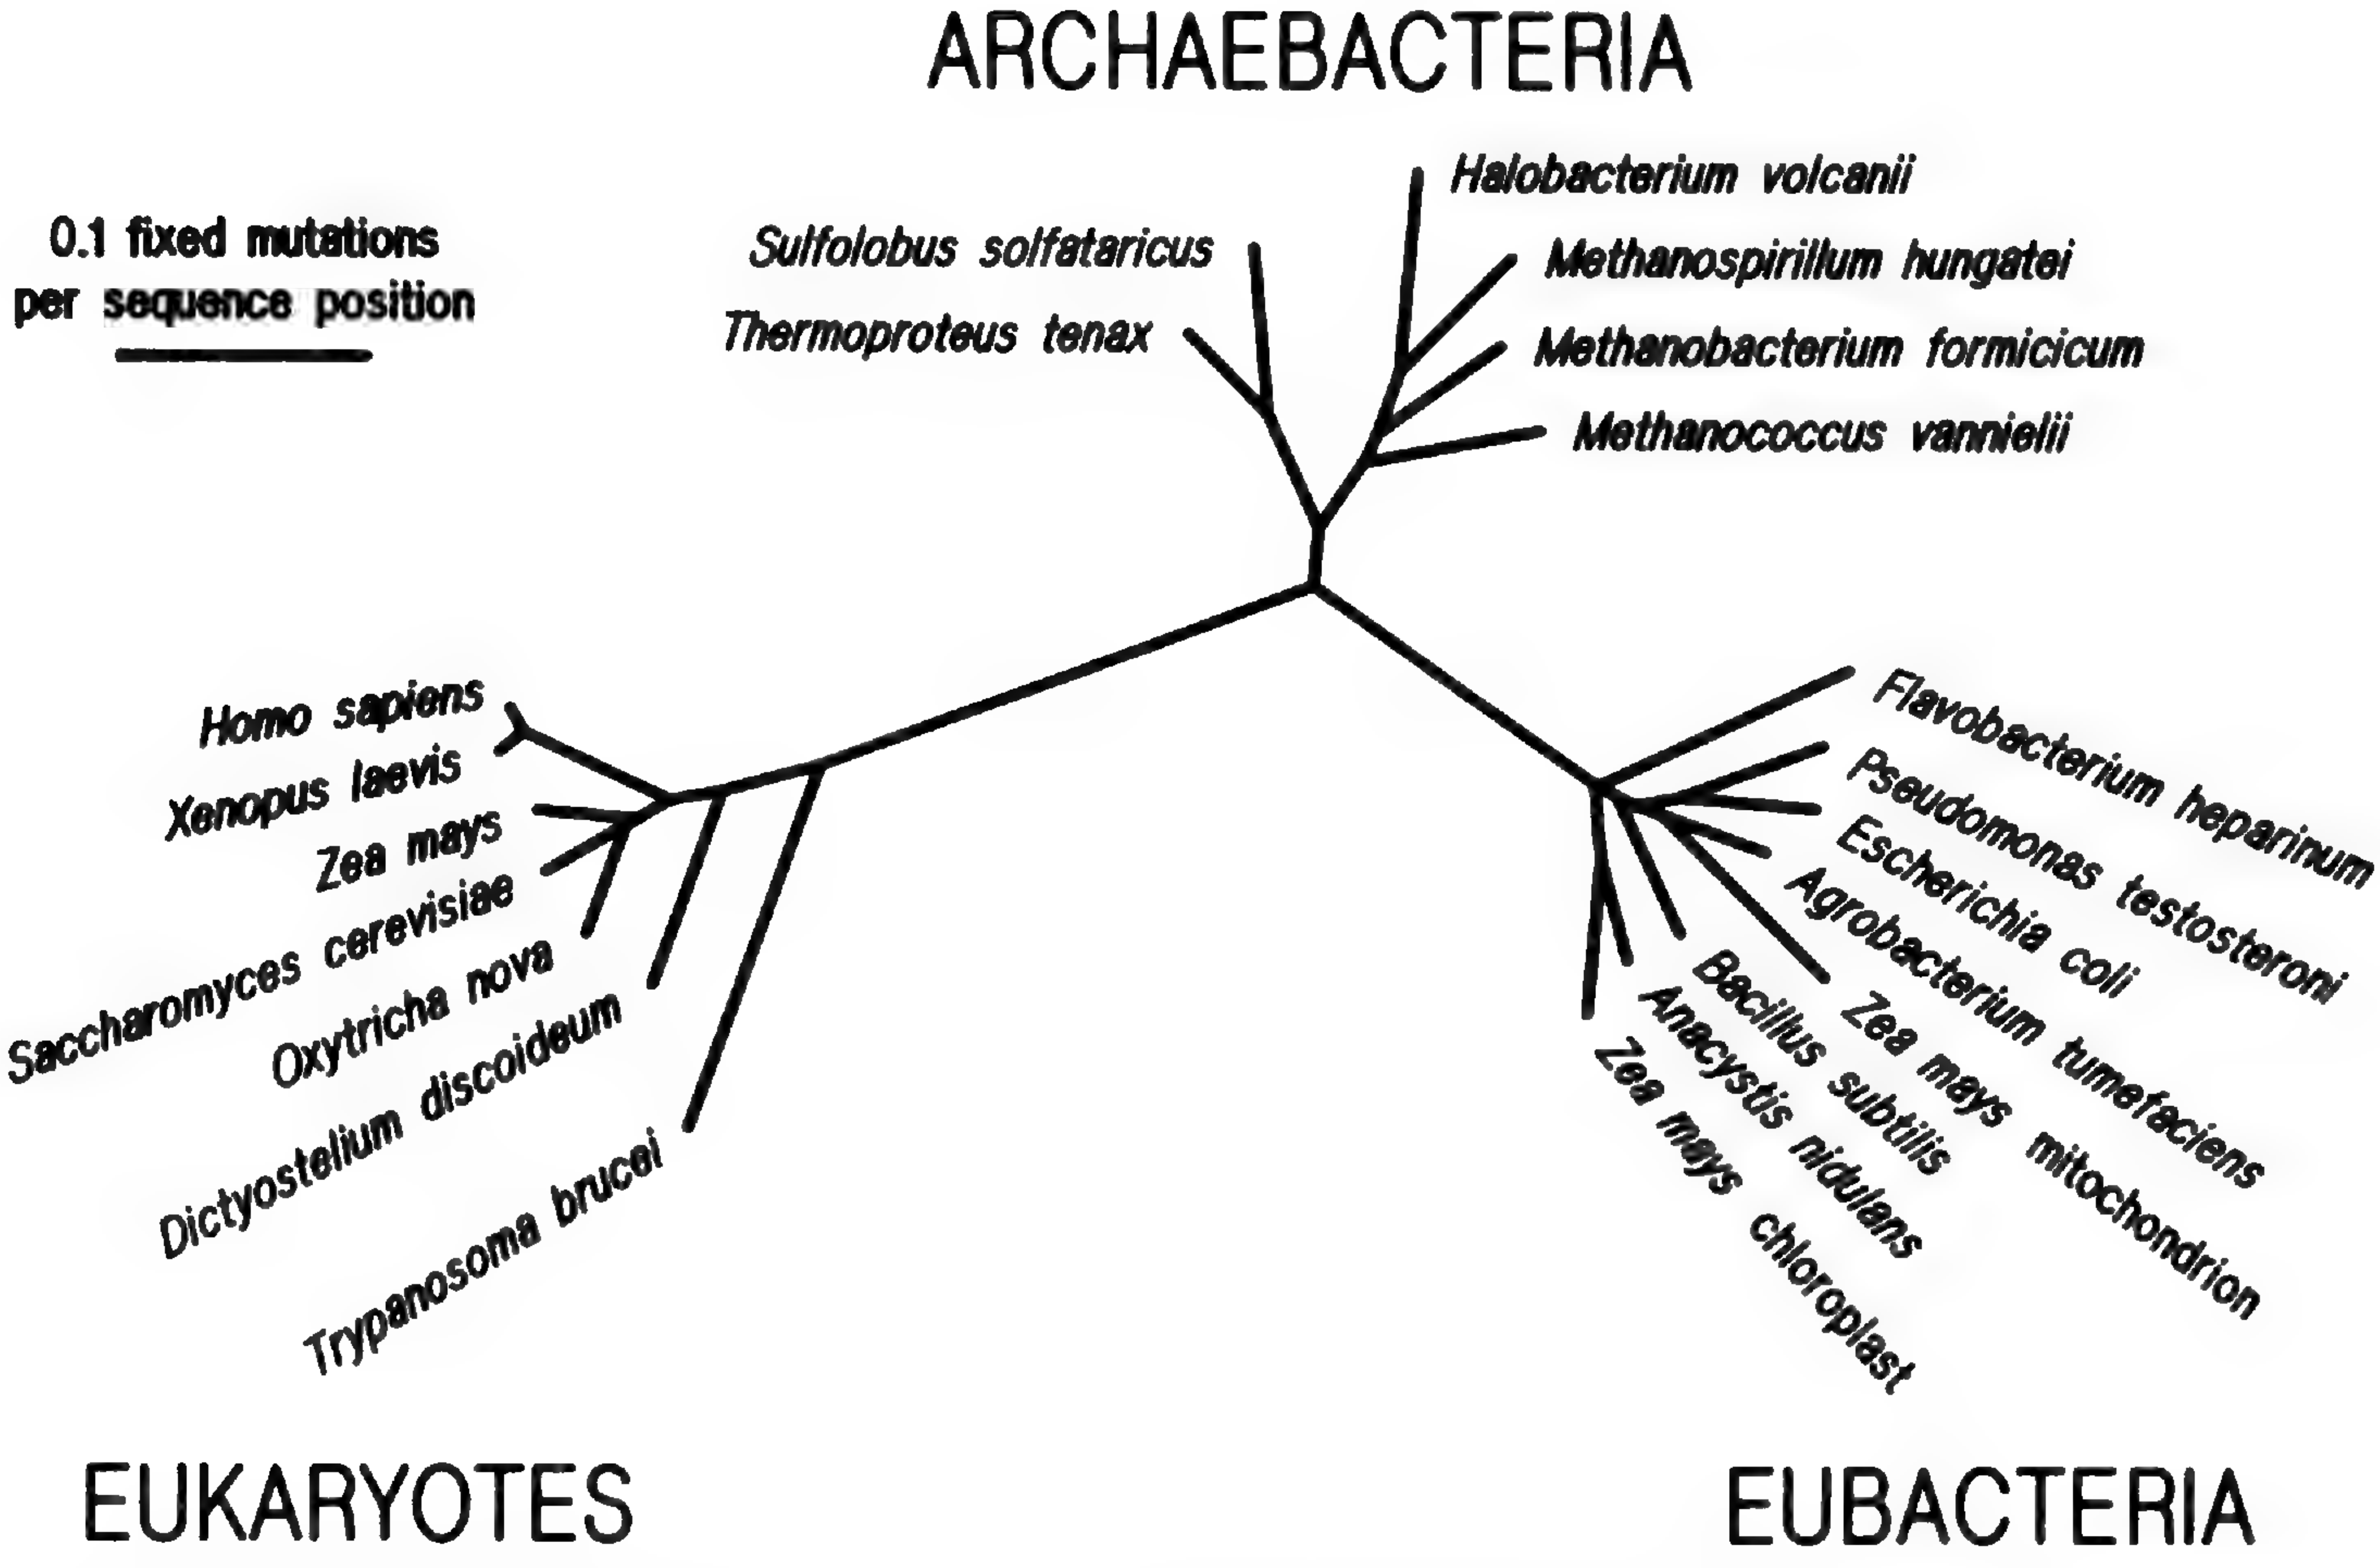

FIGURE 9. *An unrooted dendrogram based on a phenetic analysis of 16S and 18S ribosomal RNA sequences. See Pace et al. (1986) for details of tree construction and references to the primary sequence literature. Reprinted with permission from Pace et al. (1986).*

by Sytsma & Smith in this volume), direct sequencing (e.g., of *rbc*L) is a more fruitful approach. It is presently unclear, and hence unpredictable, as to why the cpDNAs of certain families are too diverse to permit comparative restriction site mapping. Factors such as the size and age (see final paragraph) of the family may in some cases be unrelated to its molecular diversity. In certain families, such as the Fabaceae, Asteraceae, and perhaps Poaceae, major rearrangements may also make significant phylogenetic contributions.

Perhaps the major accomplishment of cpDNA systematics, and molecular systematics in general, will be the resolution of the hotly debated major branchings of plant evolution, such as relationships among the families of flowering plants. DNA sequencing will be the major tool in this effort, with rearrangements serving to mark with exquisite clarity a subset of branchings. It remains to be seen whether *rbc*L will be a reliable phylogenetic indicator in all lineages. In some cases, particularly very old lineages, more conservative genes such as those encoding rRNAs may be more useful. In other cases, such as rapid radiations, sequence data from multiple genes may be necessary to provide statistically adequate phylogenetic resolution. An increasingly important component of molecular analyses as one moves back in evolutionary time will be the scope and sophistication of the computer programs that construct evolutionary trees and evaluate their statistical significance.

A frustrating but fascinating conclusion from recent cpDNA comparisons is that the rate of cpDNA sequence change may vary markedly in different, even closely related, plant lineages. These rate differences were discussed earlier in reference to the Asteraceae phylogeny shown in Figure 8 and have also been inferred from studies in the Fabaceae and Juglandaceae (J. Doyle, pers. comm.), *Populus* (K. Sytsma, pers. comm.), and *Lactuca* (E. Jandourek & J. Palmer, unpublished data). The frustrating aspect of these rate differences is the attendant inability to use molecular variation as a "clock" to date divergence times in plant evolution. The fascination stems from the fact that we presently have no satisfactory understanding of the biochemical and genetic bases of such rate heterogeneities. In conclusion, cpDNA is in general both conservative and predictable in its evolution, features which make it extremely useful for inferring phylogeny but of concomitantly lesser interest from the standpoint of molecular evolution. However, aspects of its evolution (not only differences in substitution rates, but also such remarkable mutations as the transfer of its genes to the nucleus) provide grist for the mill of the molecular evolutionist.

RIBOSOMAL DNA VARIATION WITHIN AND AMONG PLANT POPULATIONS[1]

Barbara A. Schaal[2] *and Gerald H. Learn, Jr.*[2,3]

ABSTRACT

The DNA sequences that code for the 17S, 5.8S, and 25S subunits of the ribosome have been useful in the study of plant evolutionary biology. The coding sequences are evolutionarily conservative and have provided information on systematic relationships among the species within a genus and have also elucidated higher level relationships. The intergenic spacer region of the sequence is highly variable, and variation occurs within populations and individuals. Analysis of intra- and interpopulation variation in rDNA has documented subdivision within populations of Clematis fremontii *and population and subspecific differentiation in* Phlox divaricata. *These studies indicate that rDNA provides a good genetic marker for the study of microevolutionary processes.*

Many of the current questions in population biology center on the levels of genetic variability within populations and on the factors that influence genetic variation. Levels of genetic variability are central to the study of population biology and evolution because the amount of variability directly influences the evolutionary potential of populations and species. Much attention has been given to the problems of measuring genetic variation for different features, such as morphology, life-history traits, chromosomes, and various types of molecules (e.g., Lewontin, 1974).

In recent years, a predominant technique for examining genetic variation has been allozyme electrophoresis. This technique has greatly expanded our understanding of the genetic processes that occur in plant species, and without it we would have information on the genetic structure of only a handful of noncultivated species. In spite of its usefulness and widespread application, there are some well-known limitations. Most frequently, only genes of a single class, those encoding soluble enzymes, are analyzed, and they often are selected on the basis of the ease of their products extraction and ability to migrate on a starch gel. Only nucleotide differences in genes that lead to changes in product amino acid composition can be detected, and then detection is usually limited to those changes in amino acid composition that result in a net change in charge of the product molecule. These genes may not be representative of the genome in general. For instance, there is evidence that many commonly studied allozymes are more variable than other categories of gene products, and that this variability may stem in part from such processes as post-translational modification (Johnson, 1979). Moreover, changes in allele migration were thought to result from single codon changes; in fact, differences may be the result of several changes in DNA structure (Sachs et al., 1986). Many of these concerns can be avoided if DNA that encodes different types of genes is analyzed.

Plant DNA is relatively simple to extract and purify, and DNA representing different portions of the genome can be studied by hybridization to cloned probes. In addition, current techniques of DNA analysis are many times more sensitive to changes in gene structure than are other macromolecular assays. Variation in fine structure can be detected at several levels: in nucleotide sequence, in sequence length, and in gene copy number. Finally, current DNA technologies are straightforward and require only small amounts of tissue. It is thus feasible to analyze the large numbers of individuals required for populational studies. The use of restriction site and sequence data offers

the potential to reexamine once-problematic aspects of population biology. Accurate measures of genetic variation in specific portions of the genome, determination of the amount of genetic change associated with speciation, and assessment of the amount of somatic variation and its influence on population variation are examples of areas where DNA data can provide new insights.

Populational analysis offers new insights into molecular biology as well, for example, in the study of concerted evolution. Concerted evolution takes place when the members of a multigene family are more similar to each other than expected had they evolved independently from the time of the initial gene duplication that gave rise to the multigene family (Zimmer et al., 1980; Arnheim, 1983). If concerted evolution were not occurring, each individual would have a large amount of variation among the copies of a multigene family; virtually none of the copies within an individual would be the same. Early DNA hybridization studies and subsequent populational analysis indicated that this is clearly not the case for ribosomal DNA (rDNA). Most of the rDNA copies within an individual are much more similar than would be expected had they evolved independently of one another (a limited amount of variation is seen within individuals, see below, but most rDNA repeats in an individual contain very similar sequences). It is thought that gene conversion, unequal crossingover, or a combination of these are likely responsible for concerted evolution of ribosomal genes. The balance of the processes governing both concerted evolution and the turnover of multiple copy DNA families (Dover, 1982, 1987; Dover & Flavell, 1984) and their interaction with population level phenomena (e.g., gene flow, genetic drift, and organismal selection) are complex and require much additional study. The pattern of variation in specific DNA sequences within and among populations will provide information on the pattern of molecular changes among rDNA repeats.

In the following we will examine variation in DNA sequences within and among populations of plant species. Our purpose is two-fold: to quantify the type and levels of variation at specific DNA sequences and to relate levels of variation to populational features. We will concentrate on one specific DNA sequence, ribosomal DNA, that has received a great deal of attention from molecular biologists and, most recently, population biologists. Before turning our attention to ribosomal DNA variability, we will discuss the structural and functional aspects of rDNA that affect levels of variation.

STRUCTURE AND FUNCTIONAL ASPECTS OF rDNA

Ribosomal DNA is a mid-repetitive sequence with from 500 to more than 40,000 copies per genome arranged in tandem repeats (Long & Dawid, 1980; Rogers & Bendich, 1987a). Ribosomal gene repeating units are composed of a number of regions that vary in functional constraint and, consequently, in evolutionary rate (for a review see Gerbi, 1986). Figure 1 shows the segments of the rDNA that will be discussed here. Each rDNA repeat contains a transcription unit (a through f), from which the rRNA precursor (pre-rRNA) is transcribed, and a so-called nontranscribed (or intergenic) spacer (g) between the transcription units of adjacent repeats. The pre-rRNA is cleaved after transcription into the mature rRNAs: the 17S (b), 5.8S (d), and 25S (f). The sequences of the rDNA that correspond to the mature rRNAs are the coding regions. The 5′ leader sequence (a) is the external transcribed spacer (ETS). The internal transcribed spacers separate the 17S, 5.8S, and 25S RNA coding sequences (ITS-1 [c] and ITS-2 [e], respectively). The pre-rRNA is transcribed and processed into the various rRNAs. Ribosome subunits are assembled from these gene products along with the 5S rRNA and the ribosomal proteins.

The different evolutionary rates observed for the various regions of rDNA is a likely reflection of the differences in the functional constraints that govern these regions. Portions of the coding regions have a high degree of evolutionary conservation, being invariant in all organisms examined to date. The nontranscribed spacer (NTS), on the other hand, diverges among closely related taxa. Other regions of the repeat show a range of intermediate rates. The rates of divergence determine a specific sequence's utility for studying the variation among populations or higher taxonomic levels. We will review the functions of the various coding and noncoding regions and then discuss the sorts of variation seen for portions of the rDNA repeats in plants.

CODING REGIONS

The coding regions, segments of the rDNA repeat ultimately incorporated into the cytoplasmic ribosomes, are expected to vary the least. Although this is true as a rule, limited variability is possible because of a range of functional constraints. Selection appears to act to conserve functionally important secondary structure (Wheeler & Honeycutt, 1988). Higher amounts of variation at the sequence level are seen among closely related taxa

FIGURE 1. *rDNA repeat unit organization. The line corresponds to the nontranscribed spacer region (g), while boxes (hatched or filled) represent the transcribed portion of the gene. Filled boxes represent the coding regions for the 17S (b), 5.8S (d), and 25S (f) rRNAs. Hatched boxes symbolize the transcribed spacers, the external (ETS, a) and internal (ITS-1, c, and ITS-2, e). The repeating structure of these genes is represented by the adjacent ETS (a') and 17S region.*

for the portions of the rRNAs constituting the helical 'stem' portions of the molecule. Changes may occur by compensating substitutions, in which base-paired nucleotides in opposite strands of the helix change 'in response' to one another. A degree of mismatch is apparently tolerated. Presumably occasional mismatches may slow down the rate of formation of stem and loop structures without preventing the formation of the helix. In addition to guanine-cytosine and adenine-uracil pairing, pairing between guanine and uracil is possible and does not inhibit helix formation. Furthermore, even short stretches of one or a few nucleotides of mismatch do not prevent formation of helical structure as long as they are flanked by regions of base complementarity. The most conserved sequences are in single-stranded regions (Wheeler & Honeycutt, 1988). These sequences either act enzymatically or bind to proteins (either ribosomal proteins or protein translational cofactors) or other RNAs (tRNAs and mRNAs).

Some stretches of rRNA sequence do not vary in any organism for which the sequence is known. At the other extreme, portions of the large ribosomal RNA are either variable within an individual (Gonzalez et al., 1985) or present in some species of a genus but are lacking in others (Chan et al., 1983; Hadjiolov et al., 1984). Although the evolutionary dynamics of these changes is not understood, obviously there is polymorphism within populations for rRNA coding region variants. Most studies of rDNA variation analyze restriction endonuclease sites, and little variation has been reported for sites within coding regions. Sequence analysis would be much more sensitive for detecting variation, but with the exception of Gonzalez et al. (1985), most rDNA sequences are known for only a single gene copy of each species. The expected level of variation is too low to justify such a currently expensive and labor-intensive survey.

TRANSCRIBED SPACER REGIONS

The transcribed spacer regions are the portions of the rRNA transcription unit that are not seen as mature rRNAs. They show intermediate levels of variability in interspecific studies (Appels & Dvorak, 1982b; Sytsma & Schaal, 1985; Hillis & Davis, 1986; Davis, 1986), an observation consistent with the intermediate degree of functional constraint on these sequences. While some portions of the transcribed spacers may act merely as spacer DNA with the length of the sequence being more important than its information content, analysis of ITS sequences shows substantial conservation among moderately closely related species. Presumably this reflects the presence of processing signals, for which a degree of conservation is expected. Sequence conservation is also seen for portions of the ETS, again presumably due to processing signals in this region. In addition, it has been postulated that the intermediate level of conservation in transcribed spacer regions may reflect RNA-mediated gene conversion; Appels & Dvorak (1982b) suggested that the conservation seen for rDNA may be due in part to 'correction' from the rRNA transcript of differences among ribosomal gene copies within the same nucleolus.

NONTRANSCRIBED SPACERS

This region between adjacent transcription units is in fact transcribed to a degree, so it is becoming apparent that this term is a misnomer. Transcription proceeds from the 5′ transcription unit, through the spacer, to the initiation site of the adjacent repeat; these transcripts are rapidly processed to the rRNA precursor and the ephemeral nature of NTS transcripts led to this region being so-named. The NTS is the most rapidly evolving portion of the rDNA. Since it shows the greatest amount of variation within and among plant populations, it is the region most useful as a genetic marker for analyzing microevolutionary processes. The dynamics of molecular evolution in the nontranscribed spacers in plants have begun to be elucidated recently. From sequencing studies (Appels & Dvorak, 1982a; Yakura et al., 1984; Lassner & Dvorak, 1986; McMullen et al., 1986; Toloczyki & Feix, 1986) and other fine-scale genetic analyses (Appels & Dvorak, 1982b; Rogers et al., 1986), it appears that the NTS consists of at least three regions that may differ in function and may evolve at different rates.

A series of subrepeating elements in the nontranscribed spacers is seen in all higher eukaryotes for which the sequence is known. In addition, the presence of subrepeats in a number of plant species is inferred from length variability in the NTS (e.g., Cluster et al., 1984, reviewed by Rogers & Bendich, 1987a). A degree of sequence similarity has been demonstrated between NTS subrepeats of wheat (Appels & Dvorak, 1982a) and maize (McMullen et al., 1986; Toloczyki & Feix, 1986). This presumed conservation has been interpreted as evidence that the subrepeats have a function. It has been demonstrated that one class of subrepeating elements acts as enhancers of transcription in *Xenopus* (Reeder et al., 1983; Reeder, 1984), and evidence suggests that some types of subrepeats function similarly in plants (Flavell & O'Dell, 1979; Martini et al., 1982; Flavell, 1986).

No function has been demonstrated for the region of the NTS 5′ to the presumed enhancer subrepeats. This sequence is 144 base pairs in maize (Toloczyki & Feix, 1986) and at least 241 bp in wheat (Lassner & Dvorak, 1986) but may be considerably longer in other plant taxa. The region 3′ to the enhancer subrepeats is 135 to 240 bp in maize (McMullen et al., 1986; Toloczyki & Feix, 1986); in wheat it is considerably less than 960 bp (Lassner & Dvorak, 1986). This region is assumed to contain the promoter for transcription of the pre-rRNA. Although the NTS is presumed to code for no gene products, there is good evidence for functional constraints, and the NTS is therefore potentially subject to selectional forces. It is not clear how strongly these constraints govern the evolution of the NTS region of the rDNA multigene family, but they clearly differ from those governing evolution of the coding regions (see Jorgensen, this volume, for further discussion).

VARIATION AMONG INDIVIDUALS OF A POPULATION

Because of these differences in the levels and kinds of functional constraints, variation of rDNA is very different for the transcription unit versus the so-called nontranscribed spacer. In general, within a species there appears to be only little variation in the coding regions. Such variation appears to be predominantly developmental variation due to methylation (see Jorgensen & Cluster, this volume). We will concern ourselves here with variation in the nontranscribed spacer region. When the individual plants within a population show some type of rDNA variation, it is within this region. Length variation is most common and is due to a series of repetitive elements in the nontranscribed spacer region. In *Triticum* spp. and *Vicia faba*, length heterogeneity is due to copy number differences of a series of 135-bp or 325-bp elements, respectively (Appels & Dvorak, 1982a; Yakura et al., 1984). A variable number of copies of the same or highly similar DNA sequence gives rise to the different length classes.

Because rDNA is a repetitive DNA sequence within the genome, individuals can contain several different length variants. A single *V. faba* plant can have up to 20 different length variants of rDNA (Rogers et al., 1986). Native populations of *Lupinus texensis* contain plants with up to 11 length variants, although most commonly there are three or four variants per plant (D. Baum, pers. comm.). In *Phlox divaricata*, the mean number of repeats per plant is 1.98 (Schaal et al., 1987). *Clematis fremontii* has an average of 2.65 variants per individual (Learn & Schaal, 1987), whereas *Hordeum spontaneum* contains on average 2.28 variants per plant (Saghai-Maroof et al., 1984).

Such length variation is not ubiquitous. *Solidago altissima* is highly variable in the nontranscribed spacer region but this variability is limited almost exclusively to restriction site variation (Schaal et al., in prep.). Length variation is restricted to a 300-bp insertion present in low frequency within some populations. Table 1 shows the variation in restriction sites of *S. altissima*. Variation of rDNA occurs often within individual plants. Plants are most commonly polymorphic for rDNA variants that have different restriction sites. Another feature of *S. altissima* rDNA is the genetic differentiation among portions of a clone. Several plants showed variation in rDNA types within a clone for variants based on different *Eco*RI or *Eco*RV restriction sites. Such within-clone differences may occur via somatic mutation or rapid increase of a rare variant. The occurrence of variation within plants adds a level of analysis not previously possible in populational studies.

Other species show no rDNA variability. *Rudbeckia missouriensis*, an endemic of isolated rocky habitats in Missouri and Arkansas, shows no length heterogeneity nor does it show restriction site variation in a survey of six populations of glade habitats (L. King, pers. comm.). *Gaura demareei*, a hybrid-derivative species with a narrow range, contains two length variants of 10.5 and 11.3 kb. Each plant examined in a survey throughout its range was identical for the two length variants (Schaal & Raven, in prep.). Moreover, there was no restriction site variation. Similarly, species of the

Lisianthius skinneri complex show little restriction site variation or length heterogeneity (Sytsma & Schaal, 1985).

At this time no clear correlations emerge between levels of rDNA length variability and characteristics of the population biology of various species. In the three cases where no variation is observed, the species are narrowly endemic. The *R. missouriensis* populations are isolated, although population size can be in the thousands. *Gaura demareei* has a highly restricted species range, occurring predominantly within a single Arkansas county in populations often fewer than 50 individuals. Likewise, *Lisianthius* species have a very narrow range and often consist of few populations with low plant numbers. On theoretical grounds one expects that narrowly endemic species would have little variation, due to genetic bottlenecks. Variation would be expected to be lost due to sampling, in these cases either by small population size, by founder events due to repeated colonizations, or by a recent species origin after hybridization. The generation of length heterogeneity may not occur very rapidly in these species since none of them have accumulated variation; even *R. missouriensis*, where number of individuals per population is high, remains depauperate for rDNA length variation.

In marked contrast to the results obtained for *R. missouriensis* are the levels of variation detected in *Clematis fremontii*. Populations of *Clematis fremontii*, like the *Rudbeckia*, occur on islandlike glades in Missouri. These populations are predominantly limited to two counties and are often much smaller in population number than *R. missouriensis*. On theoretical grounds one would expect *C. fremontii* to show less variation than *R. missouriensis*, but this is not the case. The *Clematis* plants contain up to four length variants, and the length variation shows spatial differentiation (see below). Thus, there is no consistent pattern here between ribosomal DNA variation and population size or species range (but see Flavell et al., 1986). Since the two species with the greatest observed length heterogeneity are both legumes (*Vicia faba* and *Lupinus texensis*, see above), one might suspect that something in the ancestry or in the biology of legume species leads to such high numbers of rDNA length variants, but length heterogeneity is not great in some other legume species (soybean and its relatives, Doyle & Beachy, 1985; other *Vicia* species, Rogers & Bendich, 1987b). Clearly, much more research is necessary before associations between levels of rDNA length variation and populational characteristics, such as gene flow, population size, breeding system, or founder events can be established.

A further aspect of rDNA variation within populations is apportionment and distribution in space. One feature that distinguishes many plant populations from most animal populations is the frequent occurrence of genetic population substructure in the former. Plant populations often show significant local genetic differentiation, many times on a microgeographic scale. Such local differentiation can result from selection on a very local scale. Local differentiation may also occur via genetic drift. Such drift can be the consequence merely of nonrandom mating due to restricted pollinator behavior or to limited seed dispersal—spatially restricted gene flow causes the population to become effectively subdivided. Random genetic drift occurs among the subdivisions, thus leading to significant local genetic heterogeneity (Turner et al., 1982). Local differentiation within plant populations has been documented for genes that cause heavy metal tolerance (Jain & Bradshaw, 1966), that result in different flowering times (McNeilly & Antonovics, 1968), that cause morphological differences (Linhart, 1974), and that encode different allozymes (Schaal, 1975).

Our study of *Clematis fremontii* has documented nonrandom geographical distribution of ribosomal DNA variants within populations. A single population of *Clematis fremontii* has been analyzed for spatial variation in the frequency of rDNA-length variants. Many of the length variants that

occurred in high frequency showed no significant spatial differentiation (Fig. 2A). However, two of the variants showed statistically significant microgeographic differentiation; the variants do not tend to be distributed randomly in space within the population, but rather are confined to specific areas within it (Figs. 2B, C). Such local differentiation of rDNA variants is consistent with population subdivision due to restricted gene flow, or perhaps it may be a consequence of a recent origin or dispersal of an rDNA variant into a population.

VARIATION AMONG POPULATIONS

Few studies have examined the pattern and apportionment of rDNA variants among the populations of a species. Most of the work to date has centered on cultivated species and is reviewed in Appels & Honeycutt (1986). Here we look at levels of variation in natural, noncultivated plant species. Levels of differentiation for rDNA variants vary among populations of a species. Some plant species show no significant heterogeneity within or among populations. Those species having low levels of rDNA variation within populations show little or no differentiation among populations. No significant genetic differences in rDNA types were detected among populations of *Gaura demareei*, *Rudbeckia missouriensis*, or members of the *Lisianthius skinneri* complex. Judging from their ranges and/or other determinations of genetic variability, it is likely that these species have undergone genetic bottlenecks and variation has been lost within and between populations. In the few highly variable examined species, significant genetic heterogeneity is detected among populations.

The best-studied example to date is the widespread woodland perennial *Phlox divaricata* (Schaal et al., 1987), in which there is clear differentiation of rDNA variants. Populations often contain unique rDNA variants and may be distinguished by the number of variants (2–6) they contain (Schaal et al., 1987). There is clear differentiation between population systems. *Phlox divaricata* subsp. *laphamii* shows less rDNA diversity than subsp. *divaricata*. The subspecies differ in the numbers and types of variants they contain, and in the overall genetic diversity (Table 2).

The variation in *Phlox divaricata* provides corroborative information on the origin of the subspecies. Based on morphological criteria, subsp. *laphamii* is considered derived from subsp. *divaricata*. This hypothesis appears to be supported by the apportionment of rDNA variation; rDNA variability in subsp. *laphamii* is a subset of the variability seen in the other, more widespread subspecies.

Variation among populations also has been analyzed in the old-field perennial *Solidago altissima* (Schaal et al., in prep.). Differentiation in this species occurs for a 200-bp sequence which is fixed in one population and is present in low frequencies in other populations. Populations are also differentiated for restriction sites. As with intrapopulation variation, too few species have been analyzed to draw conclusions about levels of rDNA variation and such populational characteristics as size, gene flow, or bottlenecks. Clearly, populations are differentiated for levels and kinds of rDNA variation. Whether the differentiation is related to selection, genetic drift, gene flow, or any other population-level genetic process remains to be determined. Although the mechanisms responsible for generating rDNA length variation obviously require further study, such variants can and have been used to reconstruct aspects of the evolutionary history of plants (see also Sytsma & Schaal, 1985; Doyle et al., 1984, 1985).

CONCLUSIONS AND PROSPECTS

The use of DNA sequences in studies of population biology is in its infancy and holds a great deal of potential for understanding processes and answering persistently elusive questions. The ability to assess variation in a wide diversity of DNA sequences is a major technical advance. Virtually any segment of DNA can be studied, whether it is a coding or noncoding sequence, or is single copy,

FIGURE 2. *Frequencies of some rDNA repeat length variants in* Clematis fremontii. *Individuals were sampled from a 160-m transect at Victoria Glade, Jefferson County, Missouri (see Learn & Schaal (1987) for details). Variants A (Fig. 2B) and E (Fig. 2C) show statistically significant local differentiation along the transect.—A. Variant C, 11.3 kilobase pairs (kb). Numbers along the abscissa refer to quadrat position along the transect. The left ordinate and the histogram bars are mean frequency of variant within individuals in a quadrat. The right ordinate and the line are proportion of the individuals within a quadrat bearing a variant C. Variant C is the most common variant in the population and does not show significant local differentiation.—B. Variant A (10.2 kb). Axes as in Figure 2A.—C. Variant E (11.9 kb). Axes as in Figure 2A.*

mid-repetitive, or highly repetitive DNA. In fact, one strategy of population analysis is to clone random portions of the genome, and study variation of restriction sites in these random sequences (e.g., Hofker et al., 1986).

From the studies discussed above, some DNA sequences, specifically segments of rDNA, vary at the appropriate levels for studies of population processes. This is in contrast to other sequences, such as chloroplast DNA, where variation is usually seen at the interspecific or intergeneric level, and is most informative for phylogenetic studies. There are clear differences among individuals and populations in rDNA. An added dimension to studying variation occurs with the use of mid-repetitive sequences, since single individuals contain many copies of a sequence and thus can themselves be polymorphic. Studies of ribosomal DNA provide an additional level of analysis, that of the individual; the apportionment of variation can be examined at the within-plant as well as the between-plant levels.

Another potentially important aspect of rDNA studies is the ability to detect somatic mutations. There currently is much speculation in the literature on the role of somatic mutation in plant population biology (Whitam & Slobodchikoff, 1981; Gill & Halverson, 1984; Walbot, 1985; Walbot & Cullis, 1985). Several workers suggest that somatic mutation and subsequent variation leads to differences in ecological parameters, such as susceptibility to insect predation. It is argued that somatic variation in DNA sequences may have an adaptive function. These ideas are contested, in part because the frequency of somatic variation is not known. With current methods of analyzing DNA sequences, it is possible to document unequivocally the occurrence and frequency of somatic variation.

A final new area where DNA analysis is potentially important for population biology is rapid genomic change. Many organisms alter their DNA in response to stress, as in the case of gene amplification in response to toxic agents (Schimke, 1983). McClintock (1984) suggested that genome change is a way in which plants routinely deal with stress. Walbot & Cullis (1985) suggested that flexibility is an important feature of the plant genome. Genome flexibility has been demonstrated in flax, where heritable variation in rDNA cistron number is induced by environmental changes (Cullis, 1986). Such heritable changes in genome size have profound implications for population biology. Alteration of genomes in response to environmental variation may contribute to the genetic adaptation of a plant species. Such a process can alter the genetic characteristics of populations and, on a practical level, can confound such experiments as reciprocal transplants. There is much future work on the interface between plant molecular biology, population genetics, and ecology; blending among these disciplines promises to add greatly to our understanding of plant evolution.

DNA AND MORPHOLOGY: COMPARISONS IN THE ONAGRACEAE[1]

Kenneth J. Sytsma and James F. Smith[2]

ABSTRACT

Comparisons of systematic information generated from both classical systematic approaches and from DNA analysis at a number of taxonomic levels in the Onagraceae are presented. Phylogenetic results from chloroplast DNA restriction fragment analysis in Clarkia *sect.* Sympherica *(=* Peripetasma*) are not entirely congruent with results from morphology, but are congruent with distribution of duplications of isozyme-coding loci. Chloroplast DNA and nuclear rDNA evidence for the origin of the monotypic genus* Heterogaura *from within the genus* Clarkia *is discussed with respect to morphological divergence between the two genera. Detailed chloroplast DNA restriction site mapping within the seven diploid sections of* Clarkia *and subsequent preliminary intersectional phylogenetic analysis are presented. These DNA-based relationships are compared with a morphological and cytological model of relationships, and to various gene duplication-based models. Section* Godetia *is implicated as the sister group to the rest of* Clarkia, *a result concordant with preliminary cladistic analysis of morphological and isozymic characters. The monophyletic nature of sections encompassing the PGI gene duplication is not rejected or supported by this cpDNA restriction site analysis. Preliminary DNA restriction fragment analysis for the nine previously described sections of* Fuchsia *and one new section is presented and then compared with published biogeographical, fossil, morphological, and cytological results. The preliminary chloroplast DNA analysis in* Fuchsia *indicates that the disjunct Old World sect.* Skinnera *was the first lineage to diverge, followed by the monotypic Central American sect.* Jimenezia. *The phylogenetic relationships of the other sections of* Fuchsia *remain unclear. Comparisons of systematic results using cpDNA restriction site variability and morphological, cytological, and isozymic variability are reviewed for the Onagraceae and other angiosperms.*

Phylogenetic analysis of plants using molecular techniques is increasingly providing detailed and often unexpected evidence of phylogenetic relationships among populations, species, sections, genera, and tribes (Gottlieb, 1977a, b; Gottlieb & Weeden, 1979; Odrzykoski & Gottlieb, 1984; Sytsma & Schaal, 1985a; Sytsma & Gottlieb, 1986a, b; Jansen & Palmer, 1987, 1988; Rieseberg et al., 1988; Soltis et al., in press). A major strength of many of these new molecular techniques—e.g., chloroplast DNA (cpDNA) restriction fragment analysis—is that they provide numerous independent characters that can be used as historical markers to define more rigorously the phylogenetic relationships of the plants (see Sytsma & Gottlieb, 1986b, and Jansen & Palmer, 1988, for examples). Those molecular techniques that provide but a single piece of information, such as analysis of cpDNA inversions or duplications of isozyme encoding genes, are still powerful, since the underlying genetic or structural bases can be clearly demonstrated and the essentially neutral character changes can be argued to be strictly homologous and rare (see Jansen & Palmer, 1987, and Gottlieb & Weeden, 1979, for examples, respectively).

The Onagraceae provide unique opportunities for the application of these "modern" molecular and genetic techniques, especially those involving proteins and nucleic acids. The Onagraceae are a well-defined family of seven tribes, 16 genera, and approximately 650 species (Raven, 1988). An abundant and detailed information base for the family has been generated already using morphology, anatomy, chromosomal features, and flavonoid chemistry. Ongoing systematic studies using proteins, nucleic acids, and formal cladistic analyses that complement the information already available are making the Onagraceae the best-studied plant family of their size (Raven, 1979, 1988).

Given the large information base generated from the more "classical" systematic approaches on Onagraceae, phylogenetic analyses using proteins and/or nucleic acids are especially applicable to the

ANN. MISSOURI BOT. GARD. 75: 1217–1237. 1988.

study of relationships among Onagraceae. First, detailed genotype-based phylogenies can be constructed for taxa within Onagraceae. Second, phylogenies resulting from morphology, anatomy, and other phenotypic characters can be compared with molecular phylogenies to determine which studies are providing similar or congruent phylogenies. This will permit identification of consistently monophyletic lineages in these independent studies. Additionally, certain kinds of characters *might* be viewed with suspicion if they suggest relationships at odds with those provided by other types of characters. Third, incongruencies found among these independently derived phylogenies can point to further research along either of two lines: (1) a reexamination of specific data sets or the techniques themselves to identify possible reasons for the incongruencies (e.g., nonhomologous characters, high levels of homoplasy, rapid or uneven rates of character divergence among lineages, and hybridization/introgression); and (2) reassessment of relationships not previously supported or even suspected with other available information.

The classic series of studies by Gottlieb and his associates using the distribution of isozyme-encoding gene duplications within Onagraceae (Gottlieb, 1977b; Gottlieb & Weeden, 1979; Odrzykoski & Gottlieb, 1984; Soltis et al., 1987) illustrate well how molecular techniques can be used in this fashion. These studies have generated phylogenetic hypotheses, made comparisons with morphologically and cytologically based phylogenies with which they often differ substantially, questioned several models of phylogenetic relationships previously supported by classical studies, and lastly initiated several new and rewarding lines of research (e.g., genetic studies of duplications and subsequent silencings, effects of different isozyme number and activity in plants, and verification of progenitor/derivative species relationships).

In this paper, we use evidence from cpDNA restriction fragment analysis and site mapping to produce phylogenies within Onagraceae, compare these with other molecular and morphological phylogenetic hypotheses, reexamine a number of lineages that are either not supported by molecular evidence or not supported by morphological evidence, and finally raise questions that these cpDNA studies now permit us to ask. Previous cpDNA phylogenetic studies in *Clarkia* sect. *Sympherica* (= *Peripetasma*) and the genus *Heterogaura* (Sytsma & Gottlieb, 1986a, b) will be reviewed and additional nuclear rDNA evidence introduced. Preliminary cpDNA phylogenetic analysis of sectional relationships within *Clarkia* will be described and compared with relationships based largely on morphology, chromosome number, and crossing relationships (Lewis & Lewis, 1955), and to relationships based on gene duplications (Gottlieb & Weeden, 1979; Soltis et al., 1987). Preliminary cpDNA phylogenetic analysis of sectional relationships within *Fuchsia* will be then presented and compared with those described by Berry (1982) and Raven (1979, 1988). Lastly, systematic results of DNA versus morphology will be reviewed in the Onagraceae and other angiosperms.

PHYLOGENETIC ANALYSIS OF *HETEROGAURA* AND *CLARKIA* SECT. *SYMPHERICA*

INTRODUCTION

Clarkia is composed of approximately 44 species, most of which are restricted to California, but with *C. pulchella* Pursh, the type species, confined to the northwest U.S. outside California. The *C. tenella* polyploid complex exhibits a disjunct distribution in California and Argentina and Chile. The largest section of *Clarkia* recognized by Lewis & Lewis (1955) is sect. *Sympherica*, the valid name for the former sect. *Peripetasma* (Holsinger & Lewis, 1986). Section *Sympherica* is comprised of three morphologically well-defined diploid subsections and the tetraploid subsect. *Prognatae*, the latter comprising only *C. similis* Lewis & Ernst, which is believed to be an allopolyploid derived from hybridization between subsects. *Lautiflorae* and *Micranthae* (Lewis & Lewis, 1955).

Relationships within sect. *Sympherica* based on morphology and crossing experiments (Lewis & Lewis, 1955; Davis, 1970) are illustrated in Figure 1. Subsection *Micranthae* consists of one strictly self-pollinating species with small, inconspicuous, and white flowers, whereas subsects. *Sympherica* (three species) and *Lautiflorae* (four species) consist of primarily outcrossing species with large, showy, and colorful flowers. Petals of subsect. *Lautiflorae* are more or less uniform in color with some flecking, whereas petals of subsect. *Sympherica* have distinct areas of color. In addition, subsect. *Lautiflorae* has terete or grooved immature capsules, whereas subsect. *Sympherica* has deeply eight-ribbed immature capsules.

Isozyme analysis challenged certain relationships within sect. *Sympherica*. Odrzykoski & Gottlieb (1984) found that the distribution of gene duplications and subsequent silencings for isozymes of 6-phosphogluconate dehydrogenase (6PGD) indicated that the plastid isozymes are coded by two loci in all diploid species examined except for two

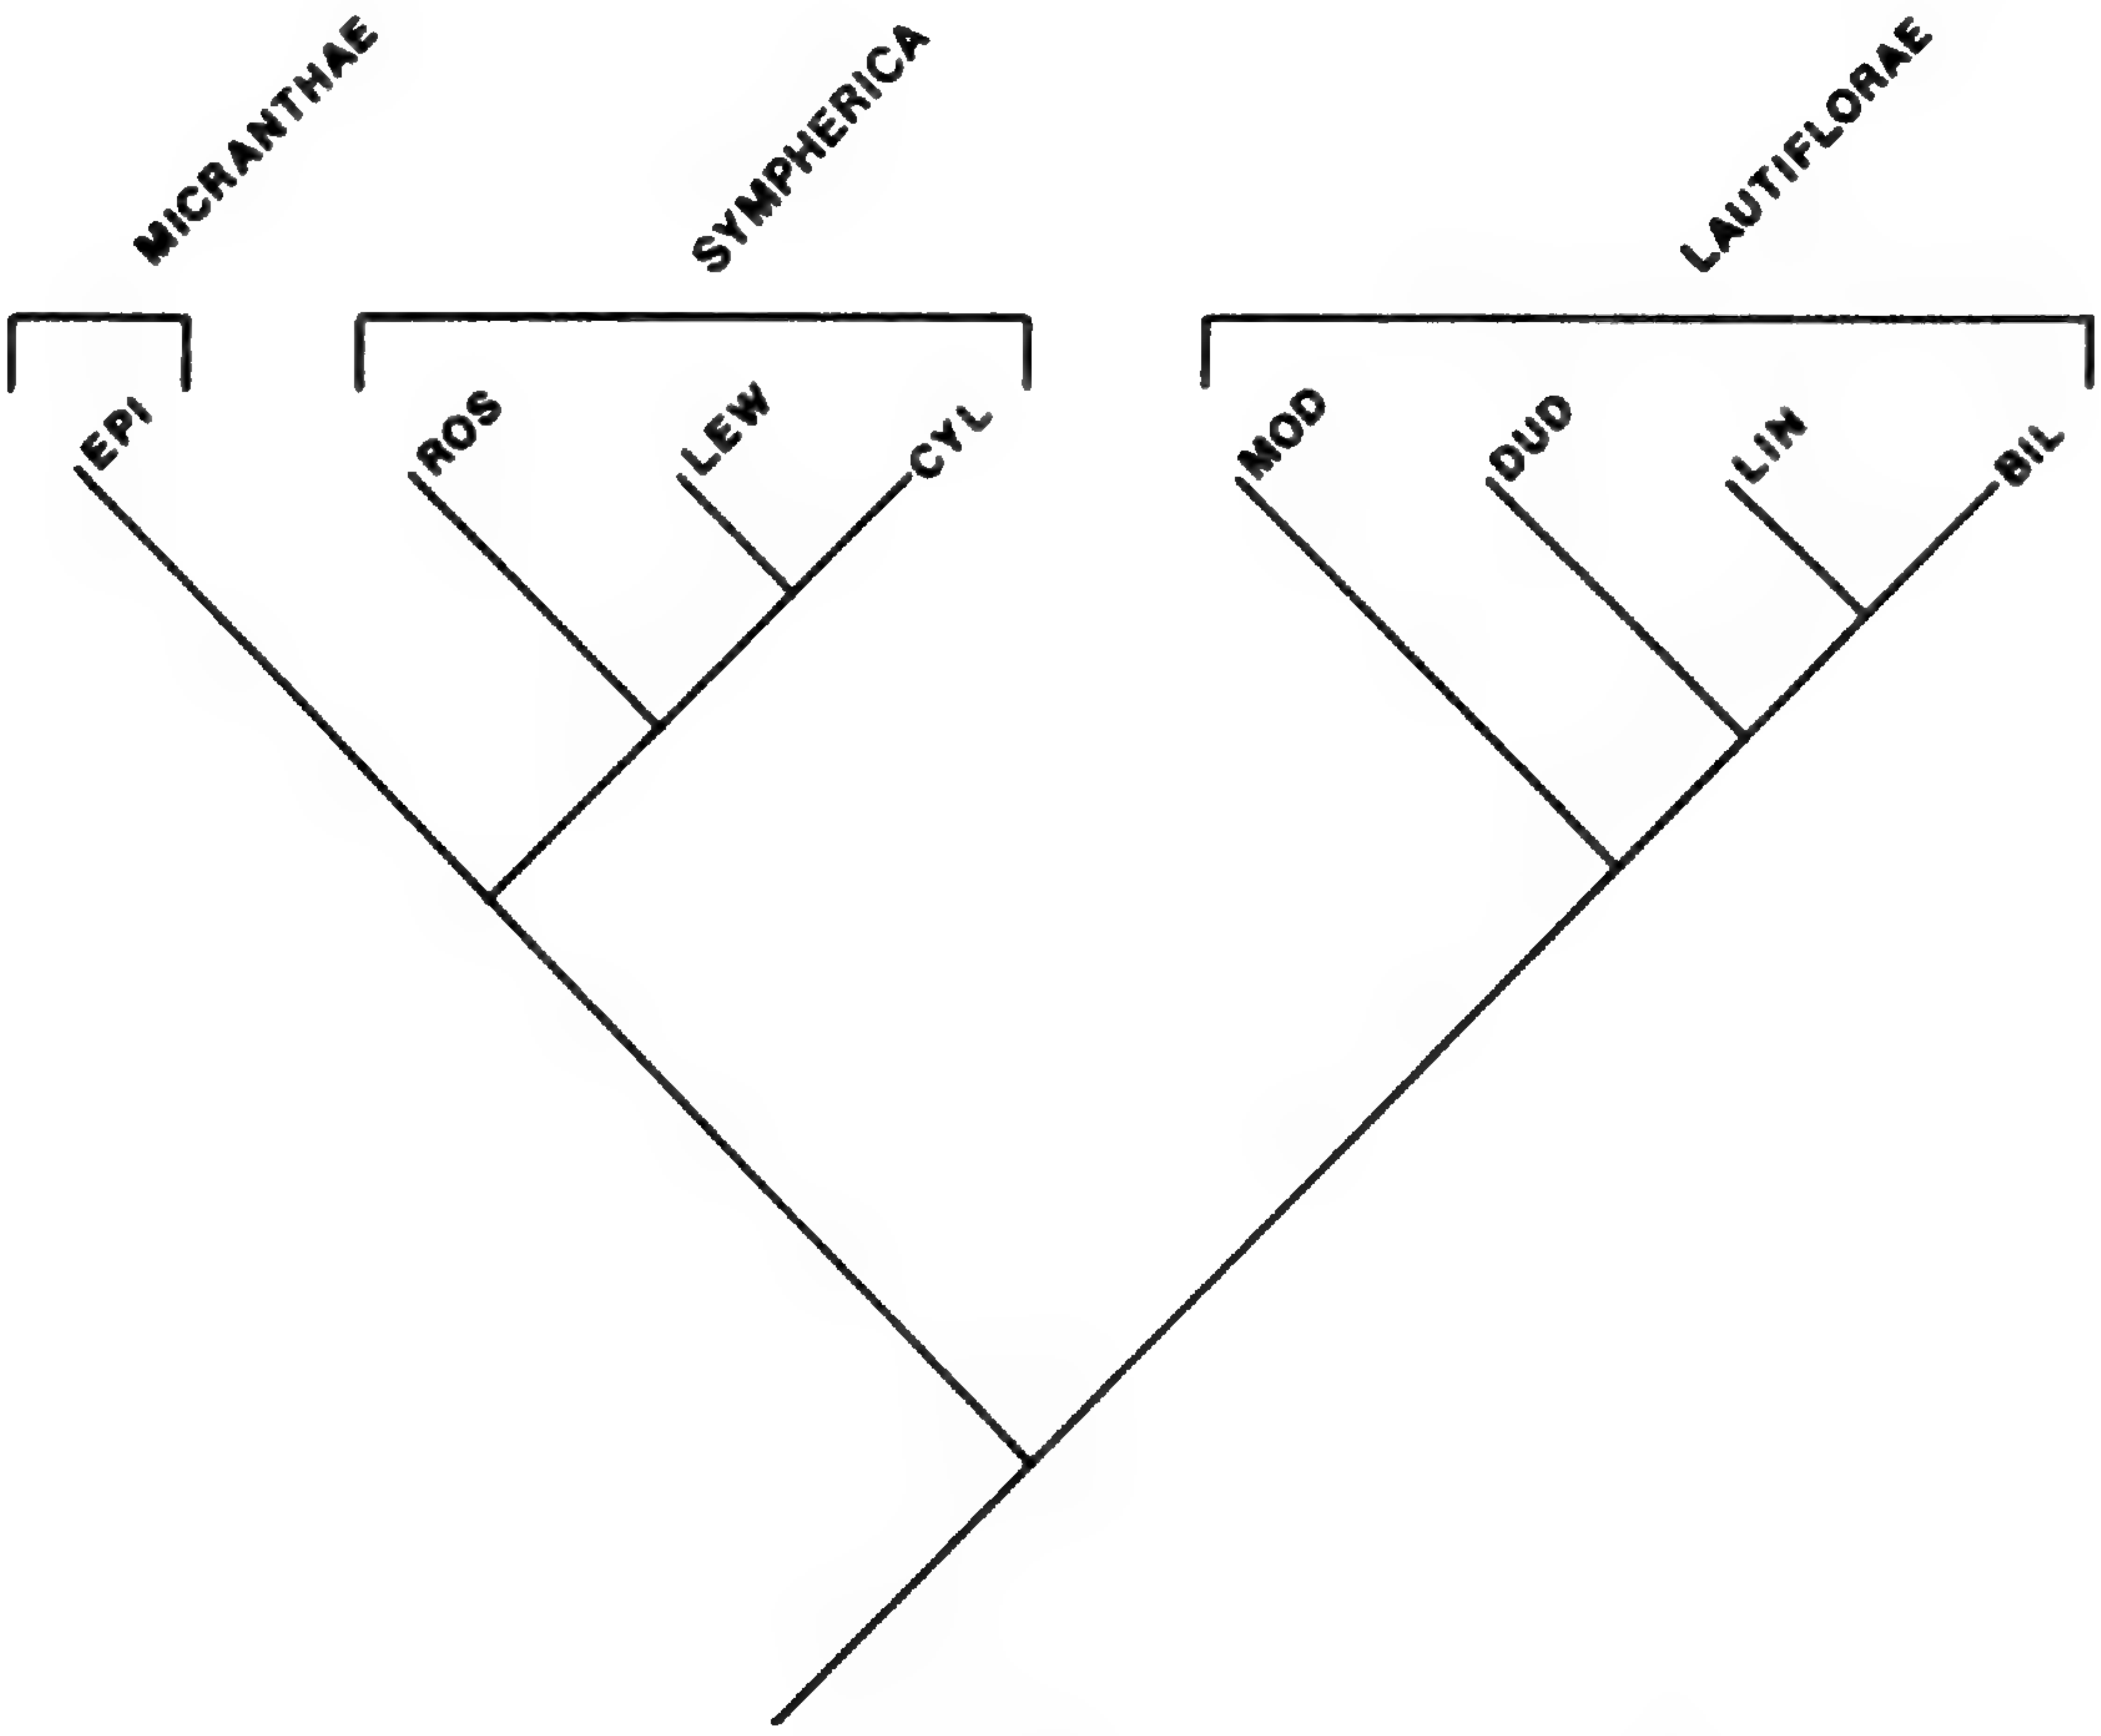

FIGURE 1. *Relationships within* Clarkia *sect.* Sympherica *based on morphological and crossing studies of Lewis & Lewis (1955) and modified after Davis (1970). Subsections are indicated above the species abbreviations.*

species in sect. *Sympherica, C. epilobioides* (Nutt.) Nels. & Macbr. (subsect. *Micranthae*), and *C. rostrata* Davis (subsect. *Sympherica*), which have a single locus coding for the plastid isozymes. In addition, all species of *Clarkia* have a single locus coding for the cytosolic isozyme of 6PGD except for four species of sect. *Sympherica*—*C. epilobioides, C. rostrata,* and the other two species of subsect. *Sympherica, C. cylindrica* (Jeps.) Lewis & Lewis, and *C. lewisii* Raven & Parnell (formerly *C. bottae* (Spach) Lewis & Lewis).

The most parsimonious explanation for the distribution of these character states as suggested by Odrzykoski & Gottlieb (1984) is illustrated in Figure 2. The duplications of the two genes coding the plastid and cytosolic 6PGD isozymes are ancestral in *Clarkia* and retained in the four species of sect. *Sympherica* subsect. *Lautiflorae: C. biloba* (Dur.) Nels. & Macbr., *C. lingulata* Lewis & Lewis, *C. modesta* Jeps., and *C. dudleyana* (Abrams) Macbr. The loss of one of the duplicated cytosolic 6PGDs occurred in the common ancestor of the four species of subsects. *Micranthae* and *Sympherica.* This cytosolic 6PGD loss was then followed by the loss of one of the duplicated plastid 6PGDs in the common ancestor of *C. epilobioides* and *C. rostrata.* Thus, subsect. *Sympherica* is paraphyletic with one species sharing a more recent common ancestor with a species from another subsection than it does with species in its own subsection. This isozyme-based phylogeny clearly contradicts the morphological model in Figure 1 in that *C. rostrata* is placed as the sister species to the distinctive selfer *C. epilobioides* rather than with *C. cylindrica* and *C. lewisii,* species it closely resembles and with which it can experimentally produce fertile hybrids.

A more dramatic difference in results between the classical and molecular techniques was seen when *Heterogaura heterandra* (Torr.) Cov. was used as the outgroup in preliminary cpDNA analysis of sectional relationships in *Clarkia* (see Phylogenetic Analysis of Intersectional Relationships within *Clarkia*). *Heterogaura* is a monotypic genus closely related to *Clarkia,* based on floral morphology, stigma surface, seed coat structure, anther anatomy, and flavonoids (Raven, 1979, 1988; Tobe & Raven, 1985, 1986; Averett et al., 1982). *Heterogaura heterandra* is a strictly self-pollinating annual limited to the slopes of the Sierra Nevada in California and Oregon. It differs markedly from *Clarkia* in having only four fertile anthers (four are sterile), an unlobed stigma, and a round nutlike indehiscent fruit with one or two seeds. In contrast, members of *Clarkia* generally have eight fertile anthers, four-lobed stigmas (although self-pollinat-

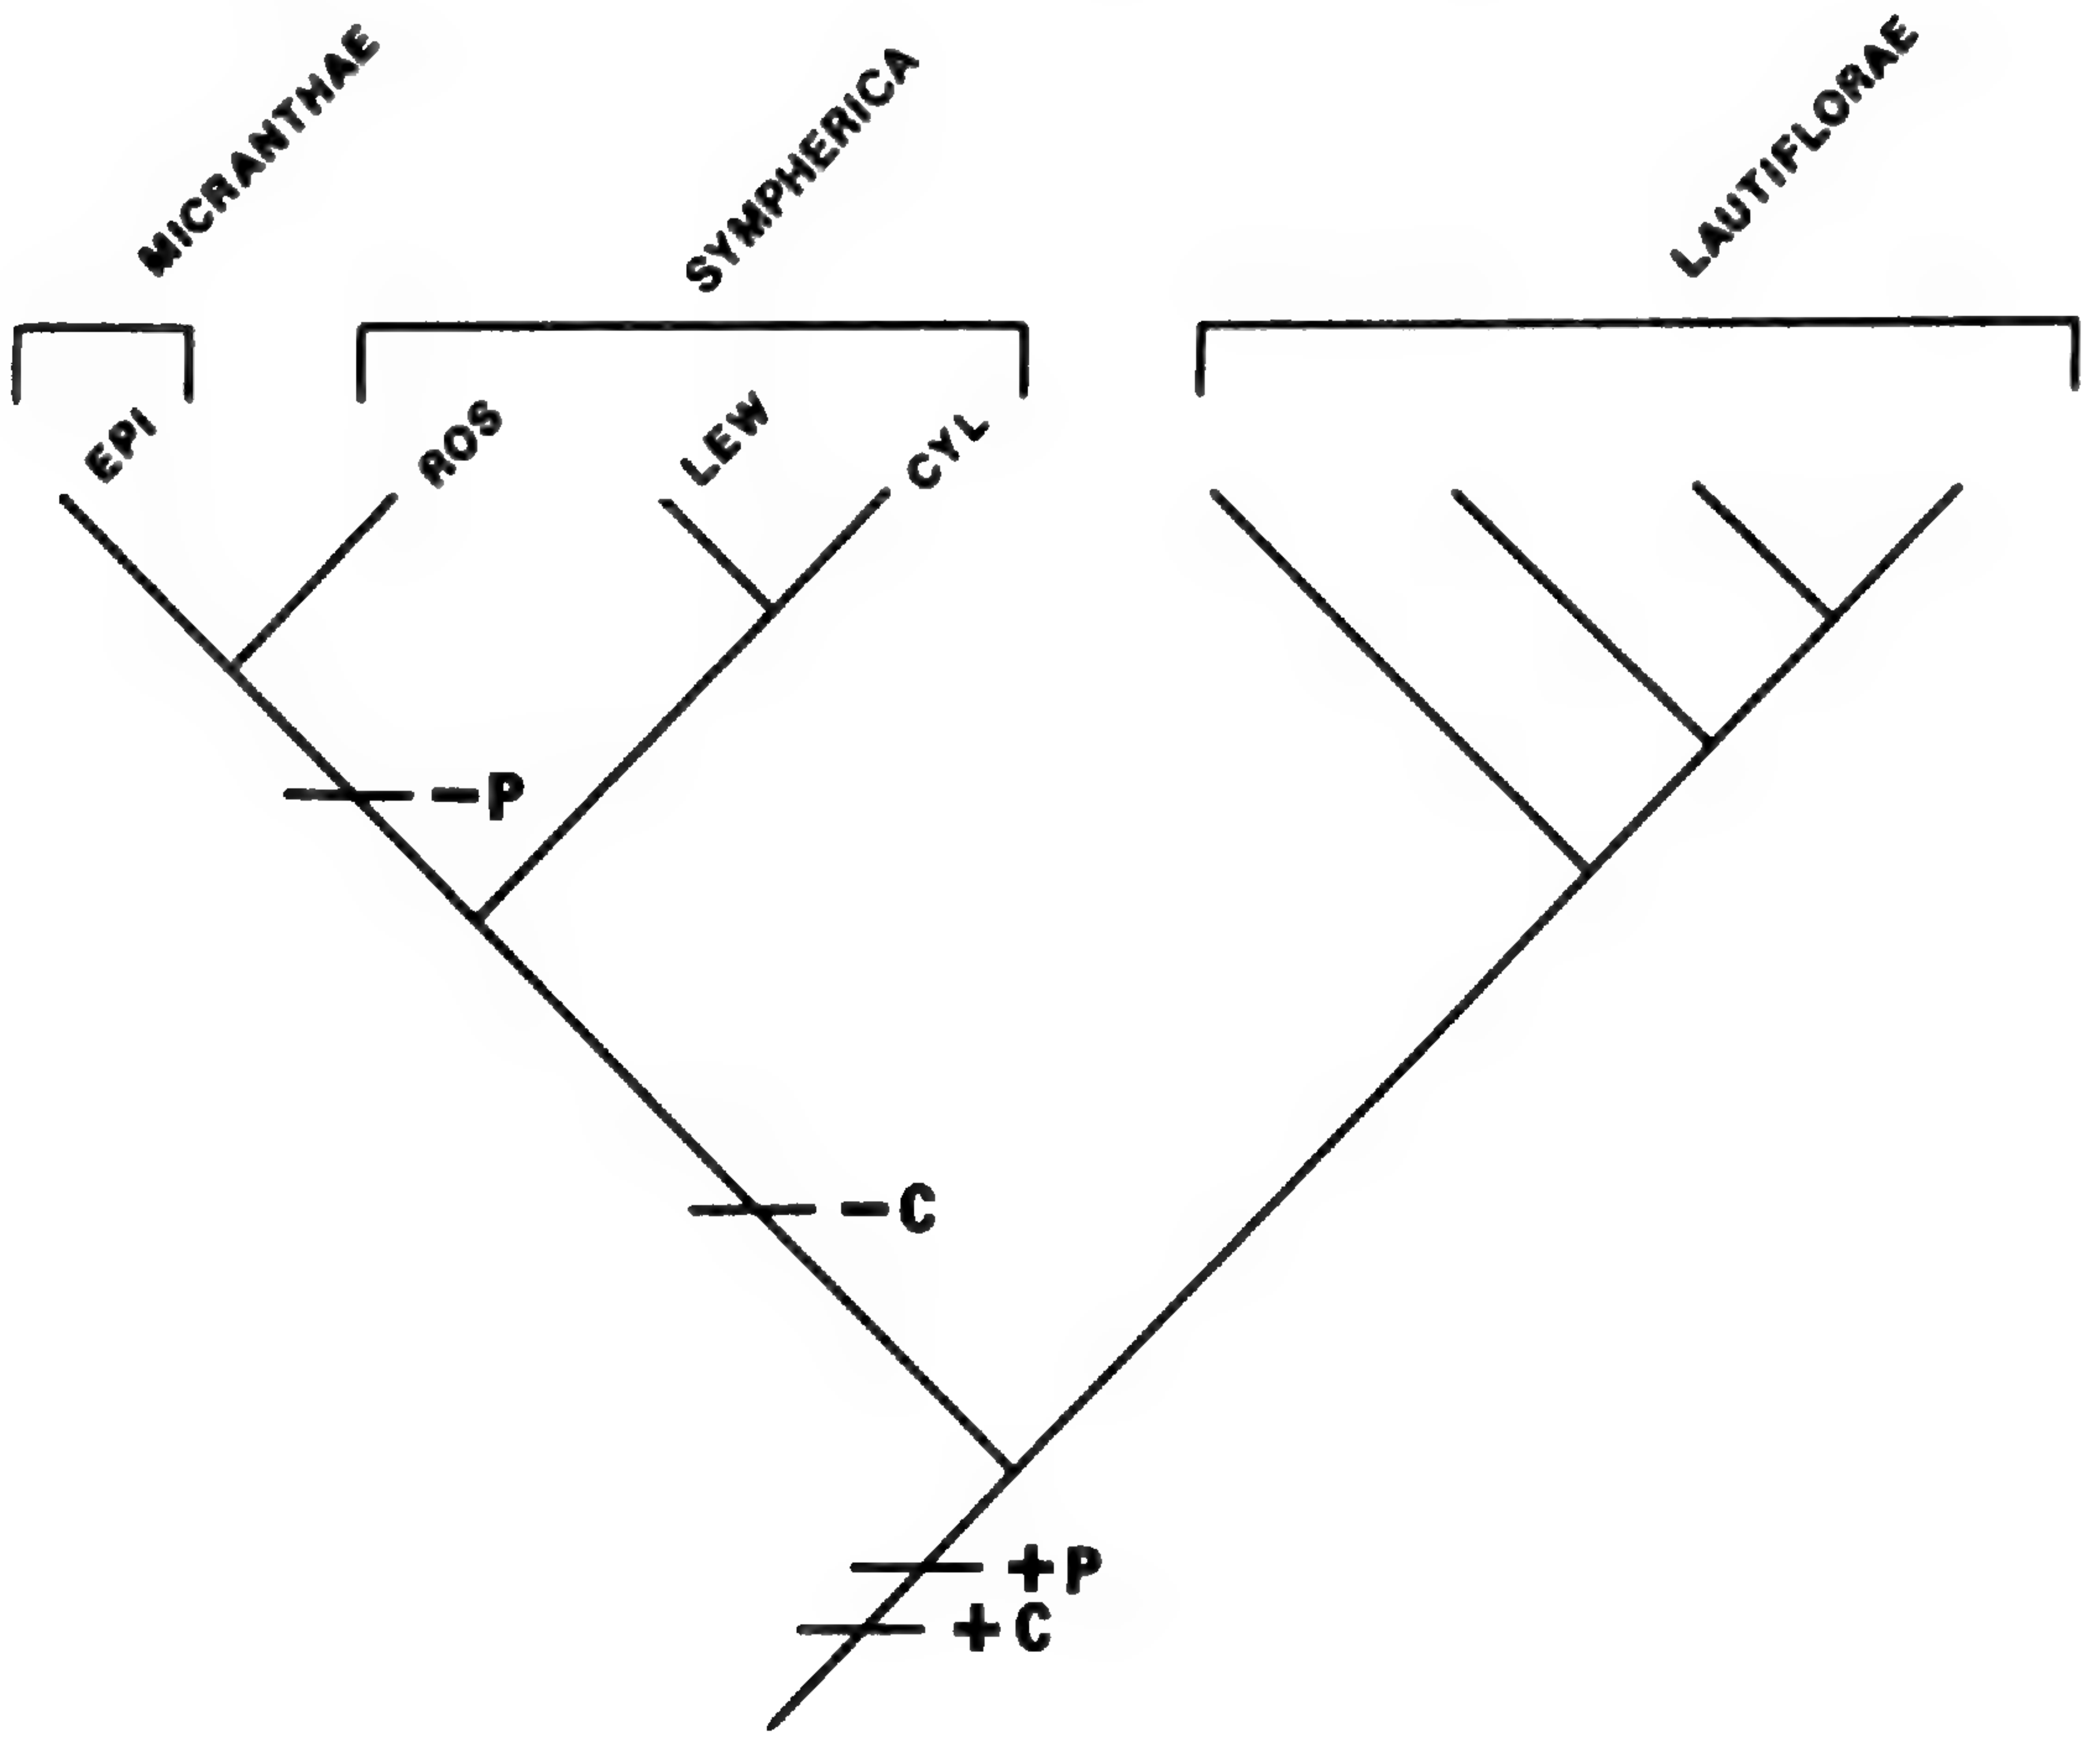

FIGURE 2. *Relationships within* Clarkia *sect.* Sympherica *based on gene number for 6-phosphogluconate dehydrogenase (Odrzykoski & Gottlieb, 1984). ing species have short lobes), and elongated, many-seeded capsules that dehisce along four septa. The floral and fruit differences between the two genera are so distinctive that they have been maintained as separate genera since 1866, when *H. heterandra* was first named.

The long-standing idea that *Heterogaura* is the sister group to *Clarkia* was questioned when it became apparent that restriction fragment analysis of cpDNA indicated that *Heterogaura* was not aligning itself as a basal clade to all of *Clarkia*. Instead, *Heterogaura* exhibited synapomorphies with certain lineages within section *Sympherica* (Sytsma & Gottlieb, 1986a). Section *Sympherica* is relatively advanced in *Clarkia* based on morphology (Lewis & Lewis, 1955) and on the presence of a PGI (phosphogluco isomerase) duplication (Gottlieb & Weeden, 1979). Thus, cpDNA analysis suggested that *Heterogaura* was not an appropriate outgroup for *Clarkia* and, more importantly, indicated that the genus might be derived more recently from within *Clarkia*.

An extensive restriction fragment and site analysis of cpDNA in *Clarkia* sect. *Sympherica* and *Heterogaura heterandra* was initiated to address these discrepancies between the classical results and the results from both isozyme gene duplication and cpDNA restriction fragment analysis (Sytsma & Gottlieb, 1986a, b).

MATERIALS AND METHODS

Seeds of *Heterogaura heterandra* and the eight species of *Clarkia* sect. *Sympherica* were germinated, grown for four to seven weeks, and total DNA extracted using the protocol of Zimmer et al. (1981). Two populations each of *C. biloba*, *C. epilobioides*, *C. lewisii*, *C. modesta*, and *H. heterandra* were assayed; one population was examined for all other species. Only one site difference was seen within a species (*C. biloba*), and this character state was autapomorphic to this one population. *Clarkia xantiana* Gray (sect. *Phaeostoma*) and *C. amoena* (Lehm.) Nels. & Macbr. (sect. *Rhodanthos*) were used as outgroups.

DNAs were digested with 29 restriction enzymes, electrophoresed in agarose gels, and Southern blotted to reusable nylon membrane. The entire clone bank of the *Petunia* (Solanaceae) cpDNA genome was used successively to probe the nylon membranes for homologous cpDNA fragments. Detailed protocols of prehybridization, nick-translation, hybridization, and washes are provided in Sytsma & Schaal (1985a).

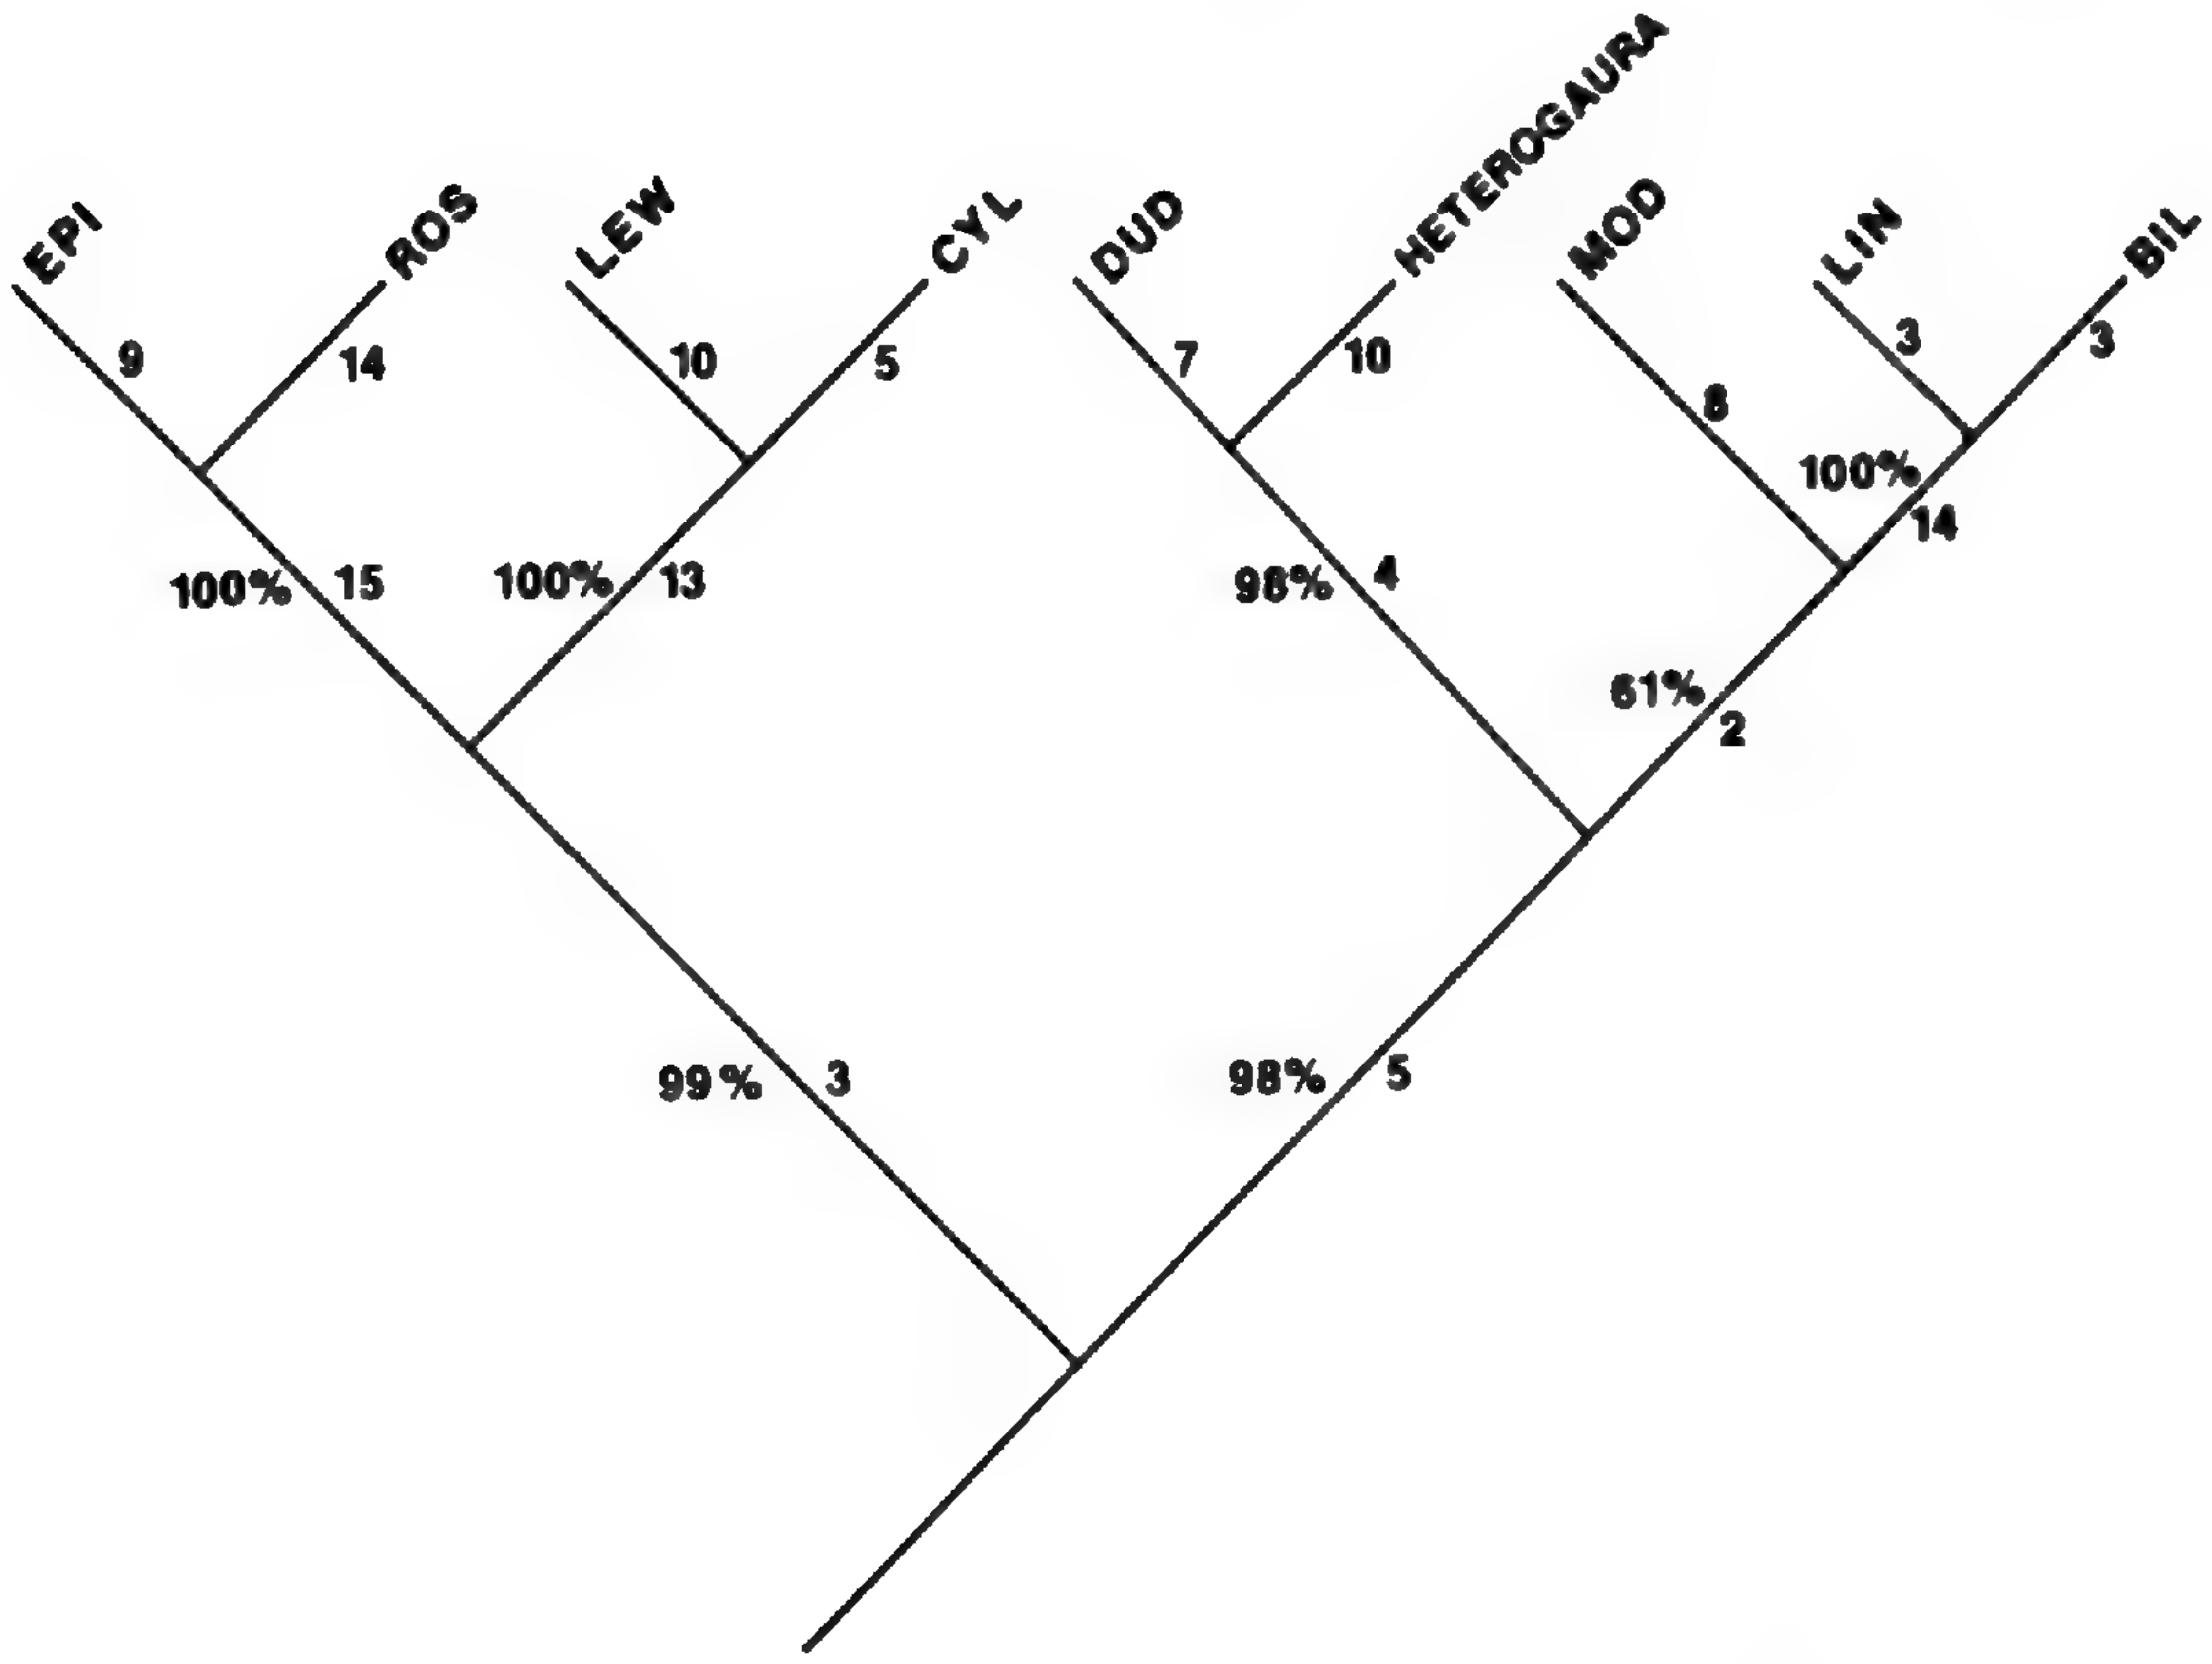

FIGURE 3. *Most parsimonious (Wagner) tree of* Clarkia *sect.* Sympherica *and* Heterogaura heterandra *generated by the "branch-and-bound" option of PAUP. The tree was rooted with* Clarkia xantiana *and* C. amoena. *The tree is 125 steps long and includes two parallel gains, three parallel losses, and one gain/loss. Numbers indicate numbers of restriction site mutations along each lineage. Percentages along branches reflect the number of times that the monophyletic group defined by that branch occurred in 100 bootstrap samples. Based on Sytsma & Gottlieb (1986b).*

Methods of phylogenetic analysis, explained in detail elsewhere (Sytsma & Gottlieb, 1986a, b), included Wagner parsimony (Farris, 1970) (PAUP version 2.4.0, Swofford, 1985), Dollo parsimony (Farris, 1977) (PHYLIP version 3.0, Felsenstein, 1985), and the Fitch & Margoliash (1967) phenetic approach using p values of Nei & Li (1979). Felsenstein's (1985) bootstrap method (in PHYLIP) was utilized to place confidence intervals on resulting phylogenies. A majority-rule consensus Wagner parsimony tree was used to construct a phylogeny indicating all inferred monophyletic lineages determined by bootstrap analysis.

PHYLOGENETIC ANALYSIS AND DISCUSSION

The 29 restriction enzymes used to digest the DNAs recognize approximately 605 restriction sites in each of the cpDNAs. Because all 29 enzymes recognize six base pair sequences, about 3,630 nucleotide base pairs were sampled in each of the species. A total of 119 site changes were documented within *Clarkia* sect. *Sympherica* and *Heterogaura* (these restriction site mutations are listed as table 3 in Sytsma & Gottlieb, 1986b), and 55 of these mutations are shared by at least two but not all members of the ingroup (including *Heterogaura*) and were used as the data matrix in the phylogenetic analyses (Table 1). The PAUP (BANDB option) and PHYLIP (MIX option) programs found a single most parsimonious (Wagner) tree of 125 steps (Fig. 3). This tree requires an additional six steps beyond the 119 site changes to account for the observed variation. The most parsimonious Dollo tree is exactly congruent to the Wagner tree but is four steps longer. The unrooted Fitch & Margoliash network based on nucleotide sequence divergences is topologically congruent to the shortest Wagner tree (see fig. 4 in Sytsma & Gottlieb, 1986b).

The shortest cpDNA phylogenetic tree provides unambiguous evidence for relationships within *Clarkia* sect. *Sympherica*. The cpDNA analysis substantiates Odrzykoski & Gottlieb's (1984) suggestion that *C. rostrata* is indeed phylogenetically closer to *C. epilobioides* than to its morphologically related species, *C. cylindrica* and *C. lewisii*. These results are the first alternative genetic confirmation of phylogenetic relationships based on gene duplication data, and they greatly strengthen the utility of the latter approach in systematics.

Lewis & Lewis (1955) first considered the populations now recognized as *C. rostrata* to be unusual northern members of *C. cylindrica*, but Davis (1970) later separated out *C. rostrata* and indicated that it was more similar to *C. lewisii* than

TABLE 1. *Data matrix of 55 restriction site characters for* Heterogaura heterandra *and the eight species of* Clarkia *sect.* Sympherica. *Outgroup states were determined from examination of* C. amoena *and* C. xantiana. *No autapomorphies are listed. The character state "0" indicates absence of a restriction site and "1" indicates presence of a site. Details concerning each character are presented in Sytsma & Gottlieb (1986b).*

to *C. cylindrica*. Moreover, *C. rostrata* can be crossed successfully with the former but not the latter (Davis, 1970). Davis concluded that the close morphological similarity among these three species of subsect. *Sympherica* suggested a common origin or even the derivation of one species from another. *Clarkia rostrata* is found the farthest north in foothills of the Sierra Nevada in Stanislaus, Merced, and Mariposa counties; *C. lewisii* is found only in the Coast Ranges in Monterey and San Benito counties; and *C. cylindrica* is found farther south and in more xeric habitats along the foothills of the southern Sierra Nevada and Tehachapi Mountains (subsp. *clavicarpa*) and in the southern Coast Ranges (subsp. *cylindrica*) (see Fig. 4). All of the progenitor-derivative species pairs examined in *Clarkia* have indicated that the direction of evolution is from north to south or from mesic to more xeric habitats (Lewis, 1962; Lewis & Roberts, 1956; Lewis & Raven, 1958; Vasek, 1958; Gottlieb, 1974). Because of the northern distribution and wide separation of *C. rostrata* and *C. lewisii* and because of the continuous and more southern distribution of the two subspecies of *C. cylindrica*, Davis (1970) suggested that the former two species may have become restricted in their distribution and perhaps preceded *C. cylindrica* or have been involved in its origin.

The gene duplication and the cpDNA data indicate that the evolutionary events within section *Sympherica* are more complex than data based on morphological similarity and crossing relationships indicate. The similarity between *Clarkia rostrata* and the lineage encompassing *C. cylindrica* and *C. lewisii* strongly suggests that the common ancestor of the lineage comprising these three species plus *C. epilobioides* almost certainly resembled the former three species. Alternatively, strong phenetic convergence in *C. rostrata* towards *C. lewisii* and *C. cylindrica* would have to be invoked. *Clarkia epilobioides* is clearly closely related to *C. rostrata* and exemplifies a lineage that has undergone a tremendous amount of morphological divergence relative to other species. *Clarkia epilobioides* ranges from San Francisco to Baja California and has a disjunct range in Arizona (Fig. 4). Because of its exclusively inbreeding mode of reproduction, but despite its northern (and southern) distribution, it is almost certain that *C. epilobioides* has been derived from an outcrossing taxon and does not represent an ancient lineage as might *C. rostrata* and *C. lewisii*.

CpDNA restriction fragment and site analysis have demonstrated clear phylogenetic relationships among the four extant species of subsects. *Micranthae* and *Sympherica* (Fig. 3). Further studies

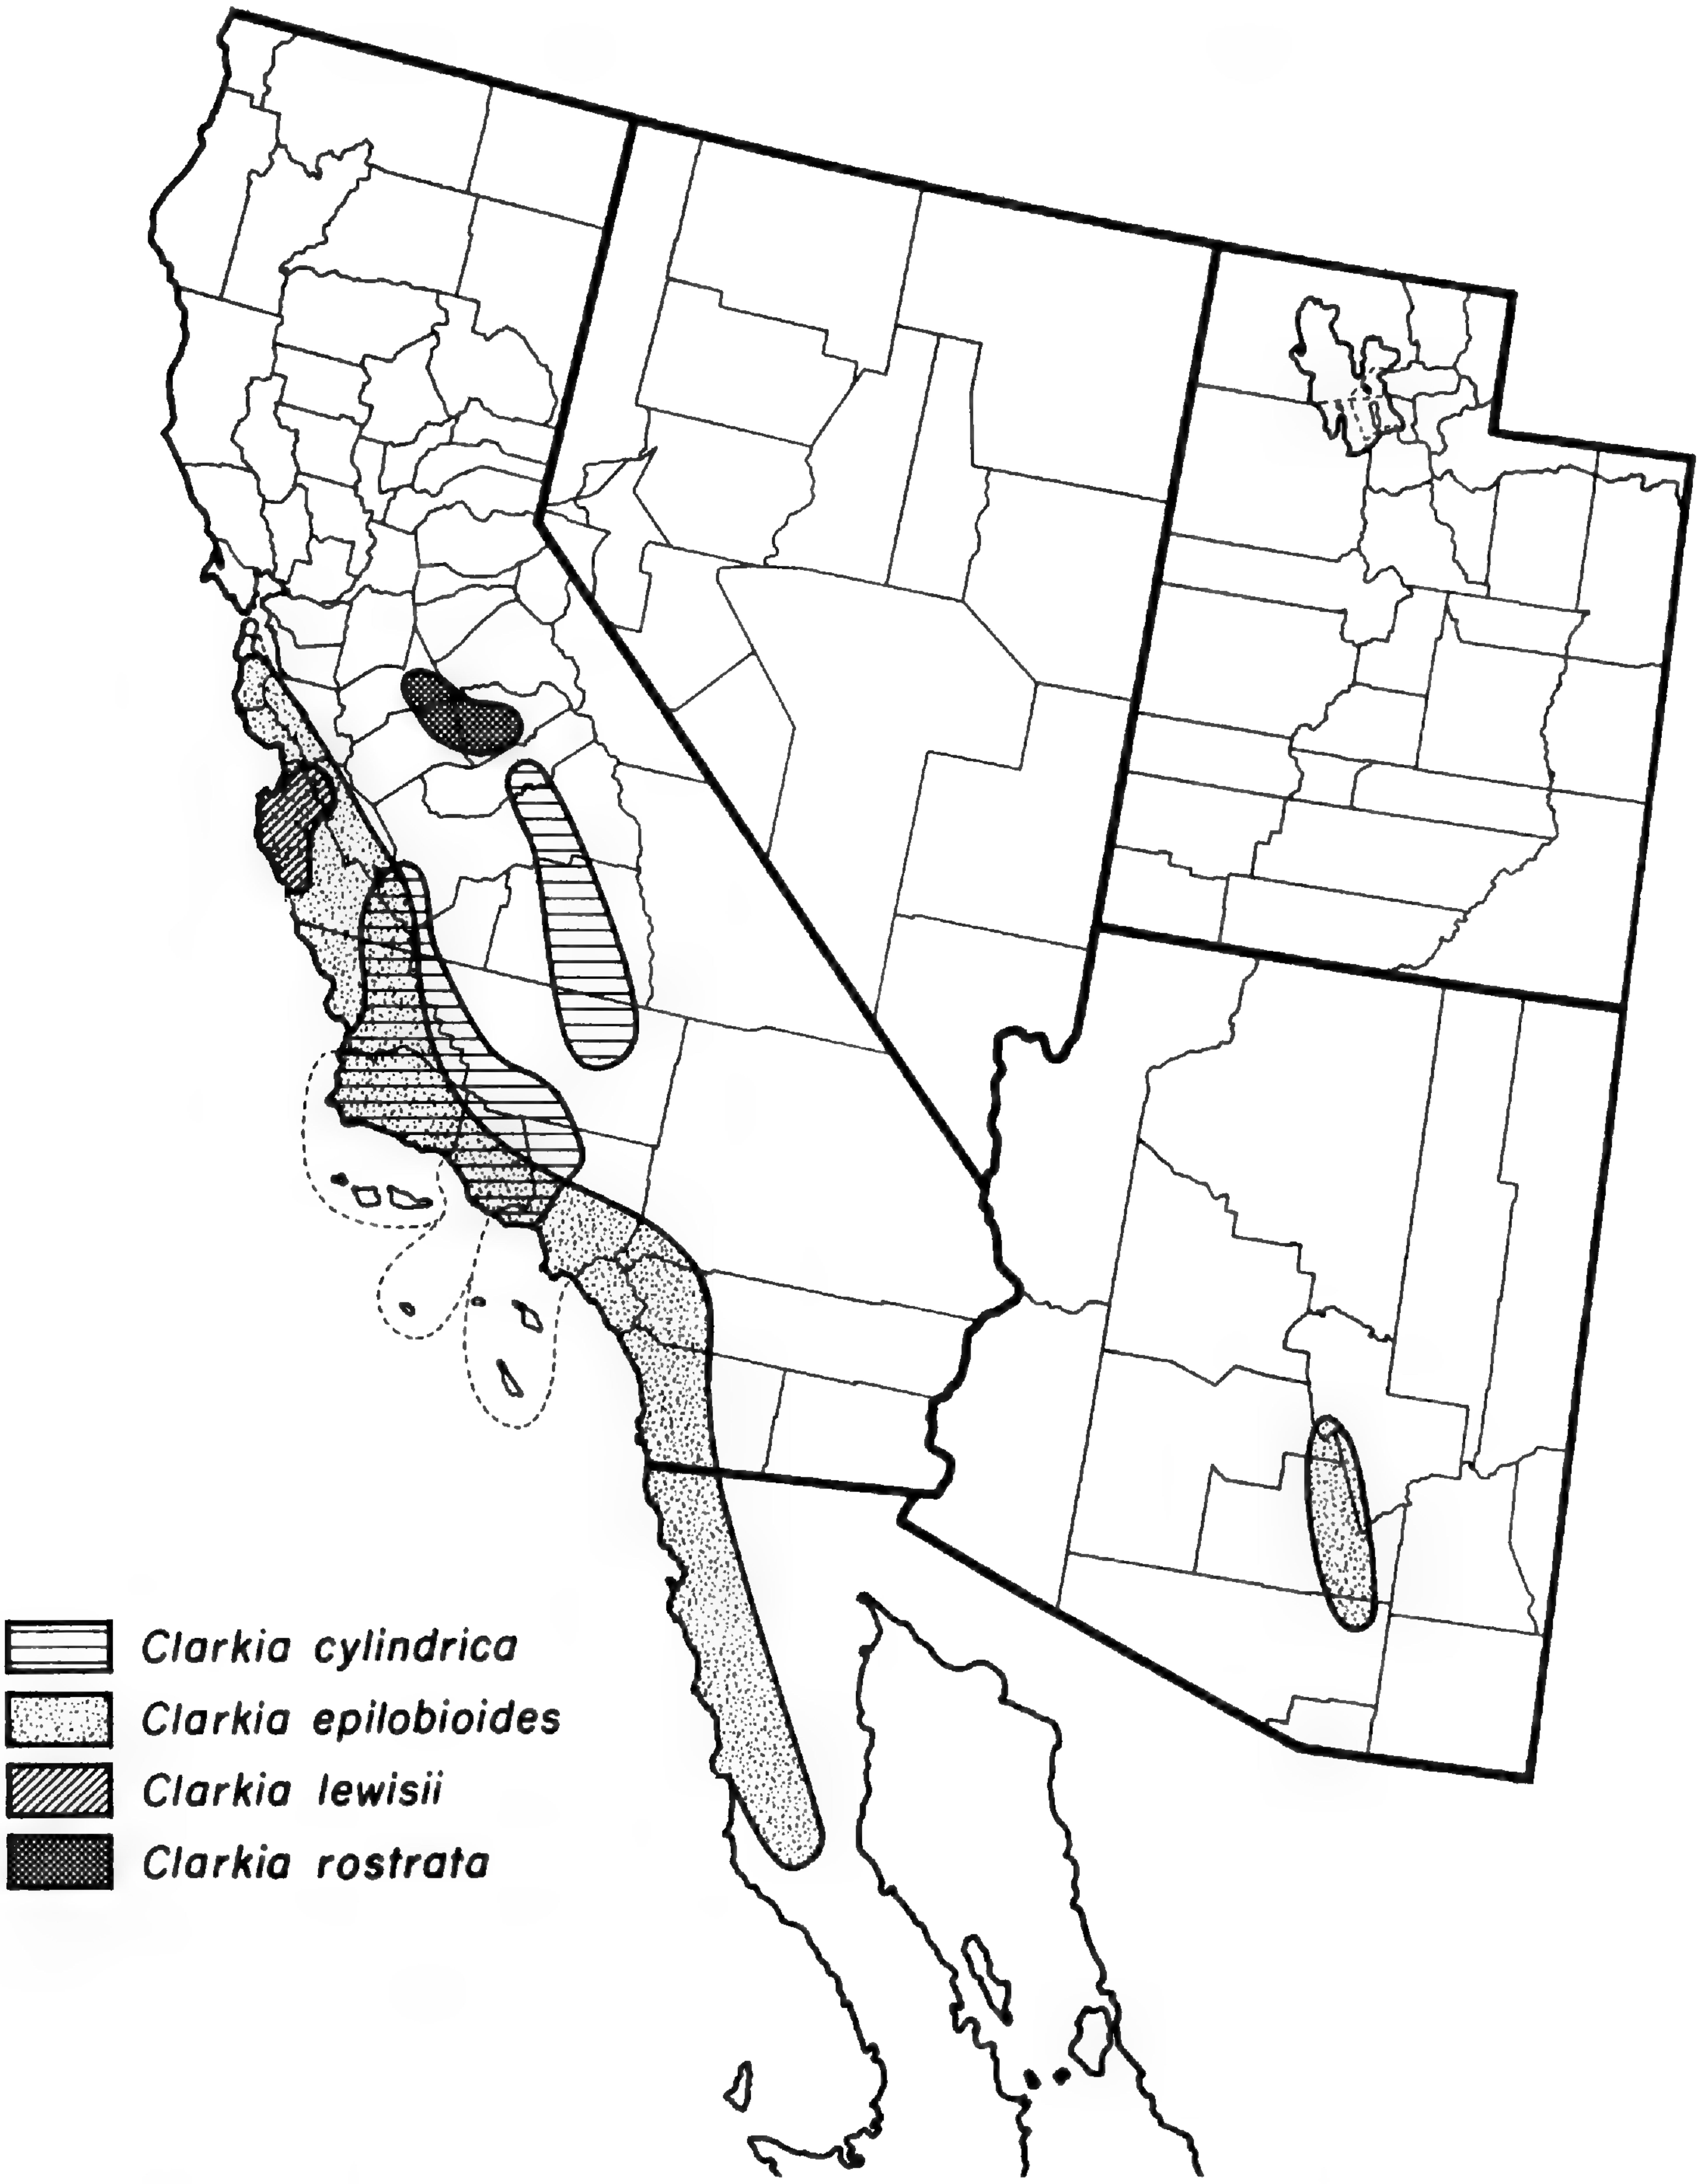

FIGURE 4. *Distribution range of the four species in* Clarkia *sect.* Sympherica *subsects.* Sympherica *and* Micranthae. *Ranges in California, Arizona, and Baja California are provided for* C. cylindrica, C. rostrata, C. lewisii, *and* C. epilobioides. *Adapted from Lewis & Lewis (1955) and Davis (1970).*

involving additional populations from throughout the ranges of these four species and involving biparentally inherited DNA (nuclear genome) are needed to clarify how these species evolved. Questions remaining include: Are *C. rostrata* and *C. lewisii* ancestral in this lineage? Did *C. epilobioides* and *C. cylindrica* diverge independently (or together) from that lineage? What evolutionary forces permitted the rapid morphological divergence in *C. epilobioides?* Can *C. epilobioides* be crossed with three species currently placed in subsect. *Sympherica*, especially *C. rostrata?*

The most parsimonious tree (Fig. 3) also clarifies the relationships within subsect. *Lautiflorae* and the relationship of *Heterogaura heterandra* to *Clarkia*. The cpDNA analysis verifies the close relationship of the proposed progenitor-derivative species pair of *C. biloba* and *C. lingulata* (Lewis & Roberts, 1956; Gottlieb, 1974). Only six mutations separate the two species. The placement of *C. modesta* is the only portion of the phylogenetic tree that is not statistically documented using the bootstrap analysis. The cpDNA analysis conclusively places it within subsect. *Lautiflorae*, but its exact position in the subsection is not certain. The position of *C. modesta* as shown in Figure 3, however, is supported by chromosome numbers. This most parsimonious tree indicates that only one aneuploid decrease from the more widespread $n = 9$ of the section to $n = 8$ (only *C. biloba* and *C. modesta*) has to be invoked. The subsequent reversal to $n = 9$ in *C. lingulata* has been amply demonstrated.

The most striking conclusion of this phylogenetic analysis is the documentation that the genus *Heterogaura* is actually derived within *Clarkia* (Sytsma & Gottlieb, 1986a). Indeed, *H. heterandra* is placed firmly within subsect. *Lautiflorae* with *C. dudleyana* as its sister species. The two species share nine cpDNA synapomorphies despite the extensive morphological divergence between the two. The derivation of *H. heterandra* from a common ancestor with *C. dudleyana* is supported by the next three most parsimonious trees as well. The extreme floral and fruit reduction in *Heterogaura* relative to *Clarkia* have masked the close phylogenetic relationship of *Heterogaura* to an advanced subsection within *Clarkia*.

Flavonoid analysis of *Heterogaura heterandra* and five species of *Clarkia* indicates that the four compounds present in the *Heterogaura* flavonoid profile are also found in the few species of *Clarkia* examined (Averett et al., 1982). Besides cpDNA and nrDNA analyses, therefore, the only evidence that supports a relationship of *Heterogaura* to specific lineages within *Clarkia* is chromosome number. Raven (1979) speculated that *Heterogaura*, with $n = 9$ (found elsewhere only in some *Clarkia* and *Boisduvalia*), "might have been derived from a species of *Clarkia* with the same chromosome number." Morphological or cytological evidence, however, could not place *Heterogaura* near any particular *Clarkia* species because their morphological divergence had completely obscured the relationships.

This study raises additional questions that can or should be addressed in the future: What are the evolutionary forces that permit such rapid morphological divergence as seen in *Heterogaura?* Is the morphological divergence seen in *Heterogaura* (and also *C. epilobioides*) common and thus indicative of what might occur frequently in plants? Can *H. heterandra* be crossed with *C. dudleyana*? How many genes were necessary to get expression of the extreme fruit and floral reduction in *Heterogaura*? Should additional mono- and ditypic genera be suspected as similar derivations from *within* related and more speciose genera instead of as sister genera to these genera (the monotypic *Stenosiphon* and closely related *Oenothera*, for example)? Is the relationship of *Heterogaura* to *Clarkia* actually more complex, involving hybridization and/or introgression, and thus the cpDNA results described here incomplete by not also using biparentally inherited nuclear DNA?

The last question is particularly important because other cpDNA studies have yielded unusual results that suggest hybridization followed by introgression (Palmer et al., 1983, 1985). In these instances, results from cpDNA analysis can be quite different from results from nuclear DNA analysis. For these reasons, restriction site mapping of nuclear ribosomal DNA (rDNA) has been initiated within *Clarkia* and *Heterogaura* to determine if nuclear DNA analysis provides phylogenetic results similar to cpDNA analysis. Methodology for rDNA analysis follows that described in Sytsma & Schaal (1985a). One preliminary piece of information directly concerns the issue of the relationship of *Heterogaura* to *Clarkia*. A partial *Sst I* restriction site map for rDNA in *Clarkia* is shown in Figure 5. *Sst I* fragments *b* and *c* are conserved across the four genera of Onagraceae examined. Fragment *a*, however, is found only in species of *Clarkia* sects. *Sympherica* (*C. biloba*, *C. lingulata*, *C. lewisii*), *Phaeostoma* (*C. xantiana*), *Fibula* (*C. bottae*), and *Heterogaura heterandra*. The *Sst I* site in the 18S gene that delineates fragment *a* is absent in other sections of *Clarkia* and in *Oenothera* and *Lopezia*. These *Clarkia* and other genera thus lack fragment *a* and instead have a large *Sst I* fragment that encompasses fragment *a*, the 18S gene, and an undetermined portion of the nontranscribed spacer region (NTS region in Fig. 5). Outgroup analysis (using *Oenothera* and *Lopezia*) would indicate that the absence of the *Sst I* site in the 18S gene (and thus absence of fragment *a*) is the plesiomorphic condition. This preliminary

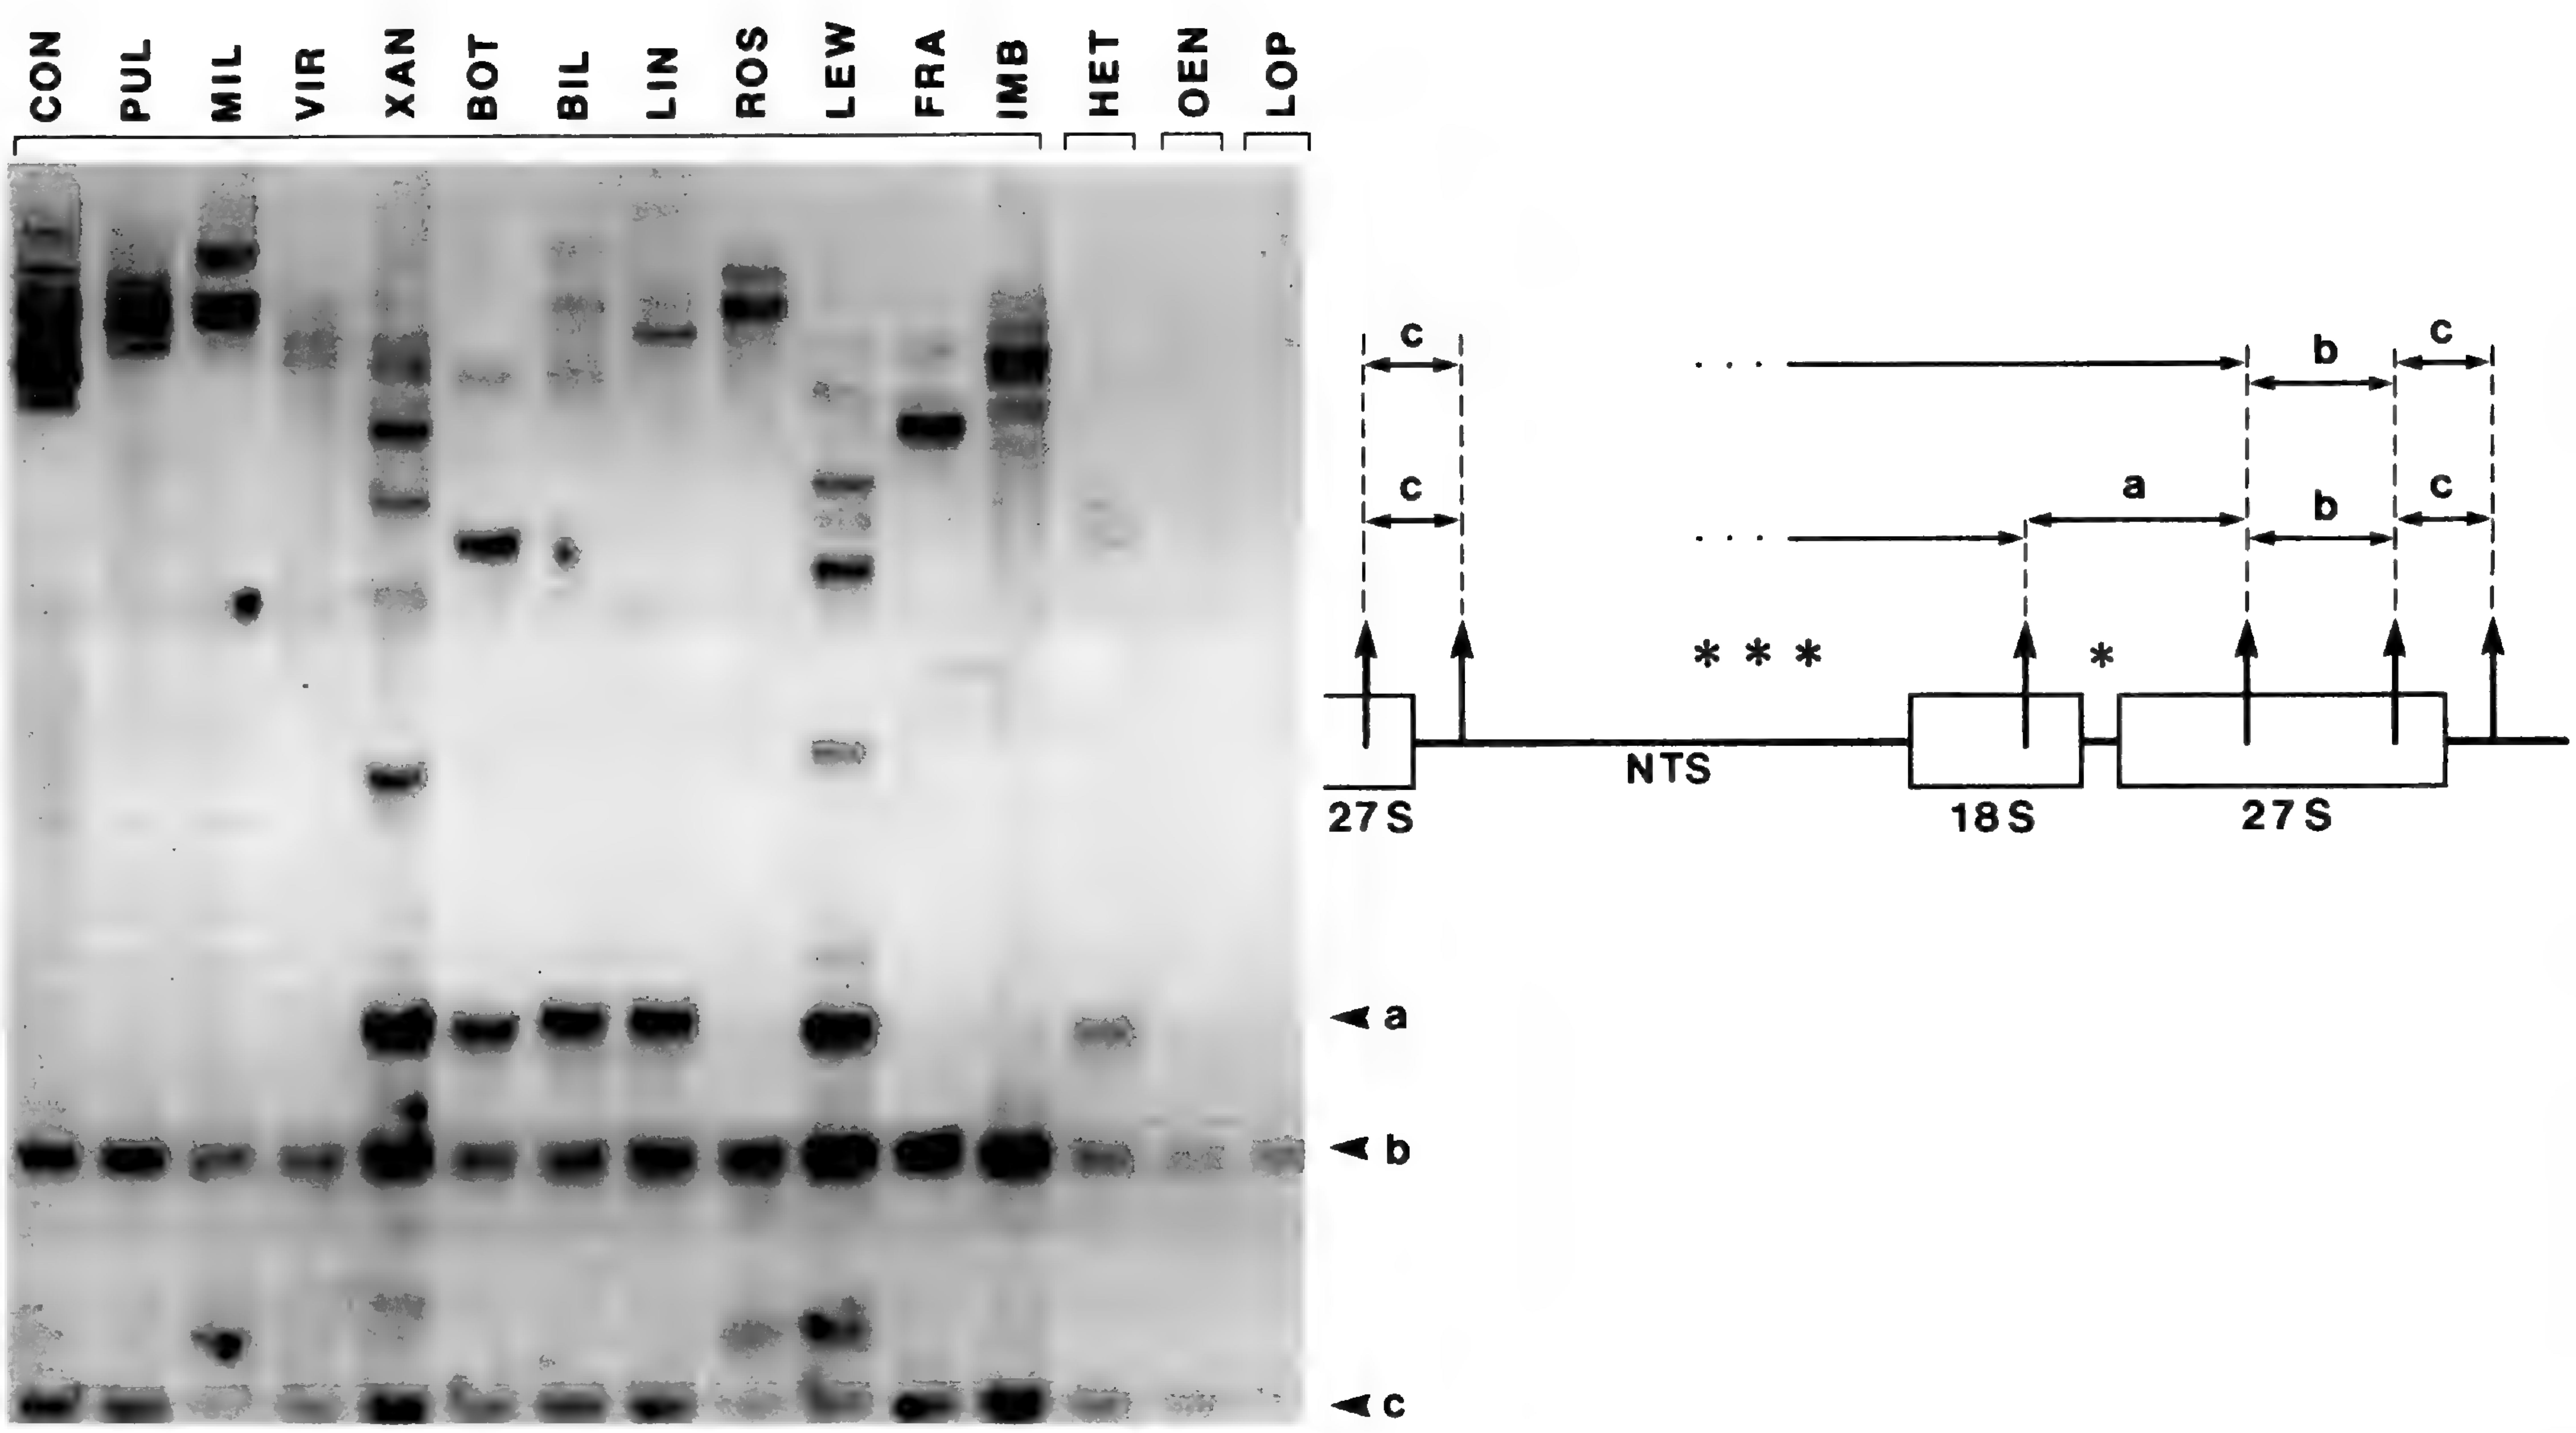

FIGURE 5. *Autoradiogram of* Sst I *restriction fragment patterns and restriction site map for nuclear rDNA in species of* Clarkia, Heterogaura, Oenothera, *and* Lopezia. *Autoradiogram resulted from probing total DNAs (each DNA represents a pooling of several to numerous individuals per population) with a* Glycine *rDNA repeat clone. Ladderlike pattern of higher molecular weight fragments is due to spacer-length variation in fragments spanning portions of the nontranscribed spacer region.*

nuclear rDNA evidence confirms that *Heterogaura* is indeed derived from within the genus *Clarkia* because the former shares a synapomorphy with sections *Sympherica*, *Phaeostoma*, and *Fibula*, sections of *Clarkia* now believed to be related based on gene duplication data (Gottlieb & Weeden, 1979) and cpDNA restriction site mapping data (see Phylogenetic Analysis of Intersectional Relationships within *Clarkia*).

A word of caution should be noted here concerning the phylogenetic use of a single molecular character as done here with rDNA. One could argue that nuclear rDNA evidence for the placement of *Heterogaura* within *Clarkia* is based solely on a single restriction site character that exhibits homoplasy. *Clarkia rostrata* has lost the *Sst I* site that is found in other members of sect. *Sympherica*, even though the weight of morphology (Davis, 1970), isozyme gene duplications (Odrzykoski & Gottlieb, 1984), and cpDNA analysis (Sytsma & Gottlieb, 1986b) fully supports its inclusion in sect. *Sympherica*. Thus, *C. rostrata* has lost the *Sst I* site secondarily. Does this homoplasy involving *C. rostrata* cast doubt on the relationship of *Heterogaura* to *Clarkia* using nuclear rDNA? No, because the loss of the *Sst I* site in *C. rostrata* (thus producing the plesiomorphic character state) is a statistically likely gain/loss type of convergence (Templeton, 1983). On the other hand, there is little such support that the gain of the *Sst I* site in *Heterogaura* is also due to convergence rather than to shared common ancestry with certain lineages within *Clarkia*. Such a convergent restriction site gain is an order of magnitude less likely to occur than a convergent loss or a gain/loss (Templeton, 1983).

PHYLOGENETIC ANALYSIS OF INTERSECTIONAL RELATIONSHIPS WITHIN *CLARKIA*

INTRODUCTION

The monograph of *Clarkia* by Lewis & Lewis (1955) was a landmark study in classical biosystematics. Prior to their work, *Clarkia* was divided into a number of distinct genera (*Clarkia*, *Godetia*, *Phaeostoma*, and *Eucharidium*). Using extensive population collections in which they examined floral and vegetative morphology, chromosome number, and crossing relationships, Lewis & Lewis were able to define convincingly 11 natural sections in the inclusive generic concept of *Clarkia*. The naturalness of *Clarkia* has been commented on by subsequent researchers (Raven, 1979, 1988) and demonstrated on molecular grounds (Pichersky & Gottlieb, 1983).

Relationships among the seven predominantly diploid sections, as viewed by Lewis & Lewis (1955), are depicted in Figure 6. Ancestral clarkias were viewed as having relatively large, lavender-pink, bowl-shaped (godetia-type) flowers with petal markings, being self-compatible but outcrossed, possessing the chromosome number $n = 7$, and having a northern distribution (Lewis, 1980). Evolution in *Clarkia* has occurred primarily from north to south and involved development of floral tubes (sects. *Eucharidium* and *Clarkia*), extensive repatterning of the chromosomes with subsequent aneuploid increases and decreases from the primitive haploid number 7 or polyploidy (all sections), and formation of autogamous breeding systems (many sections). The large classical information base for *Clarkia* and the spectacular evolutionary changes that are seen in the genus have made it a model system for subsequent evolutionary studies (Lewis, 1980; Raven, 1988).

Recent isozyme analysis, however, has challenged certain aspects of the phylogeny proposed on morphology, chromosomes, and crossing studies. Gottlieb & Weeden (1979) provided evidence that a duplication of the cytosolic gene for PGI (phosphogluco isomerase) defines four diploid sections (*Sympherica*, *Phaeostoma*, *Fibula*, and *Eucharidium*), previously not placed together by Lewis & Lewis (1955), as a monophyletic lineage. Indeed, sect. *Eucharidium*, with its distinctive stamen reduction, elongated floral tube, pollen features (Small et al., 1971), and lepidopteran pollination syndrome, represents the greatest morphological divergence from putative ancestral clarkias (Lewis, 1980). Section *Eucharidium* originally was retained within *Clarkia* only because it was strongly suspected of being involved in the intersectional derivation of the polyploid *C. pulchella* (Lewis & Lewis, 1955). The weight of this molecular evidence led Lewis (1980) to accept the argument of Gottlieb & Weeden (1979) and to propose the phylogeny illustrated in Figure 7. An analysis was initiated using restriction site mapping of cpDNA from representatives of the diploid sections to test these alternative models of sectional relationships in *Clarkia*. Presented here are preliminary phylogenetic results from this analysis; a more detailed phylogenetic analysis on an expanded data set is in progress (Sytsma et al., in prep.).

MATERIALS AND METHODS

Total DNAs of two species of each of the seven diploid sections (one species in the monotypic *Fibula*) were obtained as described above. These rep-

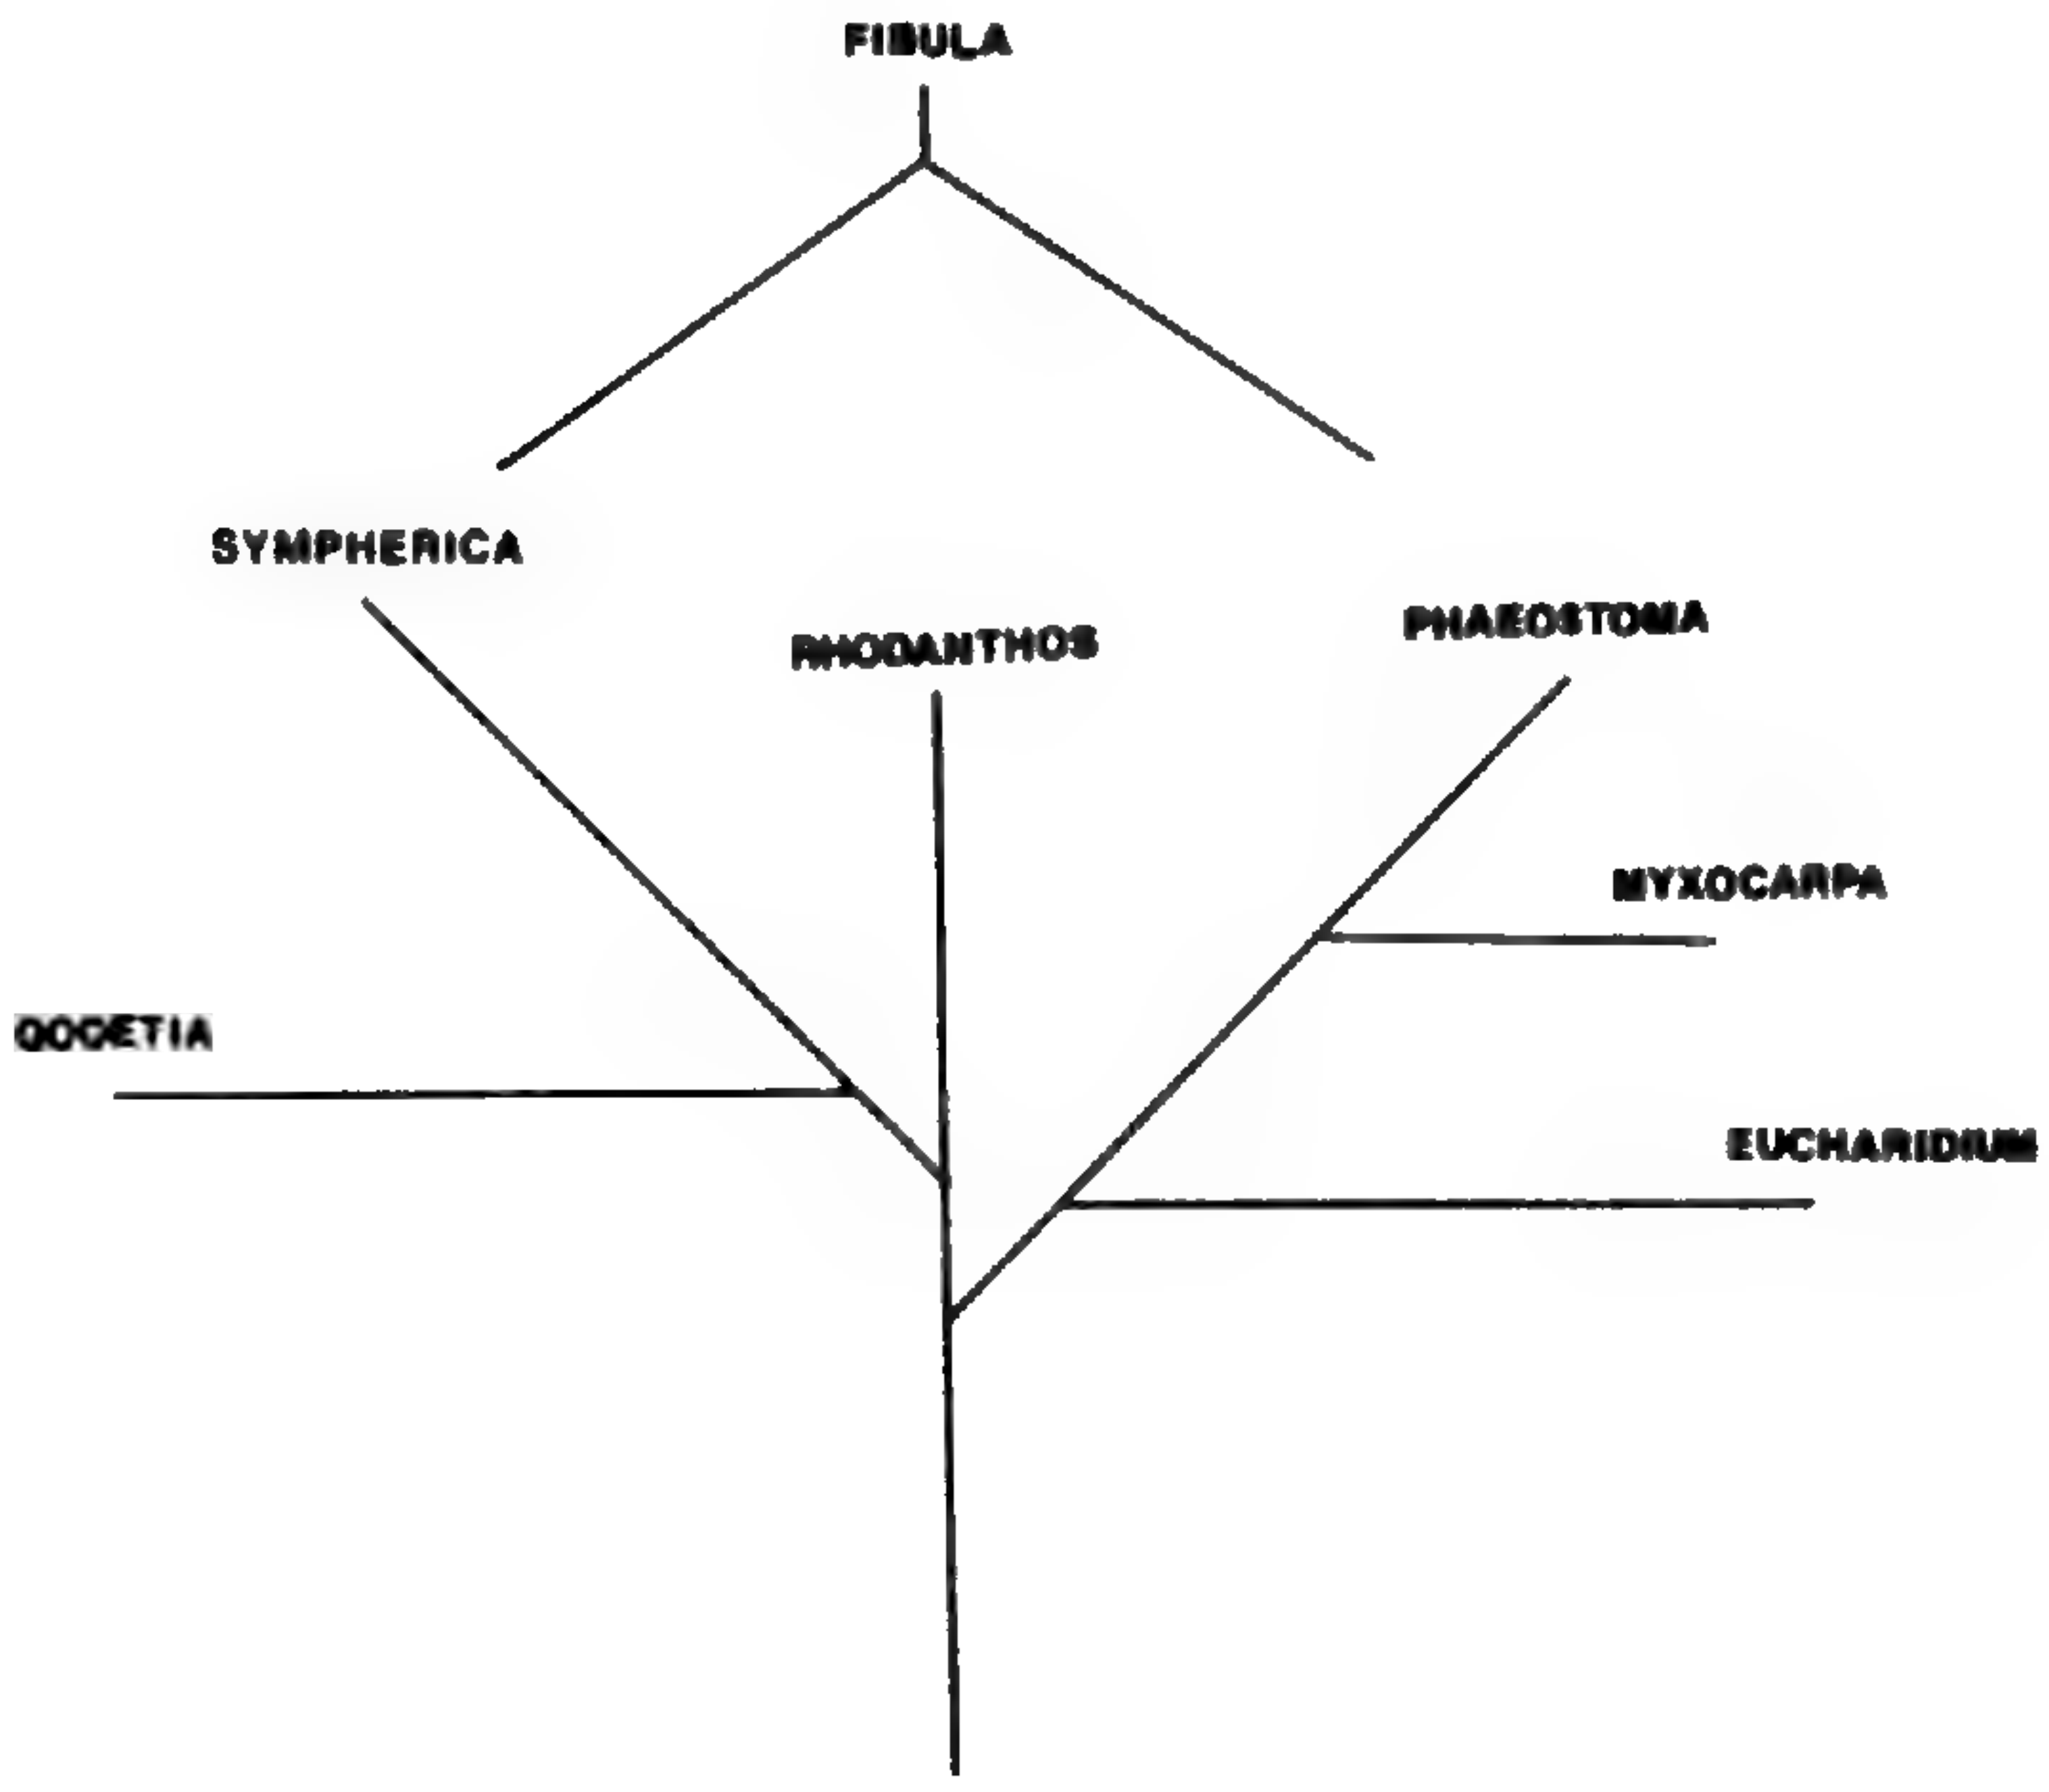

FIGURE 6. *Relationships among the seven diploid sections of* Clarkia *based on morphology, chromosome numbers and features, and crossing relationships. Phylogeny modified after Lewis & Lewis (1955). (*Rhodanthos *is the former* Primigenia, *and* Sympherica *is the former* Peripetasma.*)*

resentative species were *Clarkia amoena* and *C. lassenensis* (Eastw.) Lewis & Lewis (sect. *Rhodanthos*), *C. imbricata* Lewis & Lewis and *C. williamsonii* (Dur. & Hilg.) Lewis & Lewis (sect. *Godetia*), *C. mildrediae* (Heller) Lewis & Lewis, and *C. virgata* Greene (sect. *Myxocarpa*), *C. breweri* (Gray) Greene and *C. concinna* (Fisch. & Mey.) Greene (sect. *Eucharidium*), *C. xantiana* and *C. unguiculata* Lindl. (sect. *Phaeostoma*), *C. bottae* (sect. *Fibula*), and *C. biloba* and *C. rostrata* (sect. *Sympherica*).

Preliminary surveys of restriction fragment variation using methods described above indicated that substantial amounts of site mutations and length mutations are evident at the intersectional level in *Clarkia*. The amount of both types of variation was so high that even the small portions of the chloroplast genome examined with individual probes often exhibited fragment patterns too complex to interpret accurately. Numerous insertions and deletions made it difficult to decide what were homologous fragments. The increased frequency of multiple mutations in a given fragment often generated complex fragment patterns. For these reasons, restriction site mapping using only seven enzymes, rather than restriction fragment comparisons of numerous enzymes, was selected as the method to examine the phylogenetic relationships among sections in *Clarkia*. This method involves reciprocal double digests to map exactly an enzyme's restriction sites relative to sites of other enzymes. Although this method is more laborious and less productive in terms of numbers of mutations screened, the method produces precise cpDNA maps for groups in which variation is often too great and interpretation of homology too difficult for simple fragment pattern analysis. The restriction enzymes *Pst I*, *Sal I*, *Sma I*, *Kpn I*, *Pvu II*, *Xho I*, and *Nru I* were used to digest total DNAs alone and in double digests with at least two other enzymes. Replicate filters were successively probed with the entire *Petunia* clone bank (courtesy of J. Palmer & E. Clark), portions of the *Lactuca* clone bank (courtesy of R. Jansen), and *rbcL* and B subunit *atpase* gene clones (courtesy of G. Zurawski). Map positions for these probes are illustrated elsewhere (Sytsma & Gottlieb, 1986b, fig. 1). Alignment of the maps was facilitated by the conservative nature of the chloroplast genome (Palmer, 1985a, b, 1986a, b; Palmer & Stein, 1986) and of specific restriction sites, especially sites of *Pst I* within the *rbcL* gene and *Pvu II* and *Sma I* within the rRNA genes of the inverted repeat (Sytsma & Gottlieb, 1986b, and J. Palmer, pers. comm.).

Phylogenetic analysis utilized Wagner parsimony (PAUP) to derive the most parsimonious trees. Because *Heterogaura* is no longer an appropriate outgroup to *Clarkia*, *Oenothera* (tribe Onagreae) and *Epilobium* (tribe Epilobieae) were examined. *Oenothera biennis*, currently mapped (Sytsma & Smith, unpubl. data), is not an appropriate outgroup even though it is placed within the same tribe as *Clarkia*, because it contains a large inversion in the large single copy region of the chloroplast genome. *Epilobium brachycarpum* Presl (=*E. paniculatum* Nutt. ex Torr. & A. Gray), although placed in a separate tribe, was used as

TABLE 2. *Data matrix of 23 restriction site characters for representatives of the seven diploid sections of* Clarkia *(13 species) and one outgroup (*Epilobium*). No autapomorphies are listed. The character state "0" indicates absence of a restriction site and "1" indicates presence of a site. Details concerning each character will be presented elsewhere (Sytsma & Gottlieb, in prep.).*

the outgroup for *Clarkia*. The PAUP option BANDB (Hendy & Penny, 1982) was run to find most parsimonious trees. These trees were used to construct a strict consensus tree using the PAUP option CONTREE.

PHYLOGENETIC ANALYSIS AND DISCUSSION

Restriction site maps of cpDNAs from the seven sections of *Clarkia* and from *Epilobium brachycarpum* are presented elsewhere (Sytsma et al., in prep.). The seven restriction enzymes mapped to date recognize ± 100 sites on average in each cpDNA. This represents 0.4% of the total nucleotide sequence of each cpDNA. A total of 51 restriction site mutations were found among the 13 *Clarkia* species examined. An additional 14 site mutations were found in *Epilobium* relative to all *Clarkia*, but these are not further analyzed here because they do not provide additional information concerning relationships among *Clarkia* sections; they are being used in a family-wide phylogenetic analysis (Sytsma & Smith, in prep.). Of the 51 restriction site mutations documented, 23 are phylogenetically informative; that is, they are shared by at least two but not all of the OTUs. The data matrix for these 23 restriction site characters in the seven sections examined makes up Table 2. No autapomorphies were included in the PAUP analysis. To simplify the phylogenetic analysis further, *C. rostrata* and *C. imbricata* were removed from the phylogenetic analysis because for these 23 characters they are identical in character states to *C. biloba* and *C. williamsonii*, respectively. These species pairs are identical for the phylogenetically informative characters examined here, although a number of autapomorphies were seen for individual species.

The Wagner analysis using option BANDB found 201 most parsimonious trees of length 32. With the autapomorphies included, these trees have a total length of 60 steps and a consistency index (Kluge & Farris, 1969) of 0.850. The strict consensus tree derived from 100 of these most parsimonious trees is illustrated in Figure 8A. The high level (15%) of homoplasy in the *Clarkia* data set, which is similar to that found within the entire Asteraceae (Jansen & Palmer, 1988, pers. comm.) could be due in part to (1) multiple changes between the outgroup *Epilobium* and the ingroup *Clarkia*, (2) the more rapid divergence of cpDNA in the strictly annual *Clarkia*, and/or (3) the greater age of *Clarkia* relative to the Asteraceae. The first situation would give rise to trees where errors are made in the determination of the plesiomorphic character state. Two additional PAUP analyses were thus performed: (1) scoring the plesiomorphic state of characters involved in multiple changes from outgroup to ingroup as unknown (characters 1 and 2 scored as missing in the outgroup in this instance) and (2) removal of the outgroup taxon and use of midpoint rooting. Midpoint rooting can clearly only be justified if rates of character change throughout lineages are nearly equal. Clocklike evolution of chloroplast DNA could not be statistically rejected for *Clarkia* sect. *Sympherica* (Sytsma & Gottlieb, 1986b), thus lending support to the use of midpoint rooting within *Clarkia*. Scoring the outgroup state of characters 1 and 2 as missing and allowing PAUP to determine the plesiomorphic states resulted in the same 201 most parsimonious trees, but homoplasy was reduced by two convergences in each tree (58 total steps including autapomorphies, C.I. = 0.879, 12% rate of homoplasy). Removal of *Epilobium* completely and resorting to midpoint rooting resulted in 15 most parsimonious trees, each five steps shorter than trees generated with *Epilobium* present (55 total steps including autapomorphies, C.I. = 0.927, 7% rate of homoplasy). The strict consensus tree of these 15 trees is depicted in Figure 8B.

Phylogenetic relationships among sections of *Clarkia* as depicted in the consensus tree of Figure 8A suggest that sect. *Godetia* is monophyletic and the sister group to the rest of *Clarkia*. The early divergence of sect. *Godetia* is also seen when *Epilobium* is removed as an outgroup and midpoint rooting is performed (Fig. 8B). Section *Godetia* consists of diploid and polyploid species similar in many respects to sect. *Rhodanthos* and, according to Lewis & Lewis (1955), almost certainly derived from the "primitive" *Rhodanthos* and not clearly related to any other section. Several morphological features constant in sect. *Godetia*, notably the erect buds and rachis and the conspicuously eight-ribbed ovary, are found in portions of sect. *Rhodanthos* (Lewis & Lewis, 1955). Derivation of sect. *Godetia* from elements within sect. *Rhodanthos* is consistent with respect to chromosome number, since all diploid species of sect. *Godetia* apparently have evolved with increase in chromosome number from $n = 7$ (found in sect. *Rhodanthos*) to both $n = 8$ and $n = 9$ (found in sect. *Godetia*). Further support for this early split of sect. *Godetia* comes from a preliminary cladistic analysis of 38 characters encompassing morphology and isozyme gene duplications, which places sect. *Godetia* as the sister group to the rest of *Clarkia* (K. Holsinger, pers. comm.). It is possible that sect. *Godetia* was indeed the first lineage splitting off from ancestral clarkias, but it also appears that this ancestral group, perhaps now encompassing sect. *Rhodanthos*, continued to evolve and subsequently split off the other sections. A larger survey of species within sect. *Rhodanthos* would be needed to detect the possibility that this section is paraphyletic, with different elements giving rise independently to *Godetia* and to the other sections. This scenario is implicitly suggested by the phylogenetic model of Lewis & Lewis (1955; also see Fig. 6) and by the distribution of phosphoglucomutase (PGM) gene duplications (Soltis et al., 1987).

Relationships within the second lineage comprising the other six diploid sections is not clear, as all sections split at a polychotomous node (Fig. 8A). Of these six sections, all but sect. *Phaeostoma* are monophyletic lineages. *Clarkia xantiana* and *C. unguiculata* (sect. *Phaeostoma*) consistently do not form a monophyletic clade in most of the 100 most parsimonious trees examined in detail (data not shown). Indeed, *C. xantiana* often is aligned with *C. bottae* of sect. *Fibula*, whereas *C. unguiculata* often is aligned with *C. biloba* and *C. rostrata* of sect. *Sympherica*. These relationships are seen in the consensus tree when the outgroup is omitted (Fig. 8B). Lewis & Lewis (1955) postulated that *C. bottae* (formerly *C. deflexa*), the only species of sect. *Fibula*, represented a diploid hybrid between sects. *Sympherica* and *Phaeostoma*. If this is true, the maternal genome of *C. bottae* most likely came from a species similar to *C. xantiana* of sect. *Phaeostoma* and not *C. unguiculata* as postulated by Lewis & Lewis (1955).

The proposed monophyletic nature of sects. *Eucharidium*, *Sympherica*, *Phaeostoma*, and *Fibula* based on the presence of the PGI duplication (Gottlieb & Weeden, 1979) cannot be rejected or supported with the results of cpDNA restriction site

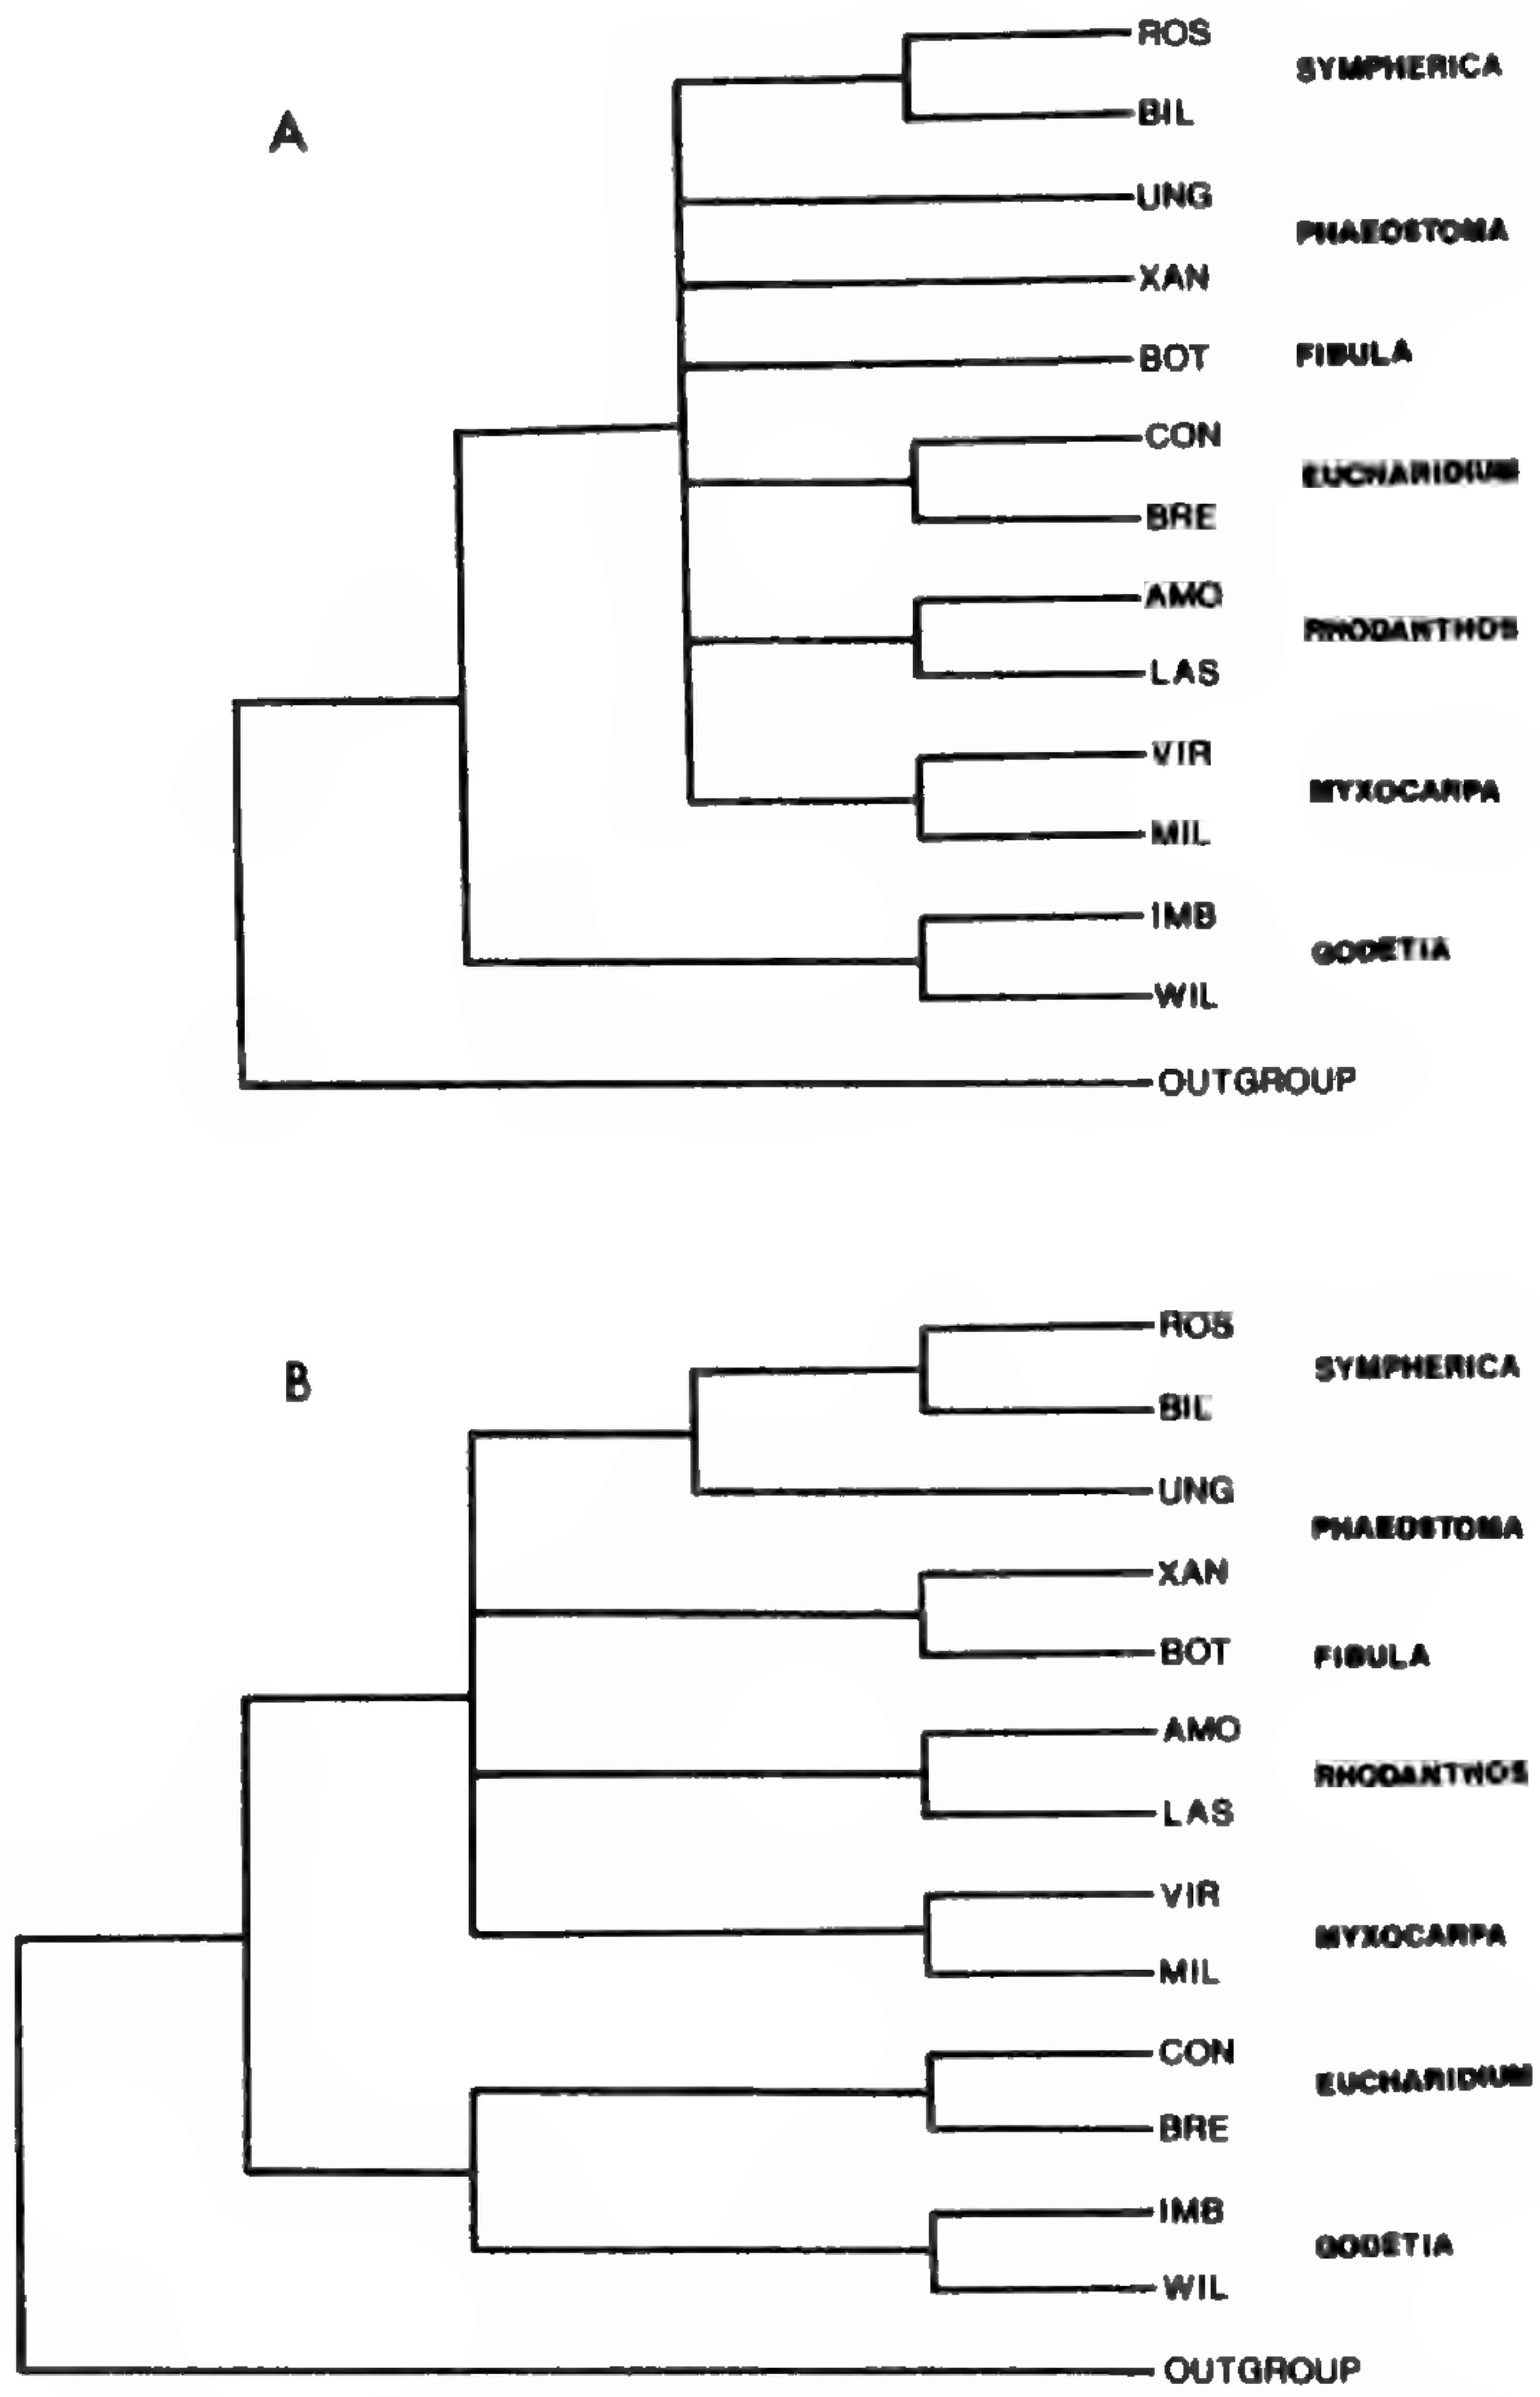

FIGURE 8. *Strict consensus trees of relationships among sections in* Clarkia *based on chloroplast DNA restriction site mapping.—A. mapping when using *Epilobium* as an outgroup, since all four sections, along with sects. *Rhodanthos* and *Myxocarpa*, split from a polychotomous node (Fig. 8A). However, when *Epilobium* is removed as an outgroup and midpoint rooting is used, sect. *Eucharidium* is placed in a lineage with sect. *Godetia* and is separate from the other three sections with the PGI gene duplication (Fig. 8B).

Preliminary nuclear rDNA evidence supports the separation of sect. *Eucharidium* from sects. *Sympherica*, *Phaeostoma*, and *Fibula*. As detailed earlier, sects. *Sympherica*, *Phaeostoma*, and *Fibula* share a synapomorphic gain of an *Sst I* site in the 18S gene of nrDNA (Fig. 5). Section *Eucharidium* retains the plesiomorphic condition also found in sects. *Myxocarpa*, *Godetia*, and *Rhodanthos* and in *Oenothera* and *Lopezia*. This rDNA site mutation could also be argued as arising within a monophyletic lineage of the four sections but *after* the split of sect. *Eucharidium*.

An obvious problem that is apparent with the *Clarkia* cpDNA data set is the low number of synapomorphic characters shared by two or more sections. A rapid and early divergence of most of the sections within *Clarkia* could account for the relatively low numbers of phylogenetically informative site changes encountered *among* sections. The slowly evolving chloroplast genome would not be expected to exhibit numerous changes in the short time intervals when the sections shared common ancestors. Conversely, most cpDNA sequence changes would be expected in the long time periods *after* most sections had already diverged. Additional restriction enzymes that recognize low numbers of sites in cpDNA (*Bgl I*, *Sst I*, for example; see Palmer, 1986a) are now being examined for variation within *Clarkia*. Additional analyses are also under way to examine individually the sets of most parsimonious cpDNA-derived trees for the number in each tree of unlikely convergent gains and loss/gains relative to the more likely convergent losses and gain/losses (Templeton, 1983). A subset of more likely trees (i.e., with fewer convergent gains or loss/gains) might then be found to demonstrate more rigorously phylogenetic relationships within *Clarkia*.

PHYLOGENETIC RELATIONSHIPS AND DIVERGENCE WITHIN *FUCHSIA*

INTRODUCTION

Fuchsia is a genus of 102 species belonging to ten sections (Berry, 1982; Raven, 1988; Berry et al., 1988). Most species of this genus of outcrossing shrubs and some trees occur in South America, including 60 species of sect. *Fuchsia* (two in Hispaniola), 14 species of sect. *Hemsleyella*, 8 species of sect. *Quelusia*, the monotypic sect. *Kierschlegeria*, and an undescribed monotypic section from northern Peru. Twelve species of sects. *Ellobium*, *Encliandra*, *Jimenezia*, and *Schufia* occur in Mexico and Central America. The four species of sect. *Skinnera* are found in New Zealand (3) and Tahiti (1).

Most lines of evidence point to an origin of *Fuchsia* in austral temperate forests of South America in Paleogene times (Berry, 1982; Raven, 1988). The species of the large South American sect. *Quelusia*, restricted to the mountains of southeastern Brazil, with one species in Chile, possess the largest suite of generalized characters in the genus and may represent the extant section most similar to ancestral fuchsias. These characters include shrubby habit, bisexual flowers, well-developed petals, bird-pollination, numerous seeds, and segmented-beaded viscin pollen threads (Skvarla et al., 1978; Berry, 1982; Nowicke et al., 1984; Averett et al., 1986; Raven, 1988). Raven (1988) postulated that *F. lycioides* Andr. (sect. *Kierschlegeria*) is related to sect. *Quelusia*, based on their polyploidy and temperate South American distribution. But *F. lycioides* has a number of derived characters, including its dry coastal scrub habitat, summer deciduousness, functional dioecy, small flowers, few seeds, and smooth viscin pollen threads.

The first offshoot in *Fuchsia* probably involved the lineage that dispersed to New Zealand and subsequently Tahiti (Fig. 9). This lineage, now comprising four species in sect. *Skinnera*, separated from the rest of *Fuchsia* at least 25 million years ago since fossil pollen has been recorded in late Oligocene and early Miocene deposits from New Zealand (Mildenhall, 1980; Daghlian et al., 1985) and eastern Australia (P. Berry, pers. comm.). *Skinnera* is the most distinctive section in the genus, with the advanced conditions of male sterility (Godley, 1955), reduced petals, and varying life forms that include a tree, a scandent shrub, and an almost herbaceous creeper.

Other early dispersal events probably included the ancestor to the morphologically related sections *Encliandra*, *Jimenezia*, and *Schufia* of Mexico and Central America (Fig. 9). These sections share unusual characters of small flowers, smooth viscin pollen threads, male sterility, and lobed adnate nectaries (Breedlove et al., 1982; Berry, 1982). These three sections are so distinctive that it is difficult to relate them to their South American relatives (Raven, 1988). The two most speciose

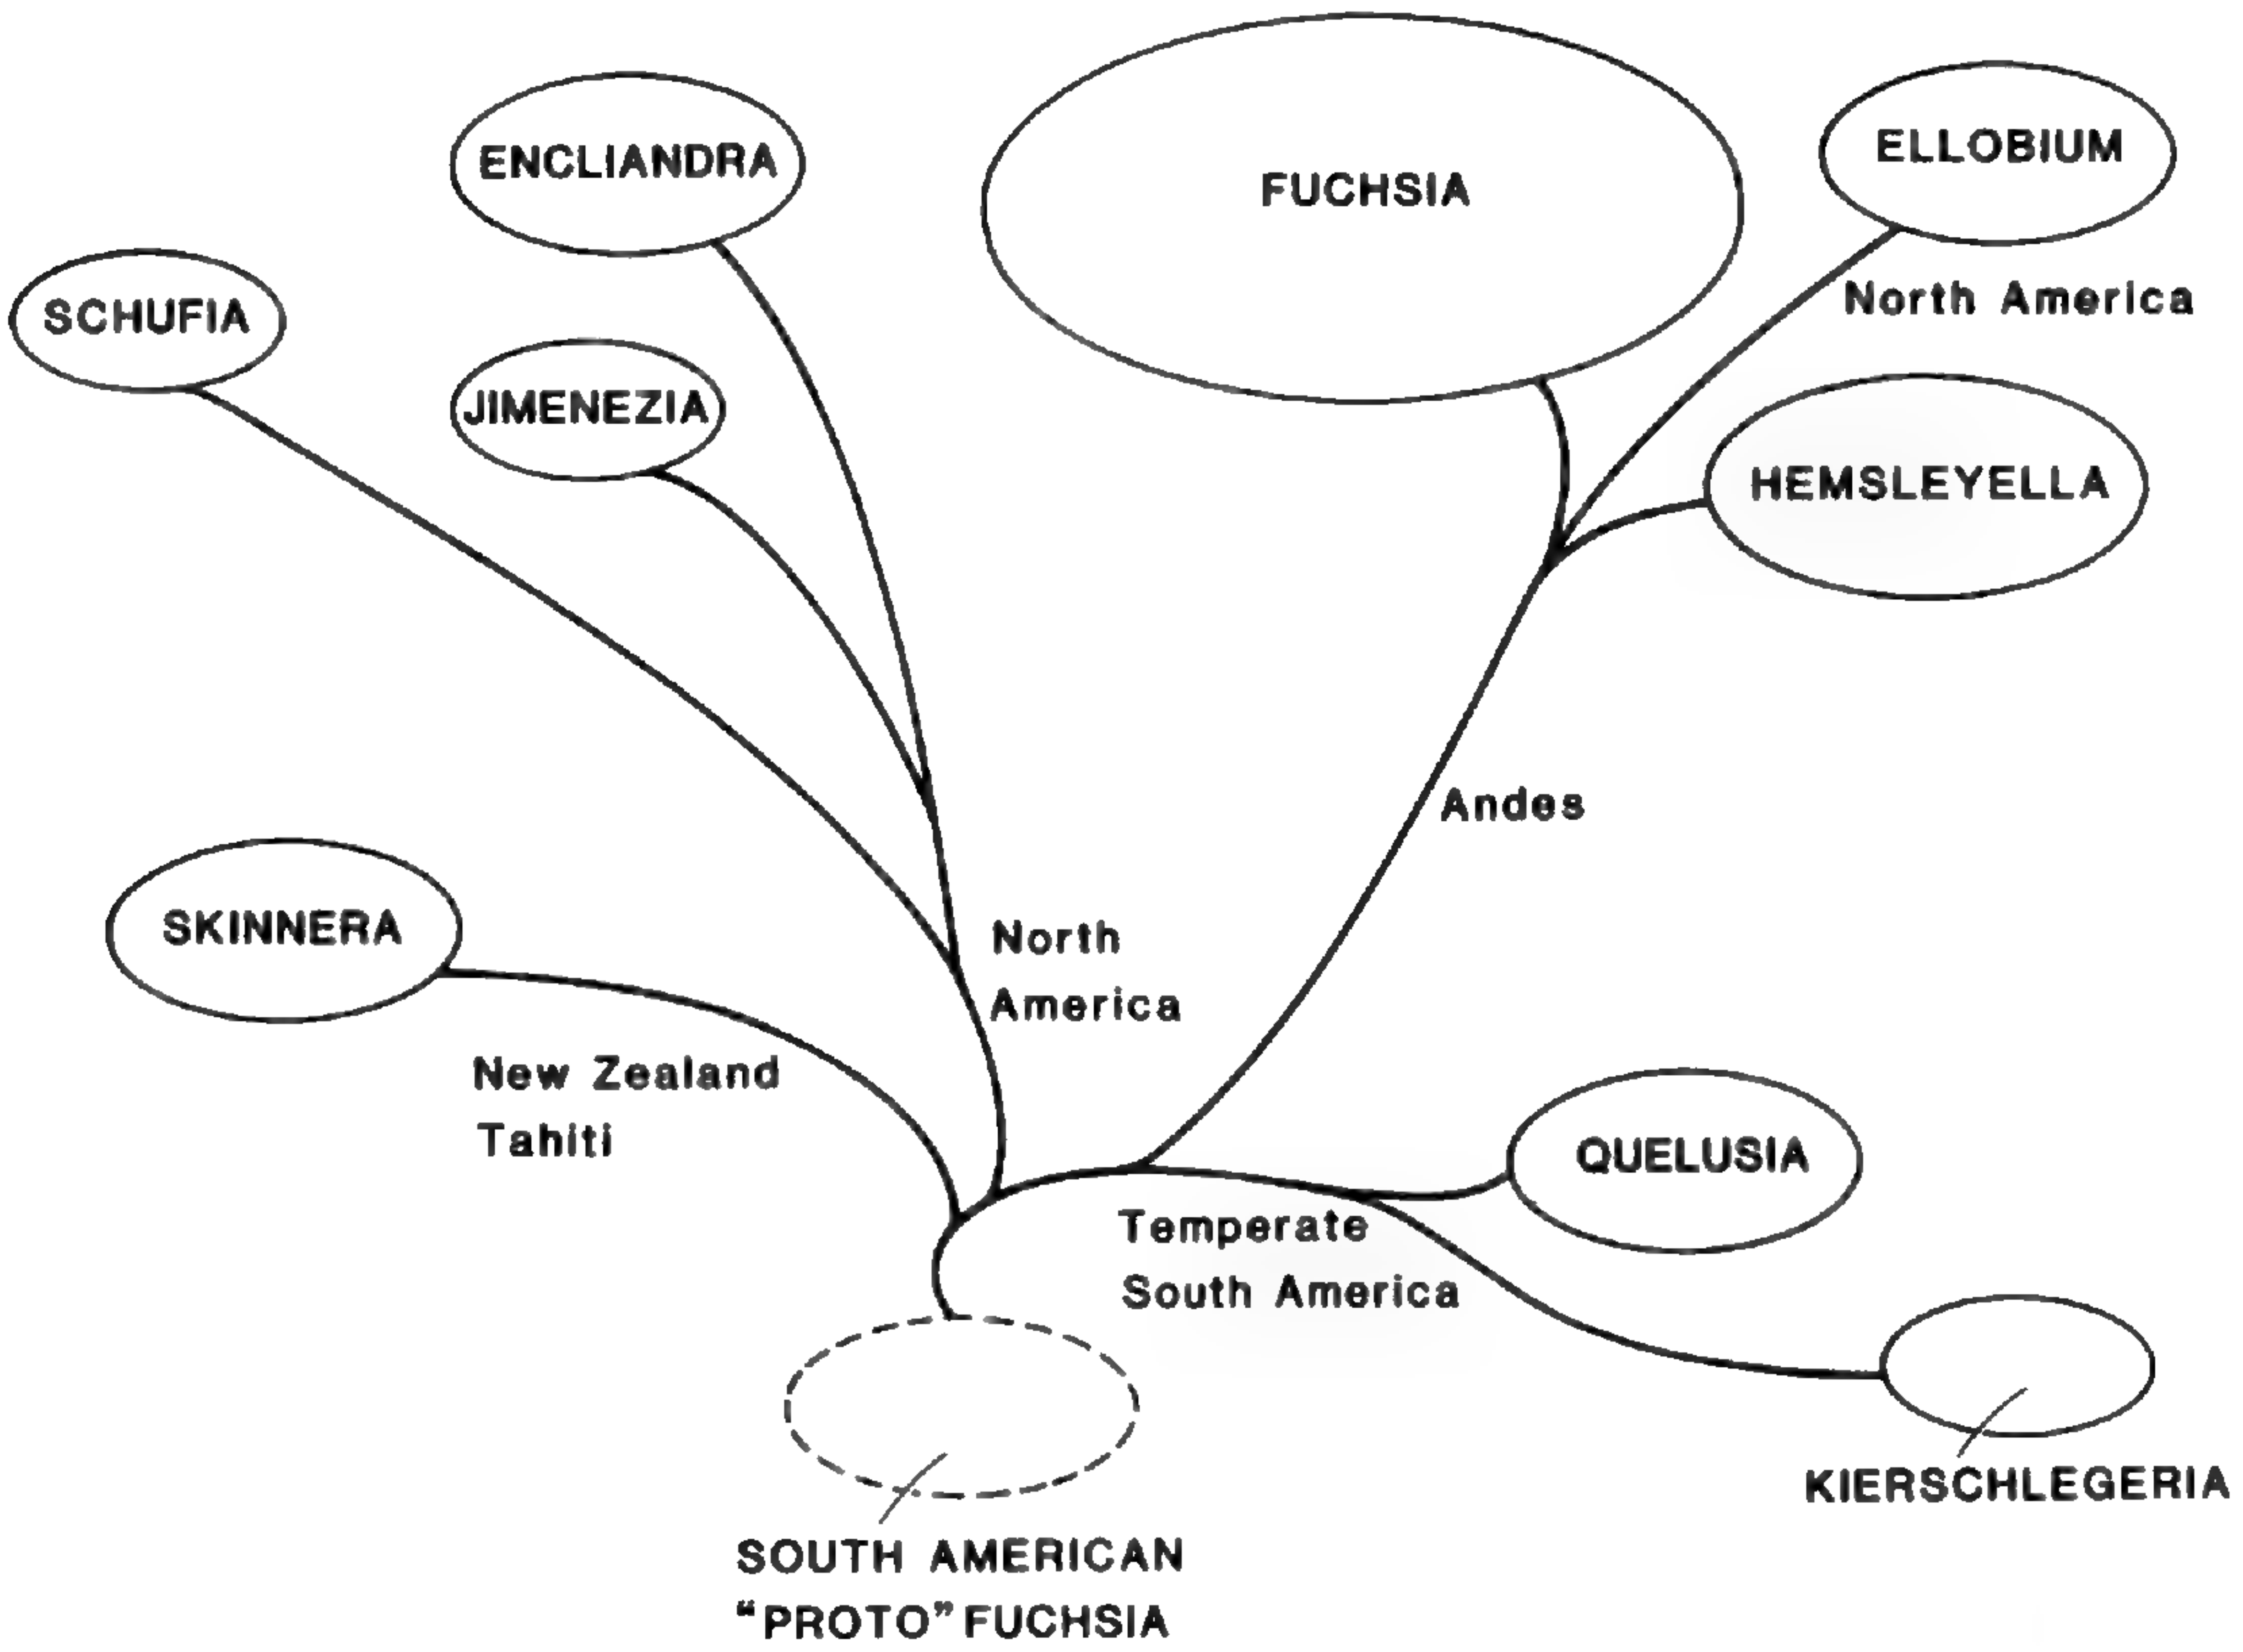

FIGURE 9. *Schematic diagram illustrating probable dispersal events in the genus* Fuchsia *(based almost entirely on ideas presented in Berry, 1982; Breedlove et al., 1982; and Raven, 1988). No extant section is depicted as ancestral to the genus. Section* Quelusia, *however, is depicted as retaining the greatest number of character states that such an ancestral fuchsia would probably have had. See text for discussion.*

sections, *Fuchsia* and *Hemsleyella*, occurring mostly on moist slopes of the tropical Andes, most certainly evolved rapidly as the Andes uplifted to their present height over the past few million years (Berry, 1982; Raven, 1988). The fourth Mexican and Central American section, *Ellobium*, is related to these two Andean sections and represents an additional and probably Neogene dispersal event of *Fuchsia* northward (Fig. 9).

Flavonoid analyses of many *Fuchsia* species have provided useful information concerning evolution within the genus (Williams et al., 1983; Averett & Raven, 1984; Averett et al., 1986). Flavones, otherwise rare in the Myrtales (Gornall et al., 1979), are found in Onagraceae only in *Circaea* and *Fuchsia*. The presence of flavones is presumed to be ancestral in *Fuchsia*, since they are found in all species of sect. *Skinnera*, in the primitive *F. splendens* of sect. *Ellobium*, in the primitive *F. magellanica* Lam. of sect. *Quelusia*, in sect. *Kierschlegeria*, and in two species of sect. *Fuchsia* (Averett et al., 1986). The presence of sulfated flavones only in sect. *Skinnera* again emphasizes the distinctiveness of the section within *Fuchsia* (Williams et al., 1983).

A chloroplast DNA restriction fragment and site analysis was begun in *Fuchsia* to look at a number of systematic and evolutionary questions in the genus. Can sect. *Skinnera* be shown to have diverged first in the genus? Do cpDNA divergence data indicate large genetic differences among the four species of the Old World which exhibit extremes in plant form? Are sects. *Quelusia* and *Kierschlegeria*, which are polyploid and inhabit putative ancestral biogeographic habitats, closely related? Does cpDNA analysis support the monophyletic origin of sects. *Encliandra*, *Schufia*, and *Jimenezia* from an early dispersal event? Does the Central American section *Ellobium* relate to the Andean sects. *Fuchsia* and *Hemsleyella* in a phylogenetic sense? What are the closest relatives of the recently discovered monotypic and tuber-bearing section from western Peru? Initial surveys of cpDNA restriction fragment variation in representatives of all sections, tentative phylogenetic interpretation, and answers to some of these questions are presented here.

MATERIALS AND METHODS

Total DNA from 16 taxa of *Fuchsia* was extracted from leaf tissue as described above. Representative species from the sections in *Fuchsia* included *F. excorticata* L. f. (sect. *Skinnera*), *F. jimenezii* Breedlove, Berry & Raven (sect. *Jimenezia*), *F. arborescens* Sims and *F. paniculata* Lindley (sect. *Schufia*), *F. thymifolia* H.B.K. (sect. *Encliandra*), *F. splendens* Zucc. (sect. *Ellobium*), *F. lycioides* Andr. (sect. *Kierschlegeria*), *F. magellanica* and *F. regia* (Vand. ex Vell.) Munz (sect.

Quelusia), *F. tillettiana* Munz (sect. *Hemsleyella*), *F. boliviana* Carrière, *F. nigricans*, and *F. verrucosa* Hartweg (sect. *Fuchsia*), and *F. pachyrrhiza* Berry & Stein (sect. *Pachyrrhiza*).

Eleven restriction enzymes were utilized (*Sst I*, *Hind III*, *Eco RV*, *Pvu II*, *Bgl I*, *Kpn I*, *Pst I*, *Sma I*, *Sal I*, *Bst EII*, and *Sph I*). Filters were sequentially probed with *Petunia* probes that cover only the large single copy region. Phylogenetic analysis followed procedures described above for the analysis of cpDNA variation within *Clarkia* sect. *Sympherica*. Polarity of restriction site changes was determined from cpDNA maps of *Clarkia* and *Epilobium* in which most of the sites for these eleven restriction enzymes have been determined (see above). Restriction fragment patterns were examined in these outgroup genera for restriction enzymes not completely mapped. Wagner analysis (PAUP) was used to determine most parsimonious trees and the CONTREE program utilized to generate a strict consensus tree.

RESULTS AND DISCUSSION

Approximately 100 restriction sites were examined in each taxon with the combination of probes and restriction enzymes. Forty-six restriction site mutations were seen among the 16 ingroup taxa surveyed. Only nine of these mutations are shared by at least two but not all species of *Fuchsia* examined and thus are phylogenetically informative (Table 3). Nucleotide divergence within *Fuchsia* is high, with p values ranging up to 4.8%. *Fuchsia jimenezii* (sect. *Jimenezia*) exhibited the most site divergence, followed by *F. excorticata* (sect. *Skinnera*). PAUP analysis generated over

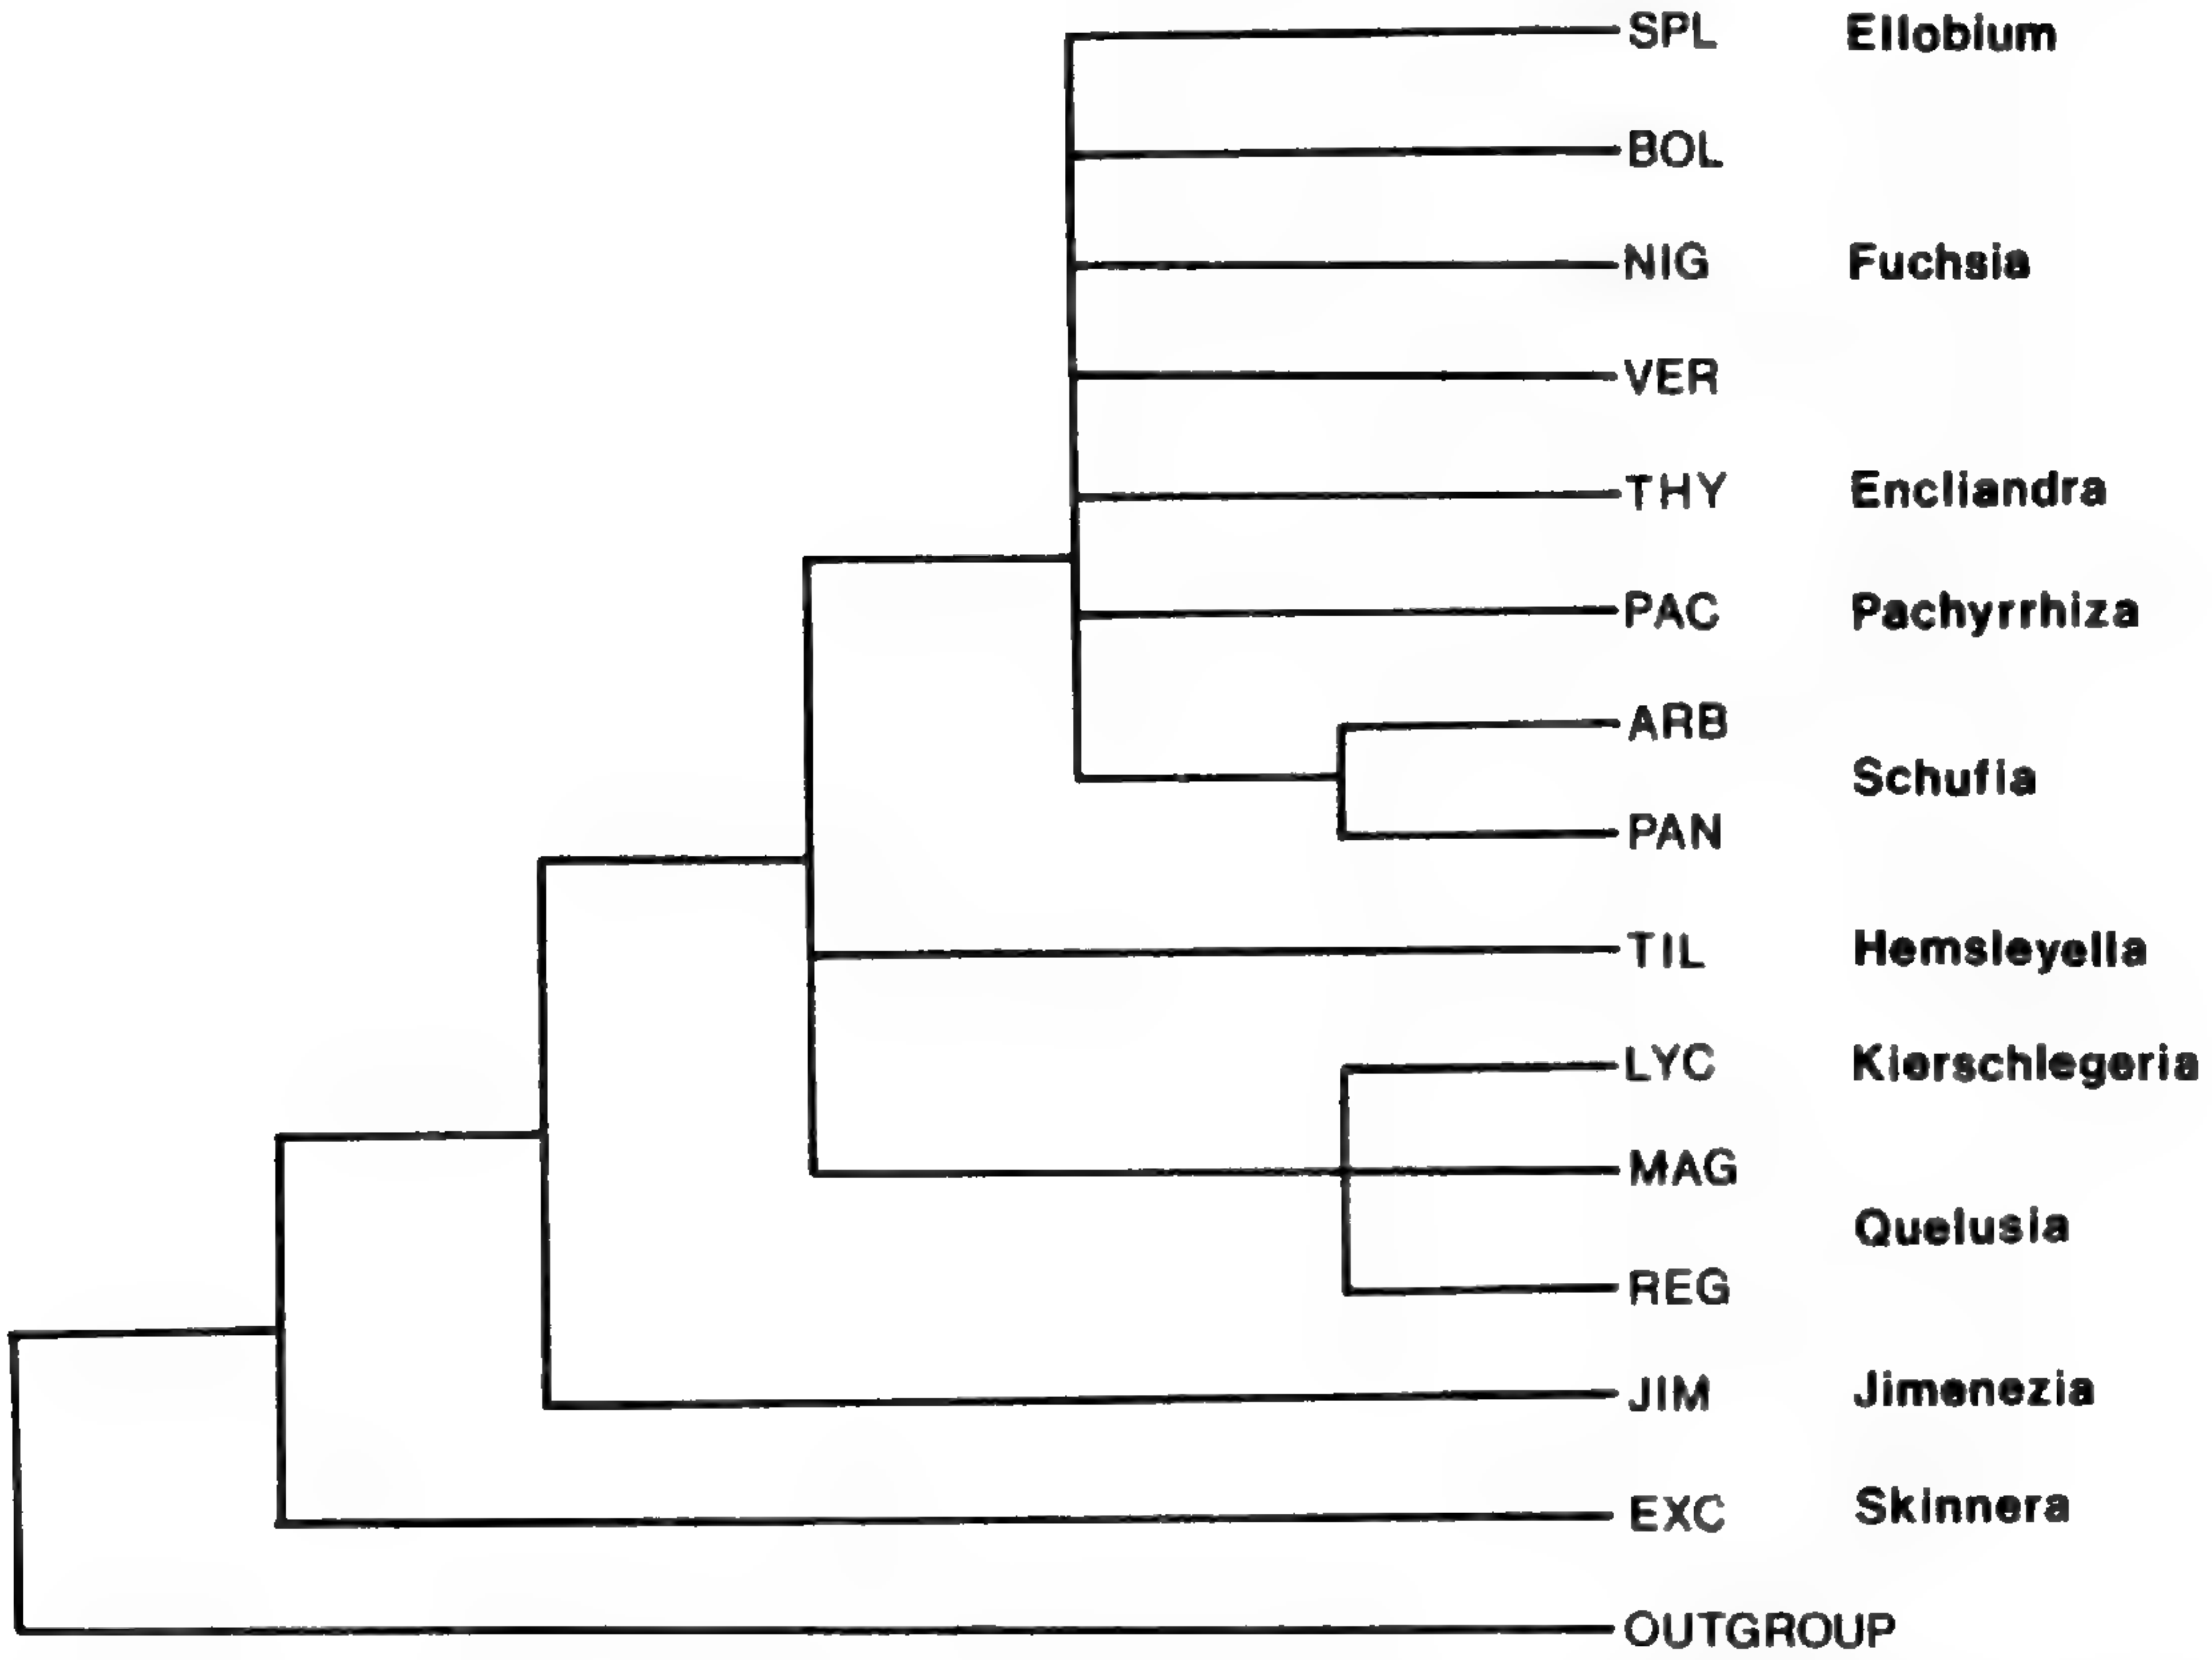

FIGURE 10. *Strict consensus tree depicting relationships among the sections of* Fuchsia *based on cpDNA restriction site mutations. The tree was generated from a subset of most parsimonious trees that lacked an unlikely convergent gain. Species are listed by abbreviation (see Table 3).*

100 most parsimonious trees of 49 steps (C.I. = 0.94). Inspection of the 100 trees retained in memory by PAUP showed that three lineages were implicated as the sister group to the rest of *Fuchsia*: (1) sect. *Skinnera*, (2) sect. *Skinnera* with sect. *Jimenezia*, and (3) sect. *Jimenezia*. Inspection of all 100 trees by the CHGLIST option in PAUP further indicated that all trees in categories (2) and (3) above required an additional unlikely convergent gain or loss/gain (see Templeton, 1983). This unlikely convergence is not found in trees in category (1). A consensus tree was obtained for all the trees not requiring this unlikely convergence and is depicted in Figure 10. This preliminary cpDNA restriction fragment analysis indicates that most mutations encountered (39 out of 49) are autapomorphies. Relationships among sections based on the available phylogenetically informative cpDNA data are thus tentative and subject to change as additional restriction site mutations are found in the ongoing phylogenetic analysis of *Fuchsia*.

The consensus tree indicates that the Old World sect. *Skinnera* and the monotypic Central American sect. *Jimenezia* are the first lineages to split off from the presumed ancestral *Fuchsia* stock in temperate South America. The consensus tree places sect. *Skinnera* as the sister group to all other *Fuchsia* sections, including *Jimenezia*. This placement, however, is based on a single and homoplasious restriction site synapomorphy for all sections excluding *Skinnera*. As indicated above, the ancient split and long evolutionary divergence of sect. *Skinnera* is supported by the presence of 30-million-year-old fossil *Fuchsia* pollen, the spectacular morphological divergence within the section, and the presence of sulfated flavones.

The large cpDNA divergence evident in the monotypic sect. *Jimenezia* relative to all sections is surprising and merits further research. Based on floral structure and reproductive characters, *Fuchsia jimenezii* has been suggested to occupy an intermediate position between the Central American sections *Encliandra* and *Schufia* (Berry, 1982). The large cpDNA divergence between sect. *Jimenezia* and sects. *Encliandra* and *Schufia* is thus contrary to results from floral characters. Berry (pers. comm.) indicates, however, that many such floral characters appear to have evolved several times independently in the genus *Fuchsia* based on preliminary cladistic analysis of floral and vegetative morphology. The distant relationship of sect. *Jimenezia* to these two other sections, as suggested by the cpDNA cladistic analysis, indicates that substantial morphological convergence is indeed present in *Fuchsia*. Again, additional cpDNA data are needed to determine more firmly the position of *F. jimenezii* within *Fuchsia*.

The remaining eight sections of *Fuchsia* share three synapomorphies, but relationships among these sections are not clear based on the preliminary cpDNA consensus tree in Figure 10. Three distinct lines diverge early: (1) a lineage comprising sects. *Kierschlegeria* and *Quelusia*, which is defined by three synapomorphies; (2) sect. *Hemsleyella*, defined by two autapomorphies; and (3) an unresolved lineage comprising five sections (*Schufia*, *Encliandra*, *Fuchsia*, *Ellobium*, and *Pachyrrhiza*), defined by one homoplasious site mutation. The lack of substantial numbers of cpDNA site synapomorphies linking any of these sections (except for *Kierschlegeria* and *Quelusia*) is very suggestive that the genus *Fuchsia* diverged rapidly and profusely following the early separation of sect. *Skinnera* into the Old World and sect. *Jimenezia* into Central America. Indeed the three species examined from sect. *Fuchsia* do not even form a monophyletic lineage within the strict consensus tree depicted in Figure 10.

The close phylogenetic relationship of the temperate South American sects. *Kierschlegeria* and *Quelusia* is supported by cpDNA restriction fragment analysis. These two sections have already been suggested to be closely related (Raven, 1988), despite the unusual derived vegetative and floral characters of *F. lycioides* of sect. *Kierschlegeria*. The lack of resolution among other sections of *Fuchsia* in this cpDNA restriction site analysis does not provide much evidence for or against the prevailing phylogeny. The phylogenetic relationships of the new sect. *Pachyrrhiza* from Peru to other *Fuchsia* sections also are not resolved. These and additional representatives of *Fuchsia* are currently being surveyed with larger numbers of restriction enzymes and with an entire cpDNA clone bank to maximize the numbers of site mutations for phylogenetic analysis. However, if most sections of *Fuchsia* did indeed diverge quickly and at about the same time, as suggested by this study, there may not be substantial and thus statistically useful numbers of cpDNA synapomorphies. A preliminary cladistic analysis of morphological and cytological characters in *Fuchsia* likewise demonstrated the early divergence of sect. *Skinnera* and also failed to resolve relationships among the remaining New World sections (P. Berry and J. Crisci, pers. comm.).

DNA VERSUS MORPHOLOGY: A REVIEW

Chloroplast DNA restriction site comparisons in the Onagraceae have substantiated many relationships based on morphology, cytology, and experimental crosses. Most relationships in *Clarkia* sect. *Sympherica* are congruent with the earlier results of Lewis & Lewis (1955) and Davis (1970). For example, subsect. *Lautiflorae* is shown to be a natural lineage, with *C. lingulata* and *C. biloba* as a close sister species pair, supporting morphological and cytological evidence (Lewis & Roberts, 1956) and isozymic evidence (Gottlieb, 1974). Large chloroplast DNA differences among sections of *Clarkia* are consistent with the results of early work, suggesting that the genus, although natural, is composed of at least several evolutionarily distinctive sections (Lewis & Lewis, 1955). Likewise, the preliminary cpDNA analysis in *Fuchsia* provides evidence in support of the early divergence of the Old World sect. *Skinnera*, an event also suggested by morphological and phytochemical studies.

However, each of these separate cpDNA studies in the Onagraceae also provides strong evidence that DNA and morphology can result in different phylogenetic conclusions. The DNA results place *Clarkia rostrata* with the morphologically dissimilar *C. epilobioides* rather than with *C. lewisii* and *C. cylindrica*, species with which *C. rostrata* is barely distinguished morphologically, an unexpected result supported by isozyme evidence (Odrzykoski & Gottlieb, 1984). Even more unexpected is the discovery that cpDNA characters, as well as nuclear rDNA characters, provide compelling evidence that the monotypic *Heterogaura* is actually derived within *Clarkia* and has *C. dudleyana* as its closest relative. This relationship is clearly at odds with the great morphological differences between the two genera involving taxonomically important floral and fruit characters. The cpDNA analysis of *Fuchsia* indicates that *F. jimenezii* is one of the most ancient lineages within the genus but provides no evidence for a relationship of *F. jimenezii* to sects. *Schufia* and *Encliandra*, sections with which it shares several derived characters.

A survey of published phylogenetic studies using chloroplast DNA in angiosperms is presented in Table 4. Although a number of these studies encountered no incongruity between the relationships generated with cpDNA and morphology, crossing studies, or isozymes, many of the studies have found at least some instances of incongruity. Various explanations for these discrepancies are provided in these studies: (1) morphology or reproductive isolation may not be good measures of phylogenetic relatedness; (2) reliance on phenetic rather than cladistic studies of morphological variation; (3) unequal rates of morphological or genomic divergence; (4) unknown levels of molecular variation *within* ancestral species; and (5) cytoplasmic exchange through introgressive or secondary hybridization. The last explanation has been used in addressing incongruities in cpDNA studies of *Brassica* and *Pisum* (see Table 4). Cytoplasmic

   B. *Lycopersicon chmielewskii* (Palmer & Zamir, 1982)
   C. *Pisum sativum* (Palmer et al., 1985)

exchange via hybridization and introgression, giving rise to different and sometimes unexpected organeller- and nuclear-based phylogenies, is probably common in angiosperms. Clearly, a molecular phylogenetic study would be more thorough (and also more willingly accepted by the systematic community) if both the biparentally inherited nuclear genome and a predominantly uniparentally inherited organeller genome are examined and compared.

Doyle (1987), in a perceptive review of the promises and pitfalls of plant systematics at the DNA level, stated that the available DNA studies (both nuclear and organeller) suggest that "sweeping statements that a particular molecular phylogeny is 'right' and that more traditional approaches, such as morphology, are 'wrong' when the two do not happen to agree are unwarranted *without further investigations*" [italics added]. If, however, further investigations using alternative genetic or molecular methods consistently provide results contrary to the traditional approaches, it is then time to reexamine these traditional approaches.

The examples presented here of *Clarkia epilobioides/C. rostrata* and *C. dudleyana/Heterogaura heterandra* might well be some of the most definitive examples of where molecular phylogeny could be considered 'right' and the traditional approach 'wrong.' In these two cases, data from chloroplast DNA, nuclear rDNA, and isozymes provide independent and congruent phylogenies, contrary to phylogenies using morphology. Doyle (1987) further stated that "it is just such instances of incongruence that are likely to lead to major revelations about the evolution of the taxa being studied—or of the molecules being used in the analysis." Thus, disparity between DNA and morphology (1) is expected to occur in some or many systematic studies, (2) should be the basis for including additional systematic procedures to examine the disparity, (3) will provide insight into relative rates of molecular and morphological divergence, (4) should provide insight into what characters (morphological or molecular) in a given group are particularly prone to convergence or parallelism and thus less phylogenetically useful, and (5) will undoubtedly permit new or previously nontraditional questions to be asked and answered.

MODES AND TEMPOS IN THE EVOLUTION OF NUCLEAR RIBOSOMAL DNA: NEW CHARACTERS FOR EVOLUTIONARY STUDIES AND NEW MARKERS FOR GENETIC AND POPULATION STUDIES[1]

Richard A. Jorgensen[2,3] *and*
Paul D. Cluster[2]

ABSTRACT

The tempo of evolutionary change determines in what manner any class of characters is informative in evolutionary studies and at which taxonomic levels. Here we describe and summarize some fundamental features of the evolution of the DNA sequences that encode ribosomal RNA genes in the nuclear genome of higher plants. By analyzing a sample of angiosperm species having known phylogenetic relationships at five different taxonomic levels ranging from the intraspecific to the interfamilial, we show that plant ribosomal DNA determines at least eleven classes of characters that can be distinguished by comparisons at the DNA level. These classes are temporal and physical subsets of three basic modes of variation: length variation, single base pair substitution, and DNA modification. We also discuss the impact of length variants on population genetic studies and the implications of these studies for understanding the molecular mechanisms of rDNA evolution.

Because DNA is the richest and most unambiguous source of genetic variability, information on its evolution is fundamentally important to evolutionary biology. Research into the evolution of DNA is still in its infancy, and workers studying DNA variation are still faced with (1) cataloging both the classes of DNA sequences (characters) that are found in the genomes of various organisms and the ways (modes) in which these characters vary among organisms, and (2) measuring the approximate rate (tempo) of change in the different character classes. From this fundamental information it is possible to begin to ascertain at which phylogenetic level a particular character is useful in reconstructing phylogeny. Here we examine modes and tempos of evolution in nuclear-encoded ribosomal DNA. The available technology allows us to estimate the tempo of evolution in three basic modes: length variation, base pair substitution, and nucleotide modification.

PHYSICAL AND GENETIC DESCRIPTION OF rDNA

Ribosomal DNA, or rDNA, is the set of DNA sequences that directs the synthesis of ribosomal RNA. Each haploid nuclear genome of a higher plant cell typically contains 1,000 to 10,000 copies of ribosomal DNA (Ingle et al., 1975), a range roughly twenty-fold higher than in animal genomes. Copies of rDNA exist in long tandem arrays at one or a few chromosomal locations. Within a species, the number of copies of rDNA varies by as much as four-fold (Cullis & Davies, 1975; Long & Dawid, 1980). Unequal crossing-over is one likely mech-

anism responsible for variations in copy number (Szostak & Wu, 1980). Although there is some heterogeneity among copies of rDNA within individuals (see below), the rDNA repeat units of an individual plant are highly homogeneous. That is, while several types of rDNA repeat unit may be found in a single plant, many hundreds of repeat units are identical as assayed by Southern blot analysis. This homogeneity was first observed in comparisons within species contrasted with comparisons between species and is presumably the result of concerted evolution of rDNA repeat units, as explained by Arnheim et al. (1980). Similarly, in species where rDNA is found to reside at two or more genetic loci, repeat units are found to be quite homogeneous within each locus. Thus, loci can usually be distinguished by their repeat types, and homogeneity is greater within loci than between loci (Dvorak & Appels, 1982; Saghai-Maroof et al., 1984).

The physical structure of higher plant ribosomal DNA (Fig. 1) is similar to that in other higher eucaryotes (Long & Dawid, 1980, for review). The three ribosomal RNA coding regions lie in the order 5′, 18S, 5.8S, 25S, 3′, and are transcribed as a single large precursor, which is processed subsequently to the mature rRNA forms. Several hundred base pairs of DNA separate the 18S cistron from the 5.8S cistron and the 5.8S cistron from the 25S cistron. These two intercistronic regions are referred to as internal transcribed spacers (ITS). The region separating the transcription units of adjacent rDNA repeats is called the intergenic spacer (IGS, formerly NTS or nontranscribed spacer; Dover et al., 1982) and in most plants ranges in length from one to eight kilobase pairs (kb). A tandemly repeating sequence comprises part of the IGS region. This sequence varies interspecifically in length, ranging generally from 100 to 200 bp, while within species its length varies only slightly. The length of this subrepeat has been shown to be 130 bp in wheat, 180 bp in peas, 325 bp (comprised of two copies of a 155-bp sequence and one 14-bp sequence) in broad bean, 115 bp in both barley and oats, and 200 bp in maize (Appels & Dvorak, 1982; Jorgensen et al., 1982; Yakura et al., 1984; Saghai-Maroof et al., 1984; Cluster et al., in prep.; and McMullen et al., 1986, respectively). The number of these elements within a given rDNA repeat unit is variable, and thus the overall length of the IGS is variable, within and between populations. This variability in length of the IGS is discussed in detail below.

An individual plant's rDNA array is often heterogeneous with respect to the three basic modes of variation: length, nucleotide sequence, and base modification (e.g., Siegel & Kolacz, 1983; Appels & Dvorak, 1982; Waldron et al., 1983; Jorgensen et al., 1982, 1987). It should be noted that a fourth mode of rDNA variation occurs, namely variation in the copy number of rDNA per haploid genome; because it is a quantitative character it is rarely measured. rDNA copy number is unlikely to be informative taxonomically because it is extremely variable within species, although in genetic analyses it may have some utility. In Figure 2 the three principal modes of variation are illustrated for a single individual of the garden pea (Jorgensen et al., 1987). This individual carries a minimum of three types of rDNA repeat units, and each of the three is distinguished by the three modes. First, each type of repeat has a different overall length due to variation in the number of 185-bp subrepeats in the IGS. Second, nucleotide substitutions are evident in several regions of the rDNA repeat unit. Type "L" repeats (see Fig. 2) carry EcoRI sites in two of their nine subrepeats that are not present in types "S" or "C," and in the nonsubre-

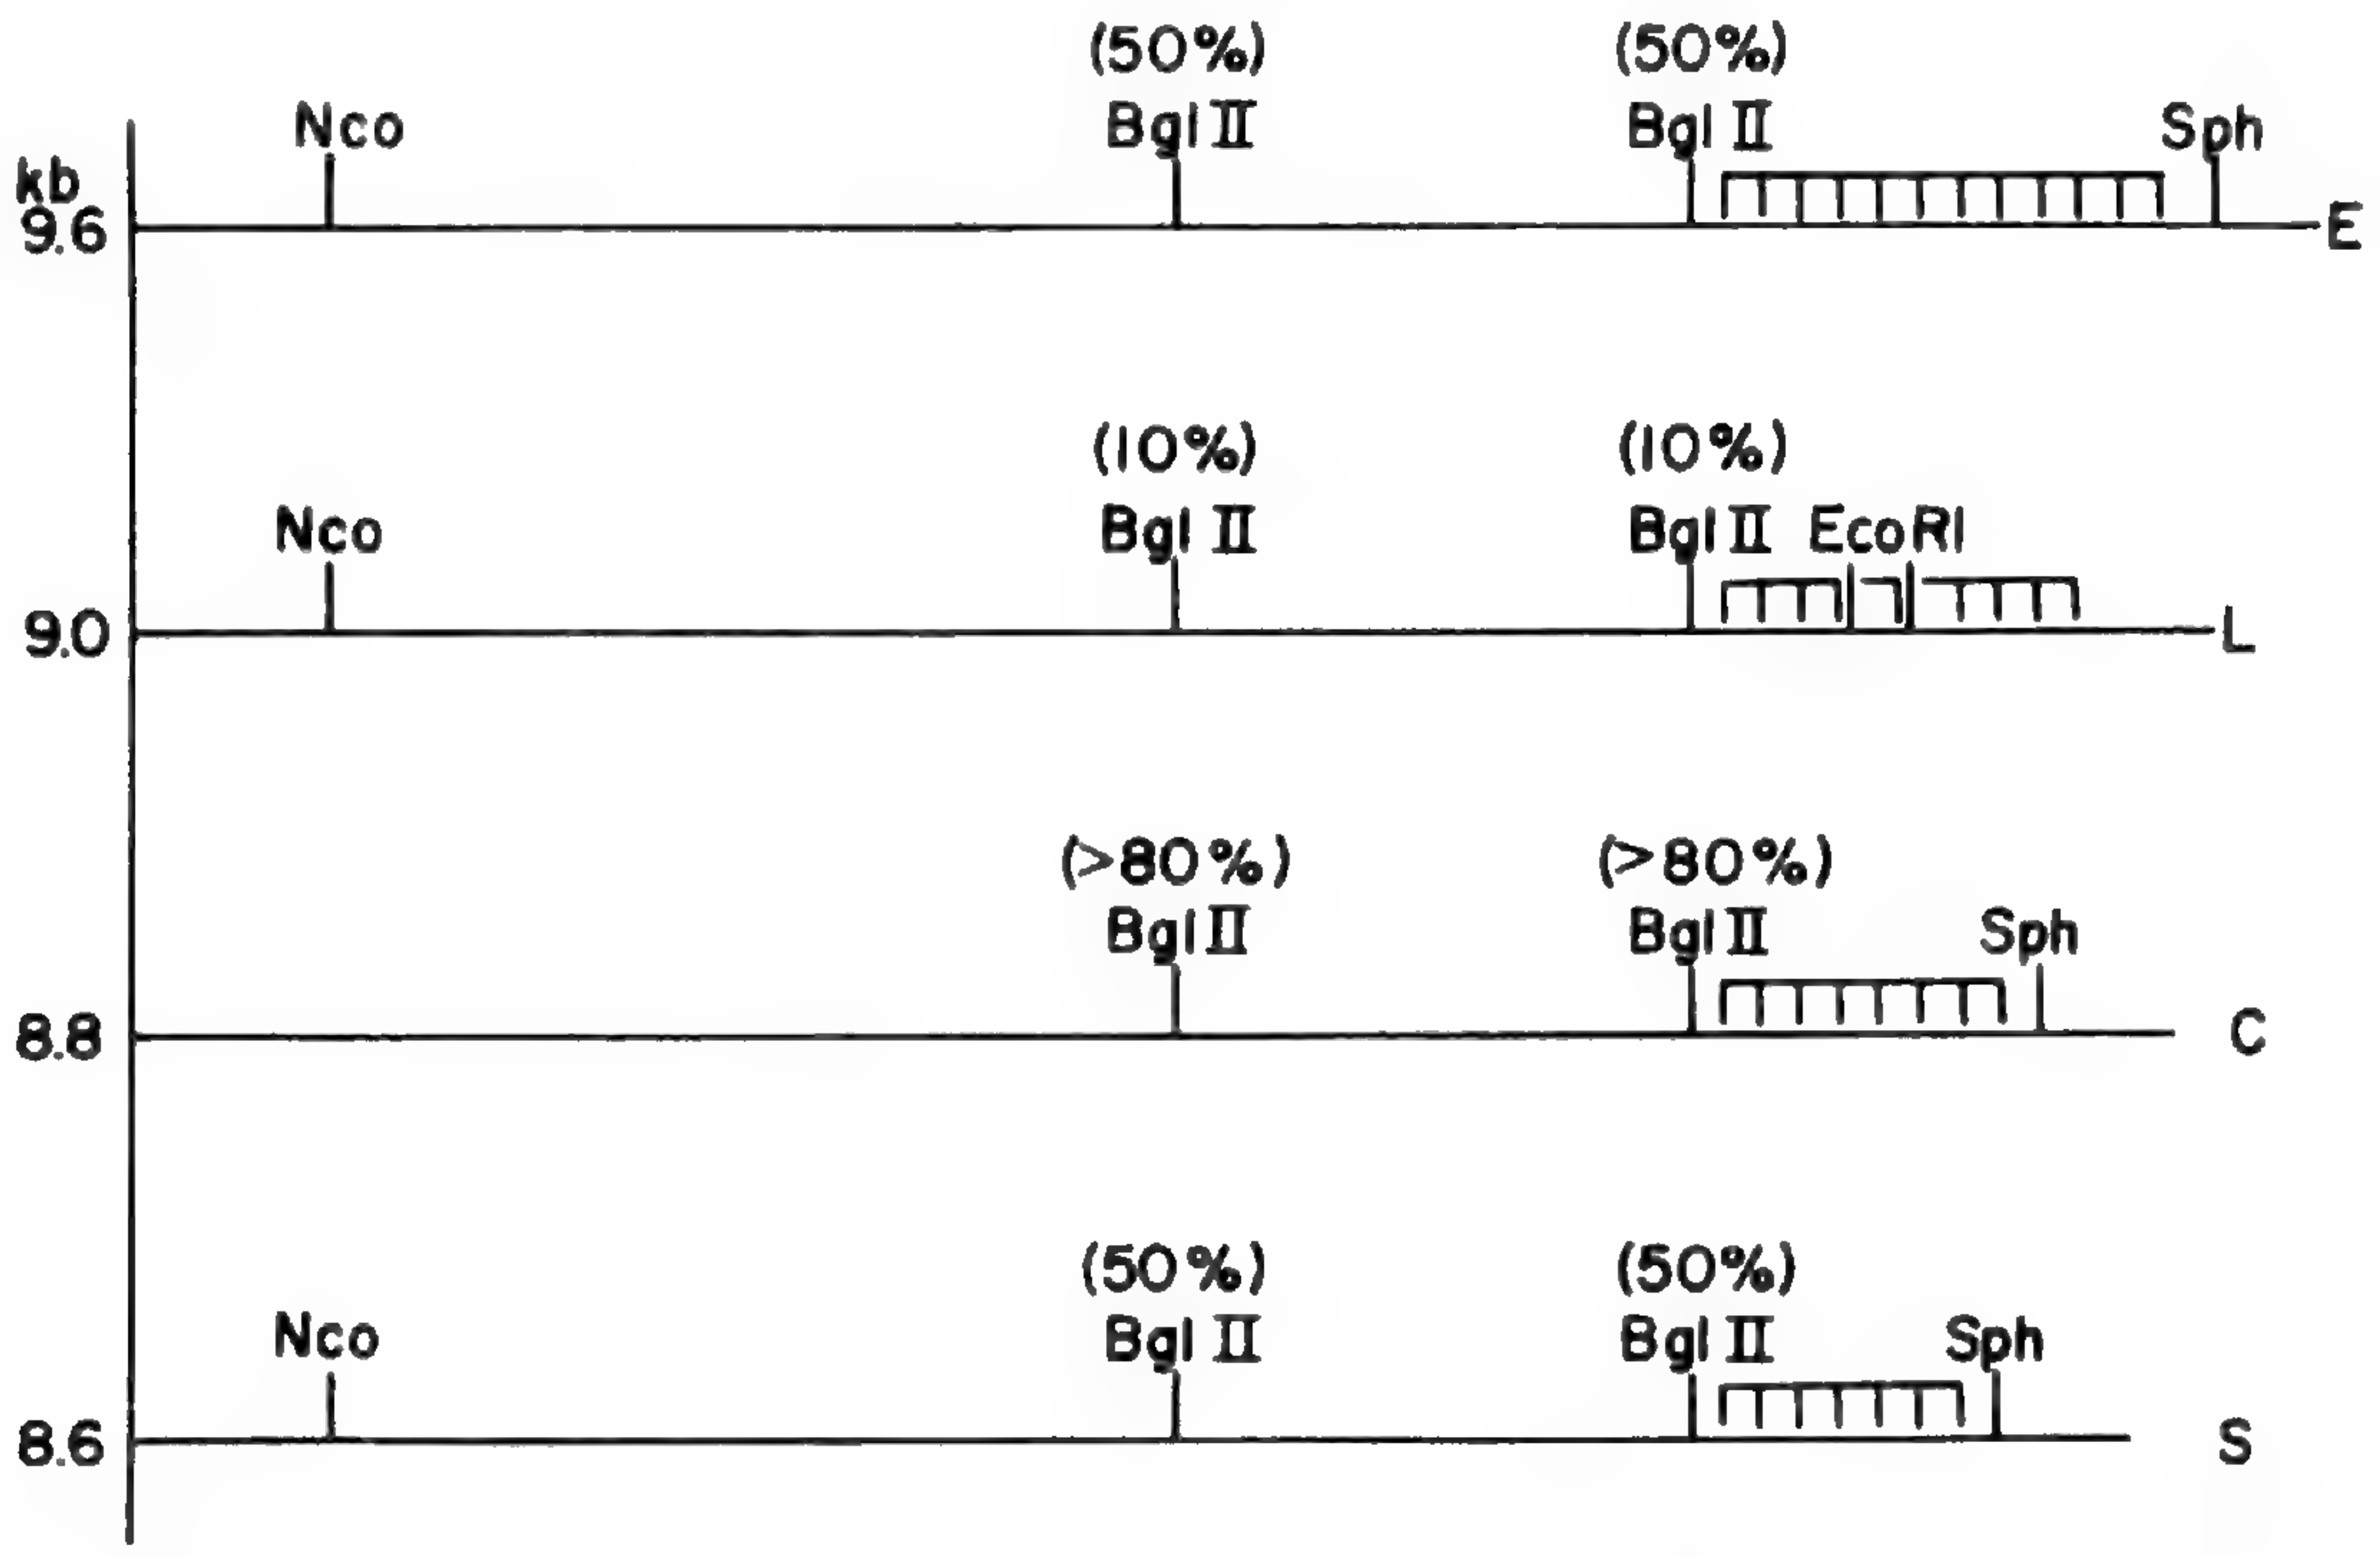

FIGURE 2. *Maps of four pea rDNA repeat units. L, C, and S refer to distinct repeat types found in a single pea plant. E refers to another repeat type found in* Pisum elatius. *Nco and Sph refer to NcoI and SphI.*

peat region of the IGS types "C" and "S" carry an SphI site not found in type "L." Within the rRNA coding sequence, an NcoI site in the 18S gene is present in both type "L"and "S," but absent in the cloned type "C" repeat. Third, the BglII cleavage sites of types "L"and "S" differ in their degree of apparent base modification such that only 10% of the BglII sites of "L" repeats are cleaved, while 50% of the BglII sites of "S" repeats are cleaved.

TEMPORAL ANALYSIS OF PLANT rDNA VARIATION

For a given mode of sequence evolution, the taxonomic level at which any segment of DNA is useful for making phylogenetic determinations is determined by the tempo at which that segment of DNA varies. Tempo can be estimated by analyzing DNA variation in species from several levels within an accepted taxonomic hierarchy. We have chosen nine legume genera for study: three (*Vicia, Pisum,* and *Lathyrus*) are from the tribe Vicieae and the rest (*Medicago, Trifolium, Lupinus, Wisteria, Cytisus,* and *Phaseolus*) are each from a different tribe. Seven genera are represented by a single species. *Vicia* is represented by five species, *Pisum* by four. For *V. sativa* and *P. sativum,* four and twenty, respectively, distinct isolates were examined. Outside the legume family we have compared the rDNA of wheat (*Triticum aestivum*) and pumpkin (*Cucurbita pepo*). Postulated phylogenetic relationships between species in this hierarchy are depicted in Figure 3.

Using the cloned rDNA repeat unit from *Pisum sativum* and detailed physical maps of both the cloned repeat and the pea nuclear genomic repeats described above, we performed nitrocellulose blot analysis (Southern, 1975) of rDNA sequences in the genomic DNA of each species. "Southern analysis" requires the use of a specific probe homologous to DNA sequences being analyzed. Different regions of the rDNA repeat unit were analyzed independently by use of seven different purified restriction fragments as probes (Fig. 4). The ITS region was analyzed by DNA sequencing because it was too small to analyze effectively by Southern analysis.

MODES AND TEMPOS OF VARIATION IN DIFFERENT rDNA REGIONS

A. Base Modifications

We have characterized in some detail two types of base modification in plant rDNA. They are distinguished both by sequence specificity and by degree of variability among taxa, as will be explained here. Most common is an evolutionarily conservative type of base modification typified by the BamHI site in the 25S gene. This site is modified in about one-half of the rDNA repeats of all the legume species in our survey, as well as in several other species (Gerlach & Bedbrook, 1979; Goldsborough et al., 1981; Jorgensen et al., 1982; Siegel & Kolacz, 1983). Siegel & Kolacz (1983) have postulated that this methylation is due to a CCG sequence of which the BamHI site (GGATCC) is a part. (That only one-half the sites are cleaved by

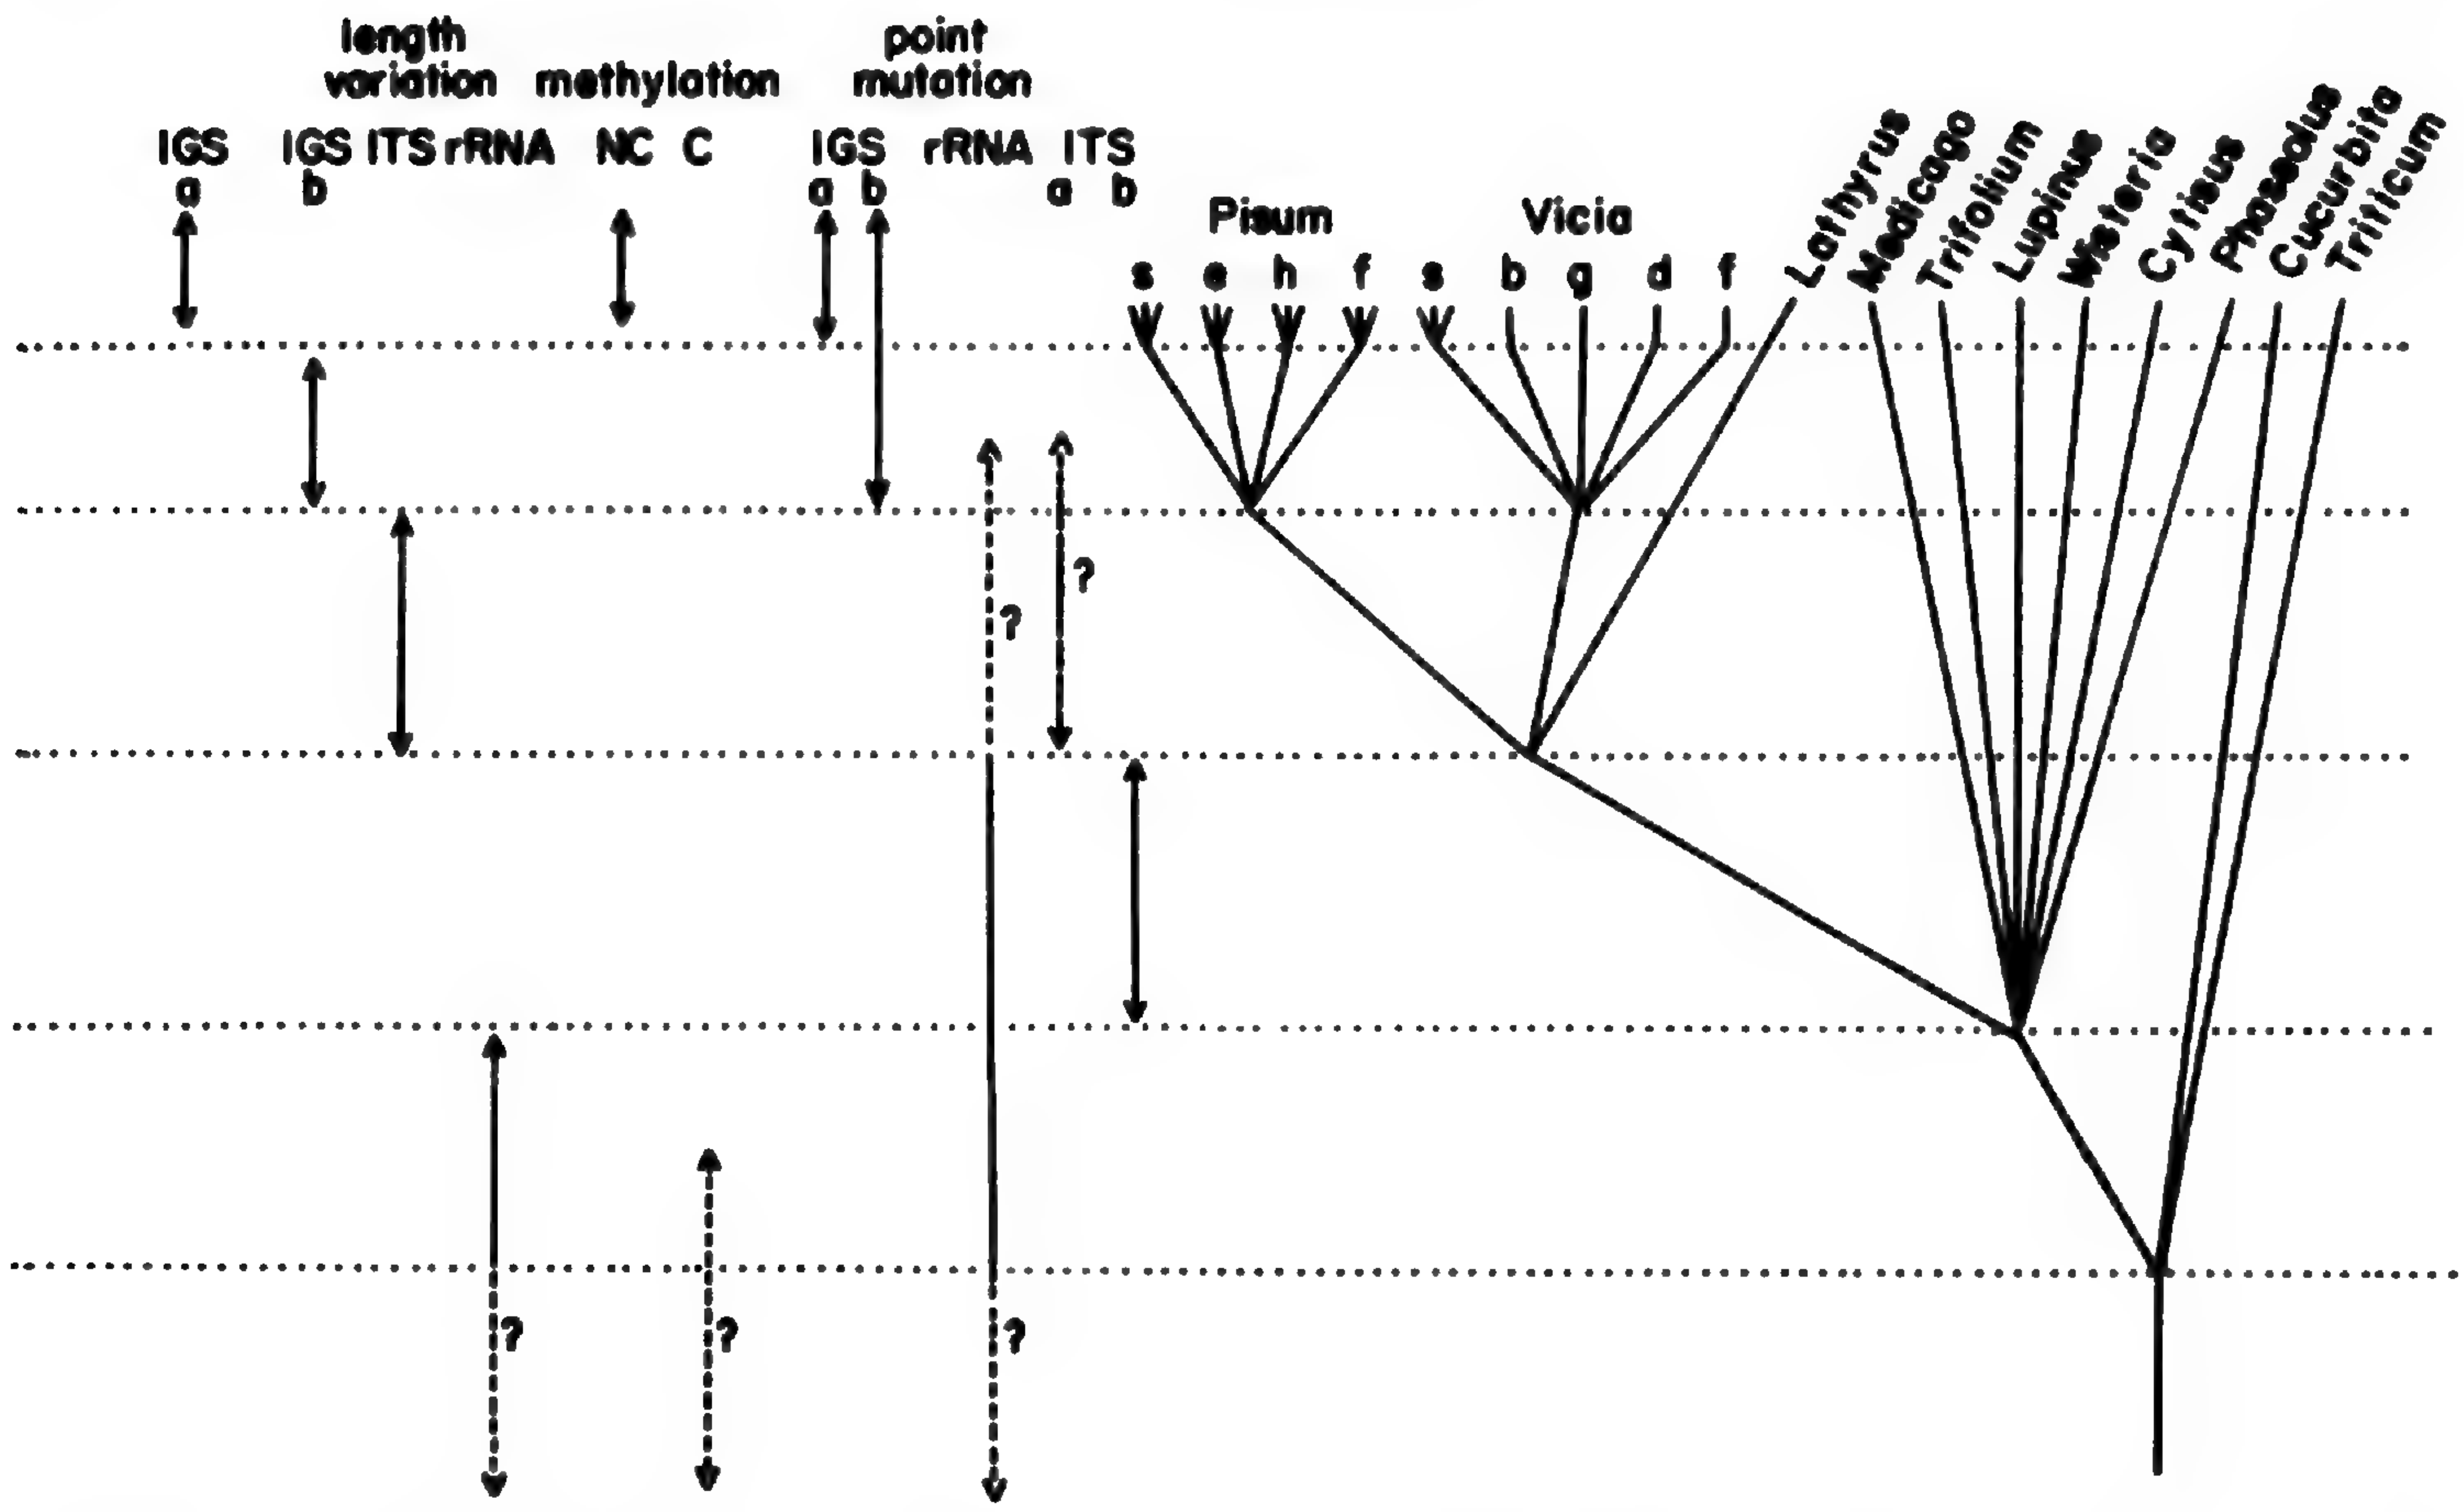

FIGURE 3. *Schematic drawing of evolutionary relationships among species analyzed and the taxonomic levels at which the eleven characters classes are proposed to be useful in reconstructing phylogeny. The taxonomic levels indicated are intraspecific [*Pisum sativum *(s)*, P. elatius *(e)*, P. humile *(h)*, P. fulvum *(f), and* Vicia sativa *(s)], intrageneric (*Vicia *and* Pisum*), intratribal (Vicieae), intrafamilial (Fabaceae), and within angiosperms. The cladogram is not meant to represent relationships but is presented only to illustrate the taxonomic levels being compared. IGS refers to intergenic spacer; ITS refers to internal transcribed spacer; NC to nonconservative; C to conservative.*

BamHI appears to be due to the fact that methylation occurs at either but not both C residues.) Methylation of CG and CXG sequences has been observed in all plants investigated to date. It is presumed that many of the other enzyme cleavage sites that contain CG or CXG sequences could be subject to evolutionarily conservative modification. However, the extreme conservatism of the 25S BamHI site modification is a specific example of the general phenomenon of plant cytosine modification, and it is unwise to generalize from this. In fact, within or near various structural genes a substantial number (and perhaps a large fraction) of CG and CXG sequences are unmethylated in a variety of plants, and the possibility of variation in plant CG, CXG modifications certainly exists.

In contrast to the BamHI modification, modification of the BglII sites in pea rDNA is apparently variable by degree among individual pea plants, just as it is variable among rDNA repeats of the same plant (Jorgensen et al., 1982, 1987). BglII sites do not contain CG or CXG sequences but could be part of CXG sequences. It is not clear whether the variable modification of BglII sites in rDNA is due to variation in (a) modification by the CG, CXG system, (b) modification by another system, or (c) sequences adjacent to the site. Adenine modification prevents cleavage by certain restriction enzymes, but these have not been analyzed for variability among plants.

B. Single Base Pair Substitutions

1. Coding Regions. The coding regions for mature rRNAs were compared in two ways: by comparing restriction maps of cloned repeats from pea, wheat, and pumpkin (Jorgensen et al., 1987) and by comparing Southern blots of legume species rDNA using probes A, B, C, and D (Fig. 4). The 18S genes of pea and wheat were found to differ at three of ten six-bp cleavage sites (at least three of 60 bp), while the genes of wheat and pumpkin differ at five of nine, and the genes of pea and pumpkin at two of eight. The 5′ end of the 25S gene shows no site conservation in comparisons of these three species, which is consistent with the fact that this is one of the last-conserved regions in comparisons among frog, yeast, and slime mold rDNA (Gerbi et al., 1982). The rest of the 25S gene shows substantial similarity among species:

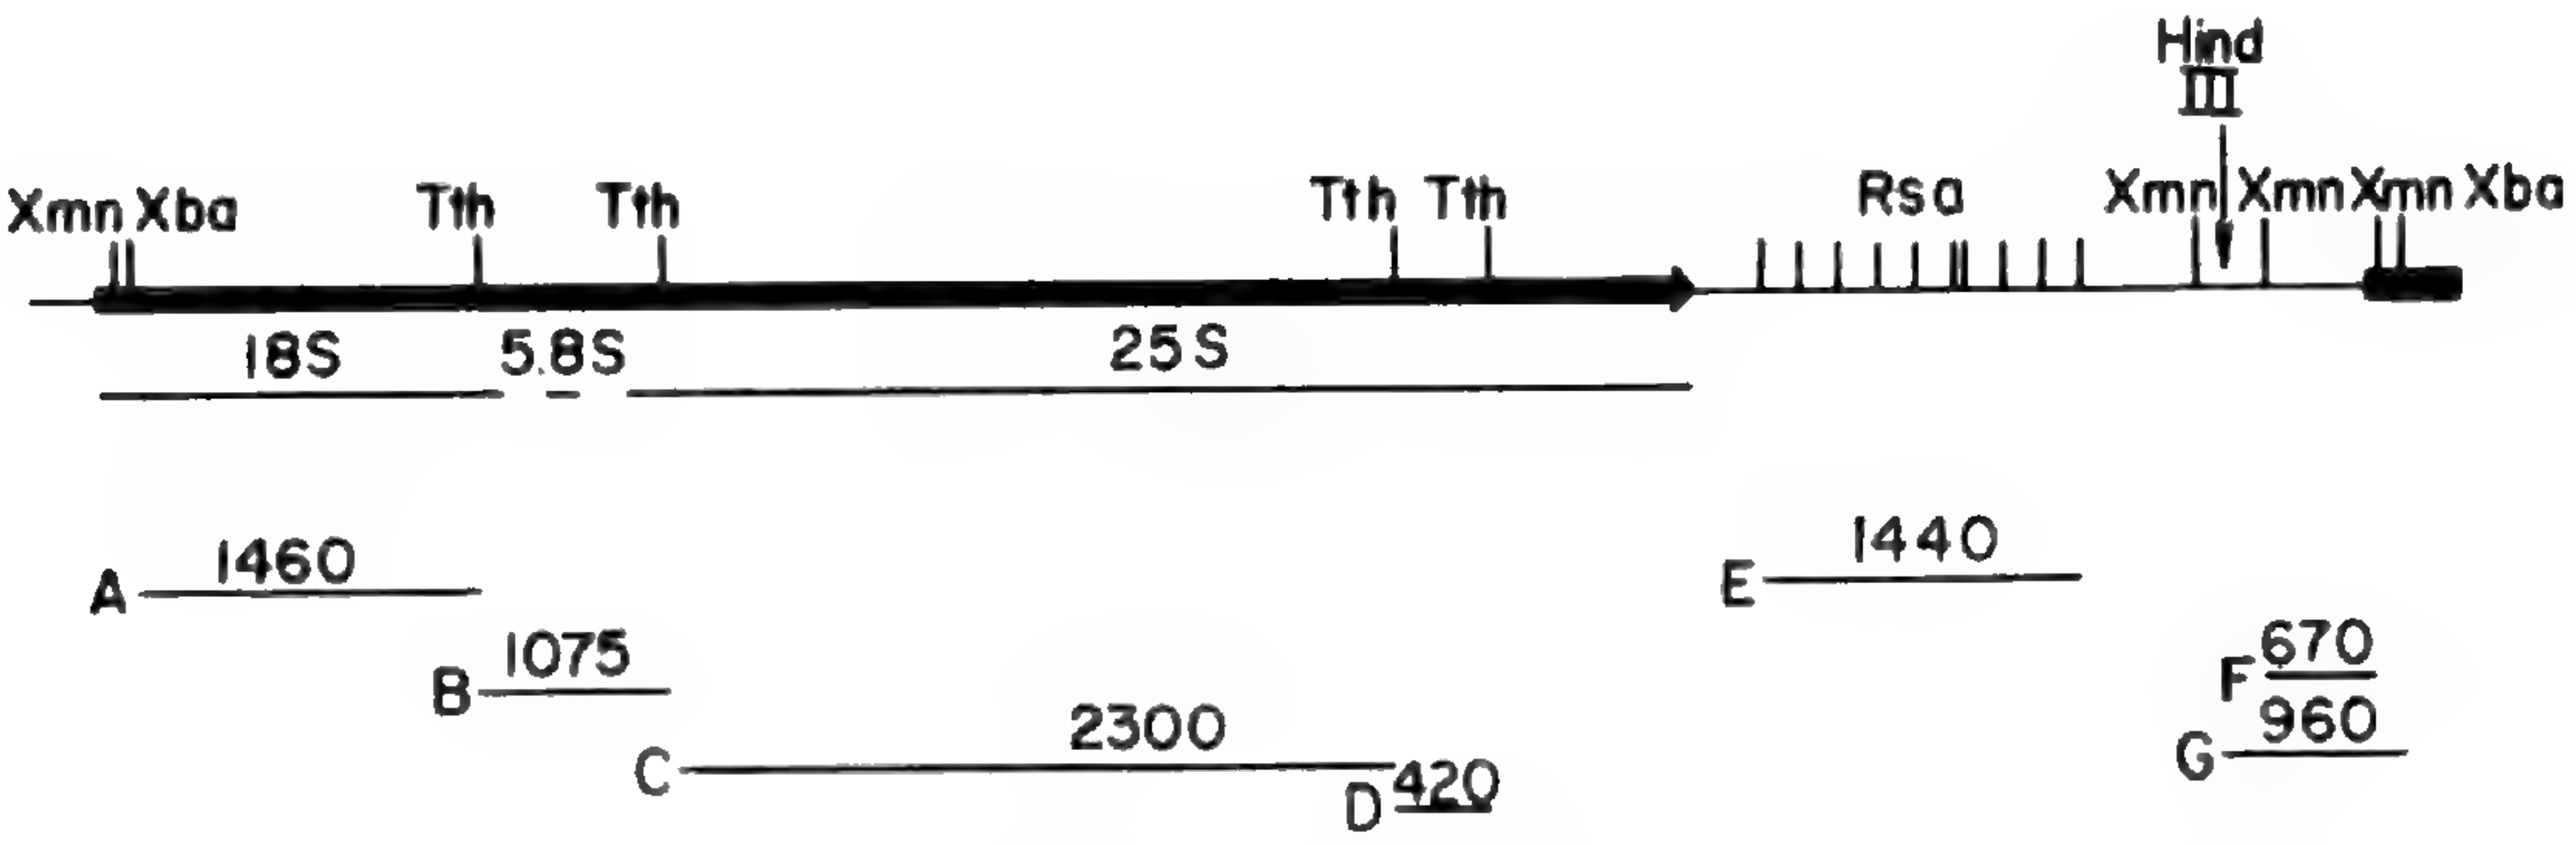

FIGURE 4. *Map indicating restriction fragments (A–G) used to study rDNA variation. Numbers indicate length of fragments in base pairs. Xmn, Xba, Rsa, and Tth refer to XmnI, XbaI, RsaI, and Tth111I.*

pea and pumpkin differ at three of ten sites, pea and wheat at eight of twelve, and wheat and pumpkin at five of ten. Although it is possible to align and compare the restriction maps of the pea, wheat, and pumpkin coding regions, a statistically significant number of mutations have not been analyzed to permit phylogenetic conclusions.

Southern analysis of different legume species reveals very little sequence divergence in the rRNA coding sequences, even after use of all available enzymes insensitive to base modification (Jorgensen et al., 1982). Figure 5 summarizes this analysis with a comparison of pea, vetch, and bean, illustrating the only two cleavage site mutations that could be detected in this survey of 19 cleavage sites (for a survey of 114 bp). The degree of sequence divergence in this rDNA region is at least several-fold less in the legume family than among peas, pumpkins, and wheat.

It is important to recognize the limitations inherent in the use of restriction enzyme analysis of plant rDNA for phylogenetic investigations. First, the choice of restriction enzymes for nuclear DNA analysis in plant genomes is more limited than for animal genomes or for plant organellar genomes due to the fact that plant nuclear DNA is methylated at most CG dinucleotides and CXG trinucleotides (Gruenbaum et al., 1981), and because many restriction enzymes that cleave sequences containing CG, CXG sequences do not cleave if these sequences are methylated. Thus, analysis of genomic rDNA by Southern blot is quite limited relative to analysis of rDNA clones using restriction enzymes with respect to the number of variants that can be detected. Cloned sequences are not necessarily a good alternative because the use of single clones from an array of thousands entails the risk of not being representative. Second, because rRNA coding sequences are only 5.5 kb long, in contrast to chloroplast DNA which amounts to about 150 kb (see Palmer et al., this volume), relatively few cleavage sites are available and relatively few variants can be detected. The obvious solution to this problem is to utilize rRNA sequencing. By doing so, Zimmer (this symposium, not published here) has shown that the conservative nature of the coding region is extremely useful in phylogenetic comparisons between distantly related genera and closely related families.

2. *ITS Region.* The ITS region, because it is small, also cannot be analyzed well with restriction enzymes. The DNA sequence of the 5.8S gene and its surrounding ITS sequences has been determined in pea and lupine (Jorgensen & Hess, unpubl.; Rafalski et al., 1983). A schematic comparison of

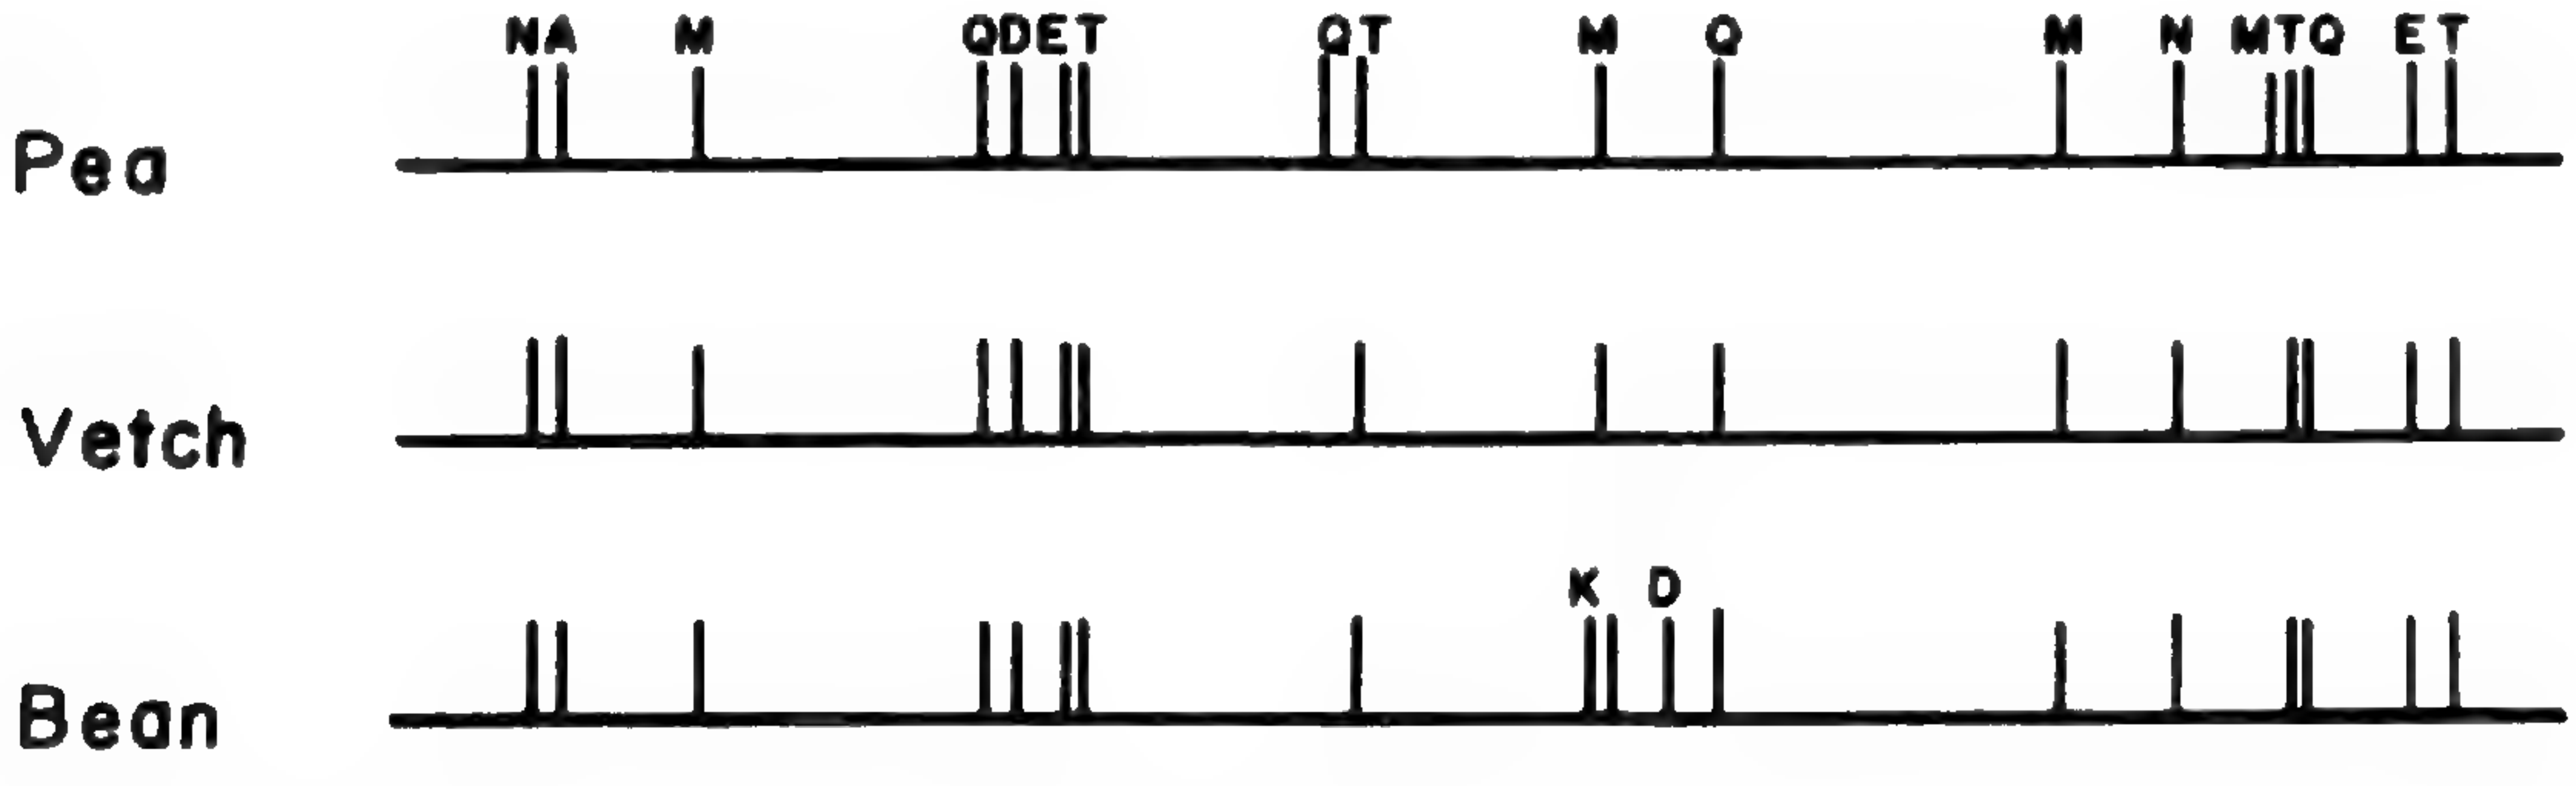

FIGURE 5. *Maps comparing coding regions of pea (*Pisum sativum*), vetch (*Vicia sativa*), and bean (*Phaseolus vulgaris*) rDNA. Symbols are coded as follows: N, XmnI; A, XbaI; M, BamHI; Q, SstI; D, BstEII; E, EcoRI; T, Tth111I; K, KpnI.*

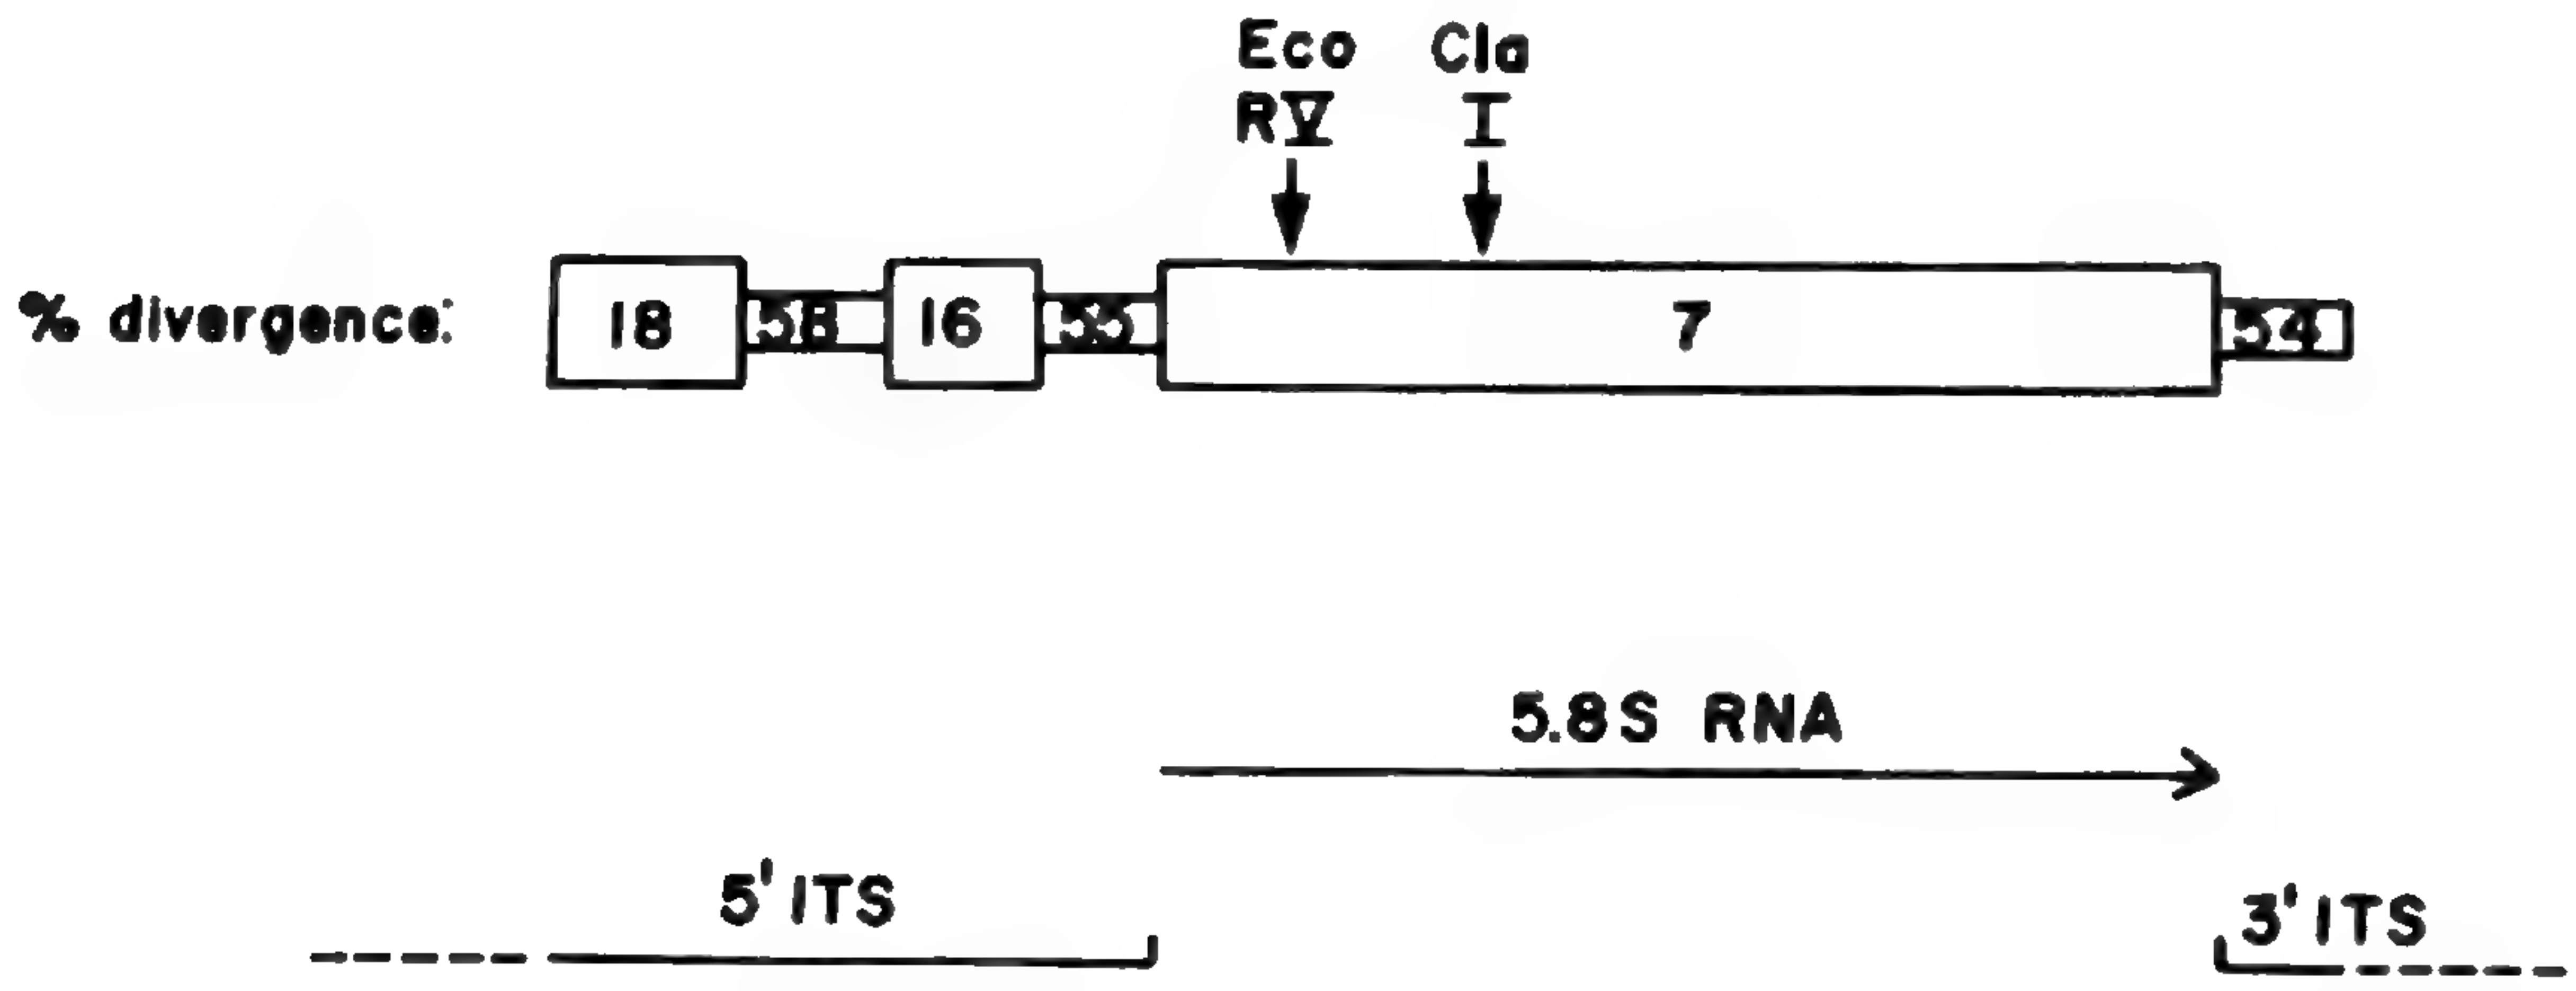

FIGURE 6. *Map of 5.8S rRNA gene and ITS regions. Numbers indicate % divergence in nucleotide sequence between* Pisum sativum *and* Lupinus luteus *rDNA clones.*

these sequences is shown in Figure 6. DNA in the ITS was observed to change at two distinct rates, both faster than that within the 5.8S gene. The 5.8S rRNA of *Vicia faba* has been sequenced (Tanaka et al., 1980) and differs from the pea 5.8S rRNA by 2%.

3. IGS Region. Restriction enzyme analysis of the nonsubrepeat segment of the IGS region reveals many cleavage site variants within legume genera (Jorgensen et al., 1982). These variants appear to have some utility in assessing phylogenetic relationships and in genetic studies of interfertile populations and species (Zimmer et al., in prep.). In the IGS subrepeats, DNA sequence and restriction pattern analyses indicate that subrepeat sequences are variable within and among individual genomes in a species (Appels & Dvorak, 1982; Jorgensen et al., 1987). This variation in single base pair substitutions in the IGS is of interest primarily within species. Because this variability is very difficult to detect with restriction analyses of total genomic DNA, it is of limited utility, except in studies of the evolution of the subrepeat itself.

C. Length Variation

1. Coding Regions. The ribosomal RNA transcription unit was surveyed for length variants by monitoring four restriction fragments (A–D) indicated in Figure 4. Fragment A, a 1,460-bp XbaI–TthI fragment, lies entirely within the 18S gene; fragments B (2,300-bp Tth fragment) and D (420-bp Tth fragment) lie entirely within the 25S gene; fragment C, the 1,075-bp TthI fragment, carries the entire ITS region and the 5.8S gene within it, as well as short portions of the 18S and 25S genes. Within the legumes, no length variations were observed (detection limit, 50 bp) in any of the three fragments that lie within the rRNA genes.

The 5.8S rRNA coding regions of pea, broad bean, and lupine have now been sequenced (Hess & Jorgensen, unpubl.; Tanaka et al., 1980; Rafalski et al., 1983). Comparison of these sequences shows that the 164-bp 5.8S gene differs in length between pea and broad bean by only one base pair and between pea and lupine by two adjacent base pairs. Length variation of this sort is very likely to be found also within the 18S and 25S genes by DNA sequence comparisons, but not by restriction fragment comparisons, as the differences are too small to detect by agarose gel electrophoresis.

2. ITS Region. Overall length variation in the ITS, as monitored by changes in the 1,075-bp TthI fragment, is much more prevalent than are length changes in the three coding sequence restriction fragments. The pea ITS 1,075-bp TthI fragment detects fragments varying in size from 1,000 to 1,200 base pairs among the nine legume genera surveyed. At least six of these size classes are distinct from all the others. Within *Pisum* and *Vicia* no length variation was observed. Thus, length variants of 50 bp or greater appear to be restricted mostly to the intergeneric level, at least in the tribe Vicieae. Whether small variants ever occur within these genera and whether observed variation results from the accumulation of many small variants or few large variants remains to be determined. For particular ITS length variants to be of practical use in studying relationships among genera, they will have to be large and rare, rather than small and common. Particular length variants in chloroplast DNA have been quite useful (in conjunction with point mutations) in developing chloroplast DNA phylogenies (Palmer et al., this volume).

3. IGS Region. By far the most variable region of the rDNA repeat unit is the subrepeat-containing region. Length variants of restriction fragments carrying this region almost always differ by a multiple of the length of the subrepeat. For example, 14 distinct fragment lengths were observed in a sample of 12 pea lines, each length differing from the others by a multiple of 180 bp. Similarly, detailed intraspecific surveys of IGS variability among hundreds of individuals have demonstrated variation produced by 15 increments of 115 bp in barley (Saghai-Maroof et al., 1984) and by 17 increments of 115 bp in wild oats (*Avena barbata*) (Cluster et al., in prep.), indicating that the subrepeat length is 115 bp in each of these species. This large number of variants results in a large number of IGS phenotypes observed within and among populations (see below). For example, 11 distinct phenotypes were observed among the 12 pea lines.

The next most length-variable region is the part of the IGS region without subrepeats. We have monitored this region in *Pisum* with a 960-bp restriction fragment (G) produced by combined cleavage with HindIII and XbaI and with two XmnI fragments (E and F) of 310 bp and 670 bp (Fig. 4). Among ten pea lines that showed extensive variation in length of IGS-a, we found only two IGS-b types. These probably resulted from a single substitution event, this resulting in several restriction site differences as well as a 100-bp length difference. This finding illustrates the need for caution in interpreting restriction patterns and consideration of the possibility that restriction site variants in the IGS-b may be the result of deletions, insertions, or substitutions rather than point mutations. Interpretation of the molecular basis of mutations in this region in the absence of direct DNA sequence information is prone to error due to the small length changes potentially involved.

D. Summary of Tempos and Modes

Based on the results described above, Figure 3 illustrates the taxonomic levels at which the 11 identified character classes may have some utility in evolutionary genetic studies. It should be noted that characters in the single base pair substitution (point mutation) mode will be best detected by sequencing of rRNA or cloned rDNA, not by restriction analysis, as is demonstrated by Zimmer (this symposium, not published here). Clearly the size of the rRNA coding region indicates that this region will provide the greatest number of characters and so will be the most informative. Further, we would expect this region to be useful at levels ranging from the intergeneric to the interfamilial. It would be interesting to test the utility of the nonrepeated IGS region for intrageneric comparisons, although length variations (i.e., additions and deletions) might preclude this possibility if they are found to occur so frequently as to obscure sequence similarities. Characters in the base modification and length modes will be best detected by restriction analyses of total genomic DNA. It appears that character classes in these two modes will be useful primarily in intraspecific genetic studies, as described in the next section.

VARIATION WITHIN AND AMONG POPULATIONS OF A SINGLE SPECIES

The rDNA spacer length (sl) phenotype of individual wild oat plants usually is comprised of 4–10 variants, out of 17 variants known in the species, often in widely varying copy numbers. From among over 500 individuals sampled, at least 40 distinct phenotypes were distinguished by scoring the most abundant sl variants (Cluster et al., in prep.). Variation of rDNA sl phenotypes among populations of wild oats in California closely tracks previously established patterns of differentiation identified by allozymes, morphological characters, and quantitative characters. Furthermore, the degree of variability suggests that it may be possible to identify and differentiate populations on the basis of rDNA variability alone nearly as accurately as with the available set of variable allozyme loci. Similarly, in 75 samples of barley, 15 distinct sl phenotypes could be distinguished (Saghai-Maroof et al., 1984). Most of these were comprised of two or three sl variants. The level of intraspecific polymorphism in the IGS is, therefore, extremely high. In the case of wild oats, the ability of sl variants to distinguish in detail among and between populations is probably the result of two genetic properties of rDNA variants in this species: (1) that these variants lie at a minimum of four independently segregating loci and (2) that each locus contains hundreds or thousands of repeat units which can be of more than one sl variant type.

Another result of genetic analysis of rDNA is the observation of nonrandom distribution of sl variants in several species, which suggests that genetic exchange occurs less frequently between than within nucleolus organizer regions. This situation occurs in barley (Saghai-Maroof et al., 1984), wheat (Dvorak & Appels, 1982), pea (Ellis et al., 1984; Polans et al., 1986), and mouse (Arnheim et al., 1982); however, random distribution has been reported in humans (Krystal et al., 1981). In wild oats the most abundant sl variants were present in nearly all isolates, including both parents of the single F2 analyzed, and so it is not possible to assess accurately whether these variants are distributed randomly or nonramdomly among loci, even though five less-abundant variants are nonrandomly distributed. In species where a degree of nonrandomness is observed, rDNA appears to be a new and useful genetic marker (Saghai-Maroof et al., 1984). However, the multilocus nature of rDNA spacer length variation may place a severe limitation on its use in population genetics because of the difficulty in determining each plant's genotype, except for those genomes possessing only a single major nucleolus organizing region (e.g., tomato and corn). Still, the great amount of phenotypic diversity will clearly be useful.

Also noteworthy is the observation that the composite frequency distribution of rDNA sl variants in California wild oats shows a nearly Poisson distribution of sl variants centered at sl variant 8. There at at least three ways to explain this distribution. First, it could be the result of classical forces in population divergence such as genetic drift and/or selection on loci at or correlated with rDNA. Second, it could be the result of stochastic molecular processes, perhaps involving DNA replication or repair. Third, it could be determined by the function of the subrepeat.

The first explanation is based on the fact that in populations that reproduce substantially by selfing, a correlational structure is imposed on all components of the genome, allowing selection at each locus to affect allelic frequencies at all other loci in the genome. Thus, sl variant frequencies at rDNA loci must reflect the selective effects of many other loci and could be determined by these forces (Saghai-Maroof et al., 1984).

The second explanation considers whether the observed distribution could be simply a consequence of the molecular mechanisms that create new spacer length variants. New variants can appear in evolutionary time by mechanisms such as unequal crossing-over, resulting in repeated cycles of amplification and contraction of arrays of both repeats and subrepeats of rDNA. Accordingly, one can hypothesize that the number of subrepeats in the intergenic spacer region would be determined by a feature(s) of these mutational mechanisms whereby very long subrepeat arrays are more likely to be shortened than lengthened and short arrays are more likely to be lengthened than shortened, resulting in a balance in wild oats, for instance, at slv-8. Since various cellular processes might affect this mechanistic optimum, it could be possible for species to differ in their optimum number of subrepeats, were such a mechanism the only one operating on the distribution.

The third explanation considers what function the IGS might have, based on recent observations on the transcriptional and structural nature of the subrepeat elements (Reeder, 1984; Flavell et al., 1987). Briefly, it is hypothesized that the IGS subrepeats function analogously to enhancer sequences, increasing the transcription of the repeat unit(s) to which they are adjacent. It has been observed that rDNA repeat units with more subrepeats are transcribed with strong preference over units with fewer subrepeats, probably due to an interaction between subrepeats and some positive transcription factor. Furthermore, loci with repeat units having more subrepeats show nucleolar dominance over loci having fewer repeats. These observations provide a simple explanation of how natural selection for longer sl variants might occur. Of course, subrepeats apparently do not increase to many tens or hundreds of copies. Therefore, we must also hypothesize that too large a number of subrepeats can be deleterious. Perhaps multiple subrepeats would sequester a transcription factor not only from rRNA promoters in unlinked loci but also from promoters in adjacent repeat units (see Reeder, 1984, for detailed discussion of this model). This situation would likely lead to a reduction in efficiency of rRNA transcription and thereby be deleterious to the individual. Thus, it is possible that natural selection can *directly* mold the rDNA sl variant pattern and influence the frequency distribution seen in wild oats.

SUMMARY

Eleven classes of useful characters have been identified for plant nuclear ribosomal RNA genes. These classes and their approximate rates of evolution are as follows:

(1) The length of the plant ribosomal DNA repeat unit is highly variable within most species and this variability has great utility in studies of populations. A 100–200-bp sequence that is repeated many times in tandem in the IGS region of rDNA forms the molecular basis for this variation in that the number of tandem copies of this sequence differs among individuals as well as among rDNA repeats within an individual. Studies of these variants appear to be helpful in elucidating the molecular mechanisms of rDNA evolution.

(2) The nonrepeating portion of the IGS region is less variable than is the subrepeat region, but is variable in length within the genera *Pisum* and *Vicia*; this variability might have utility in assessing specific relationships within such genera.

(3 and 4) Ribosomal RNA coding sequences are invariant in length in restriction pattern analyses,

but length variation is observed in the internal transcribed spacer (ITS) region. The frequency at which length variations in the ITS are detected is lower than that for length variation in either segment of the IGS. It is not likely that length variation in this region will be useful phylogenetically.

(5 and 6) Modification of Bg<III cleavage sites in pea rDNA varies quantitatively among pure lines and between wild populations. Such variants might be useful in genetic studies, but only to a limited degree since they are not as frequently observed as IGS length variants. A second class of modification is extremely conservative, as is illustrated by one of the rDNAs BamHI cleavage sites, which is modified in all legume and cereal species so far examined.

(7-11) Nucleotide substitutions accumulate in plant rDNA at several distinct tempos in distinct segments of DNA, resulting in a minimum of five character classes. In the IGS region they are found in (a) the subrepeat segment, differing among rDNA repeats of single individuals, and (b) in the nonrepeating segment within and among species of the same genus. Comparison of ITS DNA sequences of pea and lupine reveals four blocks of sequence, each of which has accumulated base substitutions at one of two levels, both greater than within the 5.8S rRNA coding sequences as determined by comparing sequences of pea, broad bean, lupine, and wheat and restriction enzyme cleavage sites of pea, broad bean, runner bean, pumpkin, and wheat.

DNA CONTENT VARIATION AMONG HIGHER PLANTS[1]

H. James Price[2]

ABSTRACT

DNA content varies well over 100-fold among diploid herbaceous angiosperms. Differences exceeding two- to three-fold commonly exist among congeneric species. There is no overall correlation between DNA content and evolutionary or genetic complexity, and apparently only a small percentage of a plant genome has coding functions. The question of adaptive versus nonadaptive roles of variation in nuclear DNA content is addressed. The geographic, ecological, and taxonomic distributions of DNA content are not random; they apparently represent the results of natural selection. Several examples of evolutionary changes of DNA content and of geographical and ecological correlates are presented. Variation in DNA content is discussed in terms of the nucleotypic theory. The nucleotype is determined by the total quantity of DNA, both genetic and nongenetic, that has been correlated with several factors, including nuclear volume, cell volume, mitotic cycle time, and the duration of meiosis. It is proposed that differences in DNA content have striking and multiple nucleotypic effects on plant development and adaptation. A precise technique for the scanning microspectrophotometric determination of DNA content from Feulgen-stained leaf epidermal cells is presented.

Extensive variation in genomic DNA content exists among plant and animal taxa (Bachmann et al., 1972; Sparrow et al., 1972; Bennett & Smith, 1976; Price, 1976). Nuclear DNA amount among diploid herbaceous angiosperm species varies well over 100-fold (Bennett & Smith, 1976; Price, 1976). For example, *Arabidopsis thaliana* (2C DNA content = ca. 0.5 pg) and *Trillium erectum* (2C DNA content = ca. 80 pg) both have a diploid chromosome number of ten, but *T. erectum* has very much larger chromosomes housing about 160 times more DNA. Even more variation is apparent when polyploid species are considered, e.g., *Fritillaria davisii* (2C DNA content = ca. 225 pg) (Bennett & Smith, 1976). Differences in genomic DNA content exceeding two- to three-fold commonly occur among congeneric species, including those in the genera *Gossypium* (Edwards & Endrizzi, 1975), *Vicia* (Chooi, 1971), *Crepis* (Jones & Brown, 1976), and *Microseris* and *Agoseris* (Price & Bachmann, 1975).

Among eukaryotes, there is no strong correlation between DNA content and organismic or genetic complexity (Sparrow et al., 1972). As stated above, even closely related species vary greatly in DNA content. Furthermore, it has been estimated that only a small percent of the base pairs of DNA are utilized for coding proteins in plants (Flavell, 1980). The general lack of a correlation between organismic complexity and DNA content, the variation in genome size (DNA amount per genome) among closely related species, and the apparent surplus of DNA above that coding for proteins have been called the DNA C-value paradox (Thomas, 1971; Raff & Kaufman, 1983).

Differences in DNA content apparently involve redundant nucleotide sequences that are without coding function (Flavell et al., 1974). It is not the purpose of this paper to discuss the nature of these sequences. The reader is referred to Murray et al. (1981), Walbot & Goldberg (1979), and Flavell (1980, 1986) for discussions concerning repetitive sequences within plant genomes.

The role of genome size variation will be discussed in terms of phenotypic effects independent of any biochemical or coding functions that the nucleotide sequences may have. Topics included are (1) selfish DNA, (2) the nucleotype, and (3) taxonomic, geographical, and ecological distribution of DNA content variation. Lastly, a critique

of techniques for determining DNA content using scanning microspectrophotometry will be presented.

SELFISH DNA

Orgel & Crick (1980) and Doolittle & Sapienza (1980) proposed that processes involved with DNA replication might allow the accumulation of DNA sequences in a genome whose presence stimulates the further accumulation of similar sequences. These sequences were considered to have no effect on the phenotype and to contribute little or nothing to the fitness of the organism. They suggested that this "selfish" or "parasitic" DNA may explain much of the variation in DNA content observed among species. These papers have resulted in an array of responses (see Nature 285: 617–620, 645–648, 1980) both favoring and criticizing the concept. In spite of controversy, the concept of selfish DNA is important because it points out the futility of searching for a biochemical function for all DNA sequences and because it stimulates thought on the origins and turnover of sequences in the genome. However, selfish DNA by definition excludes any functions for the sequences and thus diverts attention away from questions concerning evolutionary significance of variation in DNA content. If the generation of selfish DNA sequences is regarded as a mutational event that generates variation in genome size (Cavalier-Smith, 1980), then the important question becomes how much variation in DNA amount, regardless of mode of origin, is tolerated before selection comes into force.

The puzzle of genome size variation probably will not be solved at the subcellular level. Rather, the cellular effects of DNA amount are more likely reflected as a whole-organism phenomenon that can be best studied at the developmental, populational, and ecological levels. It has been proposed that the mere bulk of all the DNA in the genome exerts an influence on the phenotype so that under some circumstances selection favors accumulation of nuclear DNA more or less independently of its nucleotide sequence, while under different conditions the loss of sequences not necessary to survival may bring about considerable adaptive advantage (Bennett, 1972; Price, 1976; Bachmann et al., 1985).

NUCLEOTYPIC EFFECTS

The nucleotype is defined as the effect of DNA quantity on the phenotype apart from the coding function (Bennett, 1972). The nucleotype is determined by the total quantity of DNA, both genetic and nongenetic, and influences several cellular and developmental parameters, including chromosome size, nuclear volume, cell volume, mitotic cycle time and the duration of meiosis.

General comparisons of karyotypes of plants with similar chromosome numbers showed that those with higher DNA contents have larger chromosomes (Sparrow & Evans, 1961; Sparrow et al., 1968; and others). Measurements of individual metaphase chromosomes indicated a strong positive correlation between DNA content, chromosome volume, and chromosome mass (see Rees & Jones, 1972; Levin & Funderburg, 1979). Furthermore, a strong correlation exists between the total length of the synaptonemal complex and genome size in plants (Anderson et al., 1985).

Baetcke et al. (1967) biochemically determined DNA content and measured nuclear volume from root meristems of 30 herbaceous angiosperms representing ten families. The DNA content varied over a 35-fold range among these species, and a linear relationship (slope = + 1) was demonstrated between DNA content and the mean nuclear volume of meristematic cells of root and shoot.

Price et al. (1973) measured cell and nuclear volume of apical meristem cells of species ranging over 100-fold in DNA content. The data indicated a direct correlation between nuclear volume, cell volume (slope = + 1), and DNA content. Additional data supporting a positive relationship between DNA content and cell volume include the research with unicellular algae by Holm-Hansen (1969), a study of a polyploid series of yeast, $1X$ to $8X$ (Gunge & Nakatomi, 1972), a correlation between the fresh weight and DNA content of root meristematic cells from thirteen angiosperm species (Martin, 1966), a relationship between DNA content and cell volume among *Gossypium* species (Edwards & Endrizzi, 1975), and an increase in cell size in rye with supernumerary chromosomes (Rees, 1972).

Nurse (1985) discussed the interaction of genes and DNA amount in the determination of cell volume. Although genes that influence cell volume have been studied, they cannot account for the correlation of cell size and DNA content. Factors other than DNA content that affect nuclear and cell volume of meristematic and differentiated cells include physiological differences, nutritional and environmental state of the plant, and the genotype (Price et al., 1973). However, in light of the strong correlation between DNA content, nuclear volume, and cell size, a reasonable hypothesis is to consider DNA content as determining a fundamental nuclear and cell size that is influenced by developmental, genetic, and environmental factors. Selection for

DNA amount may be partly through its effects on nuclear and/or cellular size.

The importance of cell size to plant adaptation needs much more research. Cutler et al. (1977) suggested that smaller cells help plants resist moisture stress because they maintain turgor with solute accumulation under lower water potential values than do larger cells. Nobel (1980) related water use efficiency (WUE = net rate of CO_2 uptake divided by net transpiration rate) in plant leaves to several factors, including diffusion across the cell wall and membranes, photochemistry, biochemistry, effects of the atmosphere, leaf temperature, stomatal opening, cellular properties, and leaf anatomy. The factor A^{mes}/A (mesophyll surface area per unit of leaf area) was mathematically modeled and experimentally demonstrated to affect WUE, i.e., an increase in A^{mes}/A results in an increase in WUE (Nobel, 1980). A^{mes}/A is strongly influenced by cell size, shape, and number, e.g., leaves of the same thickness but with smaller cells have a greater WUE (Nobel, 1980).

The effect of cell size on leaf physiology described by Nobel (1980) and others may be adaptive and related to the large changes in DNA content that have occurred during angiosperm evolution. Since cell size is positively correlated with DNA content, one major effect of varying DNA amount may be on traits related to WUE and osmotic adjustment. An evolutionary change for which decreased DNA amount might be adaptive is the ecological transition of a plant group from mesic to more xeric conditions. Individuals with less nuclear DNA may be better able to withstand water stress and higher temperatures due to the development of leaves with smaller cells, higher WUE, and turgor maintenance.

Many studies have established a relationship between nuclear DNA content and the minimum mitotic cycle time among diploid angiosperms (Van't Hof & Sparrow, 1963; Van't Hof, 1965; Price & Bachmann, 1976). Plants with higher DNA contents generally have a longer mitotic cycle. The average duration of the mitotic cycle increases at the rate of about 0.38 hr./pg of DNA (Evans & Rees, 1971). The increase is accounted for mainly in a longer period of DNA synthesis (Evans & Rees, 1971). An average difference of four hours in mitotic cycle time was shown between monocots and dicots of comparable DNA amounts; the difference is accounted for mainly in the increased length of the G_1 phase in dicots, which may be due to their more densely coiled chromatin (Evans & Rees, 1971; Evans et al., 1972).

The amount of DNA per nucleus also correlates with the duration of meiosis in diploid plants. The extremes reported are 18 hr. for *Petunia* ×*hybrida* (3C DNA content = 5.7 pg) and 274.0 hr. in *Trillium erectum* (3C DNA content = ca. 120 pg) (Bennett, 1971, 1977). The increase in the duration of meiosis with DNA content in these studies resulted from a similar increase in all meiotic stages.

The reasons for the DNA content differences among and within plant species remain matters of speculation. Certainly, the shorter mitotic cycle time and smaller cells may contribute to more rapid development of smaller annuals. However, additional factors should be considered. Mowforth et al. (1982) and Grime & Mowforth (1982) suggested that selection may operate on genome size through a differential effect of temperature upon cell division and cell expansion. They proposed that at low temperatures cell expansion is inhibited to a lesser degree than cell division. Therefore, growth under low temperatures was proposed to be promoted by cell enlargement, which would favor higher DNA content and larger cells. Under warmer temperatures, the advantage of growth dominated by cell enlargement should give way to that of growth involving higher rates of division of smaller cells with less DNA (Mowforth et al., 1982). Natural selection operating on such a phenomenon could have influenced both the inter- and intraspecific patterns of DNA content and ecological adaptation in higher plants.

Nucleotypic effects of variable DNA content are predictable and apparently of adaptive significance to higher plants (Price, 1976; Bennett, 1972; Bachmann et al., 1979). Evolutionary patterns of DNA content are discussed below.

TAXONOMIC, GEOGRAPHIC, AND ECOLOGICAL DISTRIBUTION OF DNA CONTENT VARIATION

Geographic, taxonomic, and ecological distributions of genome size among herbaceous angiosperms are not random, but rather apparently represent the results of selection (Price, 1976). Karyotypic studies of grasses by Avdulov (1931) showed plants of tribes and genera centered in the tropics, or those that grow only during warm seasons in temperate climates, had uniformly small to medium-size chromosomes and nuclei. Plants of species growing in cooler temperature regions tend to have larger chromosomes. Levin & Funderburg (1979) concluded that genome sizes are generally larger in temperate compared with tropical herbs. However, in large cosmopolitan families other than the Gramineae and Liliaceae, no significant differences in genome size were detected between temperate and tropical species. It was suggested that generally families indigenous to tropical and subtropical regions have substantially smaller genomes than those of temperate regions.

Bennett (1976a, b) studied DNA content in relation to the distribution of cereal grain crops, cultivated pasture grasses, and legume pulse crops. Cultivation of species with higher DNA content tends to be localized in temperate latitudes, or the seasons and regions at lower latitudes where conditions are similar to those normally found in temperate latitudes. Bennett (1976a) suggested that man had generally chosen species for cultivation that resulted in a distribution paralleling or exaggerating the natural tropical–temperate cline in DNA content.

DNA content variation within genera is common. In cases where the phylogeny or primitive versus advanced status of taxa can reasonably be deduced, it is apparent that both evolutionary increases and decreases in DNA content have occurred. For example, Rees & Hazarika (1967) observed a three-fold variation in genome size among diploid species of *Lathyrus*. The higher values were from outbreeding perennial species and the lower from inbreeding annuals. This represented an apparent evolutionary decrease of DNA amount. Large evolutionary decreases in DNA content apparently have occurred in the evolution of annual species of *Crepis* (Jones & Brown, 1976), and in *Microseris* and *Agoseris* (Price & Bachmann, 1975). In contrast, the evolution of the inbreeding annual species of *Lolium* was accompanied or followed by an increase of about 35% in the quantity of nuclear DNA (Rees & Jones, 1967). The monotypic diploid perennial *Phalacroseris bolanderi* has more than twice the DNA of its perennial relatives of the Microseridinae. The higher DNA values probably represent an evolutionary increase (Price & Bachmann, 1975).

There is a general correlation of growth form with genome size. Bennett (1972) surveyed 271 plant species representing monocot and dicot annuals and perennials. His study showed that annual monocots and dicots have a significantly lower mean nuclear DNA content than perennials; the range of nuclear DNA amount is smaller among diploid annual species for both monocots and dicots; ephemeral annuals have a lower mean DNA content than nonephemeral annuals; and among monocots mean DNA content of obligate perennials is significantly greater than that of facultative perennials, and the mean values for facultative perennials and annuals are not significantly different. Bennett (1972) presented the hypothesis that nuclear DNA content and minimum generation time are correlated in plants, and that DNA content is causally correlated with the rate of development. He considered attributes that allow an annual species to develop rapidly in a time-limited environment (i.e., rapid mitotic cycle and brief meiosis) to require a low DNA content. Because of these nucleotypic correlates, plants with very high DNA contents should be perennials (Bennett, 1972).

DNA content has been considered in terms of evolutionary advancement within and among genera (Price, 1976) and growth forms of the species (Bennett, 1972), but it has received little attention within an ecological context. A better understanding of the apparent developmental and evolutionary significance of DNA amount comes from populational studies of diploid species that have been demonstrated to possess both interspecific and intraspecific variability in DNA content, such as western North American species in the subtribe Microseridinae (Asteraceae, Lactuceae). This group has been studied extensively by taxonomic (Stebbins, 1953; Chambers, 1955, 1963; Feuer & Tomb, 1977; Harborne, 1977), ecological (Chambers, 1955, 1957; Stebbins, 1972a), genetic (Chambers, 1955, 1963; Bachmann & Chambers, 1978, 1981; Bachmann & Price, 1979; Bachmann et al., 1979, 1981, 1983), and cytogenetic methods (Stebbins et al., 1953; Chambers, 1955, 1963). The genera *Agoseris* and *Microseris* are closely related; similar evolutionary trends have occurred within each. The perennial species of *Agoseris* and *Microseris* are taxonomically and ecologically primitive, and putative transition species morphologically bridge the gap between the genera (Chambers, 1957; Stebbins, 1972a, b). Trends toward reduction in size of all parts of the plant, more rapid growth rate, shortening of the life cycle, change of breeding structure from allogamy to autogamy, and specialization in structure of fruits and involucres have occurred in the evolution of annual species of both *Agoseris* and *Microseris* (Chambers, 1955, 1963; Stebbins, 1972a, b). The annuals have undergone a major ecological adaptive shift to drier ephemeral habitats and generally grow in late winter and early spring when moisture is available.

Relative nuclear DNA contents have been determined by scanning microphotometry of Feulgen-stained nuclei isolated from eight species of *Microseris*, four species of *Agoseris*, and *Phalacroseris bolanderi* (Price & Bachmann, 1975). A 7.7-fold range in DNA content was detected among these diploid ($2n = 18$) species. A 2.8- and 3.1-

fold range was found among species of *Microseris* and *Agoseris*, respectively. Price & Bachmann (1976) demonstrated a positive correlation between mitotic cycle time and nuclear DNA amount in the Microseridinae. Within *Agoseris* and *Microseris*, the annuals have lower DNA contents and a more rapid mitotic cycle than do the perennials.

Intraspecific variation in DNA content has been demonstrated in two annual species of *Microseris*. DNA content varies over 20% within *M. bigelovii* (Price et al., 1981a) and within *M. douglasii* (Price et al., 1980, 1981b). Within *M. bigelovii*, the lower DNA values were from geographically disjunct populations growing at the latitudinal extremes of the species. It was suggested that the small genomes may have resulted from selection for low DNA content in stressful and time-limited environments (Price et al., 1981a).

The DNA contents of 222 plants of *M. douglasii* representing 24 geographically, ecologically, and morphologically diverse populations in California were determined (Price et al., 1981b). The quantity was relatively uniform in most populations, even when there was an abundance of morphological diversity. Variation up to 14% existed among the population means. Populations with higher-DNA-content plants were restricted to more mesic sites, i.e., habitats receiving a yearly average precipitation of 20 inches or more, generally with well-developed soil. Price et al. (1981b) concluded that the observed distribution of DNA content in *M. douglasii* was not that expected by random drift; it was suggested that natural selection may have been responsible for at least part of the observed distribution pattern of DNA content.

The DNA contents of an additional 210 plants of *M. douglasii* were determined (Price et al., 1986). These data supplemented those previously reported (Price et al., 1981b) and allowed temporal changes in DNA content over several years to be detected at three populations. At one collection site near Jolon, California, temporal shifts were observed from low DNA amount in the drought year of 1962 to higher DNA values in 1973 after several years of generally more abundant precipitation, and back to low DNA content in 1977, the second of two severe drought years. These results suggested that the DNA content of *M. douglasii* may be tracking the environment and be subject to selection over seasons of drought and nondrought, respectively. Further collections (1980–1982) during the near-average to above-average rainfall years of 1978–1982 detected no reversal to a higher mean DNA content of the population. Although some high-DNA-content biotypes were detected by sampling for extremely robust growth forms, these had not become predominant over five years with very favorable moisture conditions.

A second population located near the summit of the Parkfield–Coalinga road had a mixture of very high, high, and low DNA biotypes in 1977 (Price et al., 1981b). The plants collected from 1980 to 1982 showed a progressive increase in mean population DNA content and a narrowing of the variation about the mean (Price et al., 1986). These results were compatible with the hypothesis that increased moisture availability and/or the longer growing season associated with it is conducive to selection for higher DNA values.

At a third population site near Middletown, mean DNA content was high in 1977. Since rainfall was low in 1977 in California, we expected to find after the high precipitation years of 1978–1982 a high mean DNA level in this population. Instead, the average DNA content of the samples declined between 1980 and 1982. This appears to contradict the hypothesis that increased soil moisture causes selection for higher DNA amounts. However, this site, a flat grassy swale, accumulates standing water after heavy winter rains. Factors such as the depth and persistence of standing water might affect the date of germination and the length of the time for maturation. Our field observations of late April to mid May in 1981 indicated that the plants of this population had a late start in growth, were depauperate, and were being exposed to a rapidly drying habitat during fruiting. Biotypes with lower DNA content might be favored at this site during years when winter rains produce a persistent vernal pool, which shortens the period favorable for growth and development.

The studies with *Microseris* suggest that one factor influencing the selection for DNA content is soil moisture availability. Other factors, such as length of the growing season, edaphic parameters, temperature, grazing, and competition from other plant species, apparently are of importance. The interactions of these parameters in influencing selection for DNA amount, however, appear to be complex, and DNA amount does not necessarily respond to selection in the same way at different sites if only one or a few factors are considered.

Another example of apparent adaptive intraspecific variation in DNA content is *Zea mays*. It has long been known that knob number in maize is negatively correlated with latitude in North America (Brown, 1949) and with altitude in Mexico (Wellhausen et al., 1952; Bennett, 1976b). Rayburn et al. (1985) and Laurie & Bennett (1985) independently determined nuclear DNA content from 21 and 10 lines, respectively, of maize representing a geographical range from Mexico to

Nova Scotia. DNA content varied up to 37%. A significant negative correlation ($r = -0.45$ and $r = -0.75$) exists between DNA content and latitude in both studies. Significant positive correlations existed between knob number (detected as mitotic C-bands) and the amount of karyotype consisting of C-bands ($r = 0.87$), knob number and DNA content ($r = 0.59$), as well as percent C-band heterochromatin and DNA content ($r = 0.70$) (Rayburn et al., 1985).

Corn is considered to have arisen in Mexico or Central America and then to have been taken northward by man. The selective pressures imposed in the northward migration of maize included a shorter and cooler growing season and maximum plant size permitted by climatic constraints (Rayburn et al., 1985). This selection for maximum plant size and rapid maturation appears to have involved reduction in DNA content through its nucleotypic effect of a shorter mitotic cycle time. The DNA primarily eliminated is apparently the 185-bp simple sequence satellite DNA that has been shown to be associated with chromosome knobs of maize (Peacock et al., 1981). Other possible effects of knob heterochromatin, such as influencing the expression of closely linked genes, could be of adaptive importance. Such phenomena remain to be detected at the molecular level.

Succinctly, nuclear DNA amount apparently has predictable and multiple nucleotypic effects on plants. Studies of development and physiology of closely related species or biotypes with different DNA contents, in relationship to their ecological adaptations and restraints, should lead to a better understanding of the evolutionary role of genome size.

TECHNIQUES—DETERMINATION OF DNA CONTENT

DNA content of nuclei from plant tissues is most commonly determined by scanning microspectrophotometry following Feulgen staining. Other methods include the biochemical extraction and measurement of DNA from an estimated number of cells (Martin, 1966; Baetcke et al., 1967), flow cytophotometry of isolated nuclei (Galbraith et al., 1983), and various nonscanning microspectrophotometric methods. Specific precautions for Feulgen staining and scanning microspectrophotometry will be discussed along with a specific protocol for DNA-content determination (Price et al., 1980).

SOURCES OF ERROR

Estimates of DNA content can vary among experiments due to many factors, including source of tissue, different preparation of fixative and stain, length of hydrolysis, temperature fluctuation, and adjustment and sensitivity of the microspectrophotometer.

The source of tissue is very important for DNA-content determination. Nuclei from similar tissues at the same stage of development from healthy plants are necessary if small differences in DNA content are to be accurately detected. It is not proper to compare interphase nuclei from one plant with mitotic nuclei of another.

The fixation of tissue is critical. Generally ice-cold 3 : 1 absolute ethyl alcohol and glacial acetic acid for 24 hr. provide adequate fixation. Some species or tissues may require a shorter fixation period. Standard and experimental tissue should be fixed with freshly prepared fixative from the same bottle. The material is transferred to cold 70% ethyl alcohol and stored in a refrigerator for up to approximately two months before staining.

One potential source of error is in the hydrolysis of tissue prior to Feulgen staining. Error due to hydrolysis can be minimized by performing a careful hydrolysis scheme and choosing a hydrolysis time that results in maximum staining of nuclear DNA. Too little hydrolysis will give reduced staining, and prolonged hydrolysis results in extraction of DNA and hence reduced staining. Therefore, the use of a hydrolysis curve can greatly reduce experimental error. Once an optimal hydrolysis period is established, it is important to hydrolyze together the standard tissue and the tissue being compared so that each receives a similar hydrolysis. Most species analyzed in my laboratory have maximum Feulgen staining following hydrolysis in 5 N HCl for 40–50 min. at 25° C.

Another source of error may result from different densities of nuclei. Polyploid cells and nuclei with high amounts of heterochromatin tend to have DNA amounts underestimated by Feulgen densitometry (Verma & Rees, 1974; Narayan & Rees, 1974). This problem can be overcome by measuring interphase nuclei rather than mitotic figures.

A frequently cited source of error is glare (Goldstein, 1970; Bedi & Goldstein, 1974). Error involving well-spread metaphase or telophase mitotic figures is potentially greater than that involving prophase or interphase nuclei (Bennett & Smith, 1976). Glare can be partially corrected electronically in the microspectrophotometer and by careful measurement of nuclei, including severe restriction of the area illuminated. In actual practice, stray light effects have been found to be negligible with the procedures using most modern microspectrophotometers.

After all sources of potential error have been minimized, measurements are then subject to sensitivity of the microspectrophotometer. The assemblage initially used in my laboratory was a Zeiss Universal-II scanning microscope with a 03 photometer system, 0.5-μm scanning stage, modified 45-control unit, modified PMI-indicator, and a value average module. The latter three components have been recently replaced with a Zeiss Zonax, which contains a fully programmable set of controls and graphics system. Both systems allow for very accurate and precise measurement of DNA amount. The variance due to instrumentation in measurements accomplished with these systems is less than 1% of the mean.

In practice, the minimal differences in DNA content that can be detected by Feulgen microdensitometry are in the 2.0–5.0% range. To approach these, techniques must be used that minimize all sources of error, including slide-to-slide variation. This is achieved by the use of an internal standard on each slide (Dhillon et al., 1977; Price et al., 1980).

PROTOCOL FOR DNA CONTENT DETERMINATION

A technique for determination of DNA content from interphase leaf epidermal nuclei is outlined below. This technique leads to the highly controlled, internally standardized, and precise measurement of relative DNA content (Price et al., 1980) and has been successfully applied to several genera, including *Microseris*, *Agoseris*, *Coreopsis*, *Helianthus*, and *Zea*.

1. Peel epidermis from the middle third of nearly fully expanded healthy leaves of standard and experimental plants. It is best to use plants that have been grown in a growth chamber. The standard for *Microseris* is an inbred strain of *M. douglasii*.
2. Fix in ice-cold 3 : 1 absolute ethanol and glacial acetic acid for 24 hr., transfer to cold 70% ethanol, and store under refrigeration.
3. Place 5-mm squares of epidermis in a drop of H_2O on a cleaned (0.5 g gelatin, 1 g $CrK(SO_4)_2 \cdot 12\ H_2O$) microscope slide. Epidermis of the standard should be placed adjacent to that of the experimental.
4. Place coverslips over the epidermal squares with slight hand pressure and remove after freezing over dry ice. Floating slides over liquid nitrogen on a raft made of screen and styrofoam also works well and is more economical.
5. Air dry slides.
6. Hydrolyze for 40 min. in 5 N HCl at 25°C (hydrolysis time may vary in different species). Rinse in distilled H_2O.
7. Stain for 2 hr. in Schiff's reagent (see next section for preparation of Schiff's reagent).
8. Rinse for 10 min. in two separate SO_2 water (600 ml H_2O, 36 ml aqueous 1% $K_2S_2O_5$, 30 ml 1 N HCl) baths and 10 min. in H_2O. Blot away surplus H_2O with a paper towel.
9. Place a drop of enzyme solution (2% cellulysin (Calbiochem), 0.5% macerase (Calbiochem), 0.001 M EDTA, pH 5.6) over each epidermis for 30 min. (Feulgen staining is not affected by this treatment).
10. Dip slides gently into H_2O and absorb surplus water with a paper towel.
11. Place a cover glass on the tissue over a drop of 45% acetic acid. Apply moderate hand pressure. This releases nuclei from the cells and facilitates their movement to clear areas of the slide.
12. Remove cover glasses after freezing over dry ice or liquid nitrogen and air dry slides.
13. Mount No. 1 cover glasses over Permount. Let Permount harden for several days in the dark.
14. Spectrophotometrically measure (560 nm) DNA content of nuclei from the standard and experimental tissue on each slide. The values of individual nuclei of the experimental material on each slide are adjusted by multiplying the amount needed to increase or decrease the mean of the standard to a predetermined value. For the *M. douglasii* standard, it is 22.54 absorbancy units.
15. DNA values in picograms can be obtained by comparing the standard species with another species of known DNA amount.

PREPARATION OF SCHIFF'S REAGENT

Schiff's reagent quantitatively reacts with DNA during Feulgen staining and absorbs light at a peak wavelength of about 560 nm.

Prepare Schiff's reagent by dissolving 2 g basic fuchsin (Certified Biological Stain) in 400 ml boiling H_2O. After cooling, add 40 ml 1 N HCl and 4 g $K_2S_2O_5$. Store overnight in a dark stoppered bottle. Add 1 g decolorizing carbon, shake and vacuum-filter through No. 1 filter paper. The reagent should be used fresh; older reagent results in reduced staining of DNA.

ADVANTAGES OF EPIDERMAL PROCEDURE

The leaf epidermal technique with an internal standard on each slide has several advantages over root tips or other cell types for microspectrophotometric determination of DNA content. For most composites, nearly all leaf nuclei are arrested at the G_1 phase of the cell cycle and are 2C in DNA content (Brossard, 1977; Nagl, 1978; Price et al., 1980). With *Zea mays,* 2C and 4C nuclei are readily identifiable. The epidermis from an inbred line of the same species used as an internal standard on each slide reduces errors due to variation in hydrolysis and staining from slide to slide and experiment to experiment. All values adjusted to the internal standard are directly comparable between slides and staining batches (Price et al., 1980). Spherically shaped interphase nuclei released by enzyme treatment are preferable to mitotic nuclei for microspectrophotometry, since hydrolysis and potential optical problems with compacted chromatin (Duijndam & van Duijn, 1975) are minimized. Lastly, the variance of interphase nuclei is among the lowest reported, with a CV generally under 5 or 6%.
